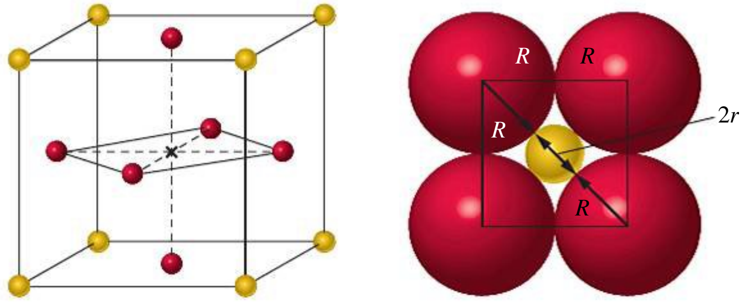
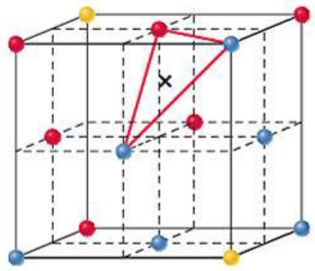
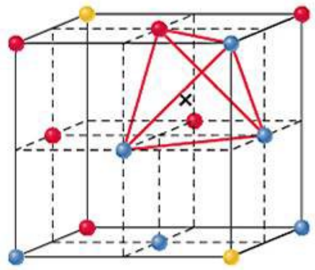
Another arrangement adopted by binary ionic solids is the simple cubic arrangement. The simple cubic arrangement is not a closest packed structure and has larger holes than the cubic closest packed arrangement. The simple cubic structure has a cubic hole at the center of the unit cell. The size of the cubic hole is $r = 0.732\,R$; of the cubic unit cells considered here, this is the largest hole.



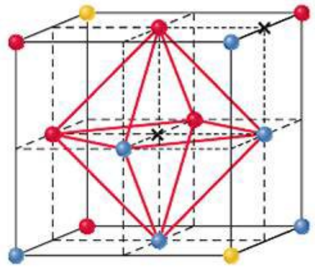
▲ FIGURE 12-47
Cross section of an octahedral hole



(a) Trigonal hole



(b) Tetrahedral hole



(c) Octahedral hole

▲ FIGURE 12-46
Holes in a face-centered cubic unit cell
(a) The trigonal hole is formed by two face-centered spheres and one corner sphere. **(b)** The tetrahedral hole is formed by three face-centered spheres and one corner sphere. **(c)** The octahedral hole is formed by all six face-centered spheres in the cube.

Which hole does the cation occupy in a closest-packed array of anions? The cation occupies a hole that maximizes the attractions between the cation and anion and minimizes the repulsions between the anions. This can be accomplished by accommodating cations into holes that are slightly smaller than the actual size of the ion. This pushes the anions of the closest packed array slightly apart, reducing repulsions, while the anion and cation are in contact, maximizing attractions. Therefore, if a cation is to occupy a tetrahedral hole, the ion should be bigger than the tetrahedral hole but smaller than the octahedral hole; that is,

$$0.225\,R_{\text{anion}} < r_{\text{cation}} < 0.414\,R_{\text{anion}}$$

or in terms of the *radius ratio* of the cation (r) to the anion (R)

$$0.225 < (r_{\text{cation}}/R_{\text{anion}}) < 0.414$$

Similarly, if a cation is to occupy an octahedral hole, the radii will be governed by the radius ratio inequality

$$0.414 < (r_{\text{cation}}/R_{\text{anion}}) < 0.732$$

where the upper limit of the inequality corresponds to the hole in a simple cubic lattice. When the cation is too large, that is, bigger than 0.732 R, the anions adopt a simple cubic structure, which allows the cation to be accommodated in the cubic hole of the lattice.

To summarize, if

$0.225 < (r_{\text{cation}}/R_{\text{anion}}) < 0.414$	tetrahedral hole of fcc array of anions occupied by the cation
$0.414 < (r_{\text{cation}}/R_{\text{anion}}) < 0.732$	octahedral hole of fcc array of anions occupied by the cation
$0.732 < (r_{\text{cation}}/R_{\text{anion}})$	cubic hole of simple cubic array of anions occupied by the cation

The criteria given here provide a useful way of rationalizing the structures of binary ionic solids. However, as with all simplified models, we must be aware of the limitations of the model. In developing the criteria given, we have assumed that there are no interactions other than coulombic attractions between the ions. The criteria will fail if this is not the case. Nonetheless, we will find the criteria to be very useful.

In defining a unit cell of an ionic crystal we must choose a unit cell that

- by translation in three dimensions generates the entire crystal
- is consistent with the formula of the compound
- indicates the coordination numbers of the ions

Unit cells of crystalline NaCl and CsCl are pictured in Figures 12-48 and 12-49, respectively. We can investigate these structures for their consistency with the formula of the compound and the type of hole the cation occupies.

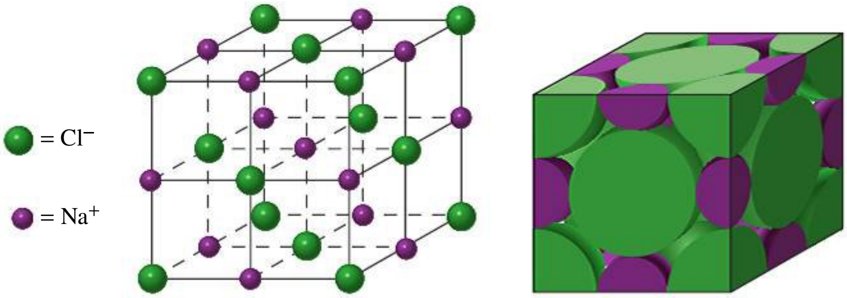
The radius ratio for NaCl is

$$\frac{r_{\text{Na}^+}}{R_{\text{Cl}^-}} = \frac{99\text{ pm}}{181\text{ pm}} = 0.55$$

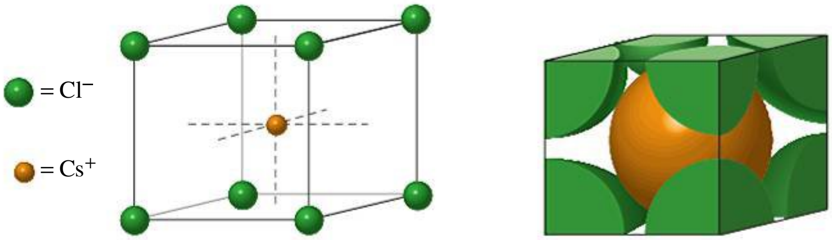
We expect Na^+ ions to occupy the octahedral holes of the cubic closest packed arrays of Cl^- ions. The sodium chloride unit cell is shown in Figure 12-48. To establish the formula of the compound, we must apportion the 27 ions in Figure 12-48 among the unit cell and its neighboring unit cells. Recall from Figure 12-42 on how this apportioning is done. Each Cl^- ion in a corner position is shared by *eight* unit cells, and each Cl^- in the center of a face is shared by *two* unit cells. This leads to a total number of Cl^- ions in the unit cell of $(8 \times \frac{1}{8}) + (6 \times \frac{1}{2}) = 1 + 3 = 4$. There are $2\,\text{Na}^+$ ions along the edges of the unit cell, and each edge is shared by *four* unit cells. The Na^+ ion in the very center of the

KEEP IN MIND

that a cubic closest packed array of spheres produces a face-centered cubic unit cell.



▶ FIGURE 12-48
The sodium chloride unit cell
For clarity, only the centers of the ions are shown. Oppositely charged ions are actually in contact. We can think of this structure as an fcc lattice of Cl^- ions, with Na^+ ions filling the octahedral holes.



▶ FIGURE 12-49
The cesium chloride unit cell
The Cs^+ ion is in the center of the cube, with Cl^- ions at the corners. In reality, each Cl^- is in contact with the Cs^+ ion. An alternative unit cell has Cl^- at the center and Cs^+ at the corners.

unit cell belongs entirely to that cell. Thus, the total number of Na^+ ions in a unit cell is $(12 \times \frac{1}{4}) + (1 \times 1) = 3 + 1 = 4$. The unit cell has the equivalent of 4 Na^+ and 4 Cl^- ions. The ratio of Na^+ to Cl^- is $4:4 = 1:1$, corresponding to the formula NaCl.

To establish the coordination number in an ionic crystal, count the number of nearest neighbor ions of opposite charge to any given ion in the crystal. In NaCl, each Na^+ is surrounded by *six* Cl^- ions. The coordination numbers of both Na^+ and Cl^- are *six*. By contrast, the coordination numbers of Cs^+ and Cl^- in Figure 12-49 are *eight*. The difference in the structure of CsCl from that of NaCl can be accounted for in terms of the radius ratio for this compound.

$$\frac{r_{Cs^+}}{R_{Cl^-}} = \frac{169\text{ pm}}{181\text{ pm}} = 0.934$$

EXAMPLE 12-11 Relating Ionic Radii and the Dimensions of a Unit Cell of an Ionic Crystal

The ionic radii of Na^+ and Cl^- in NaCl are 99 and 181 pm, respectively. What is the length of the unit cell of NaCl?

Analyze

Again, the key to solving this problem lies in understanding geometric relationships in the unit cell. Along each edge of the unit cell (see Figure 12-48), two Cl^- ions are in contact with one Na^+. The edge length is equal to the radius of one Cl^- plus the diameter of Na^+, plus the radius of another Cl^-.

Solve

The solution is,

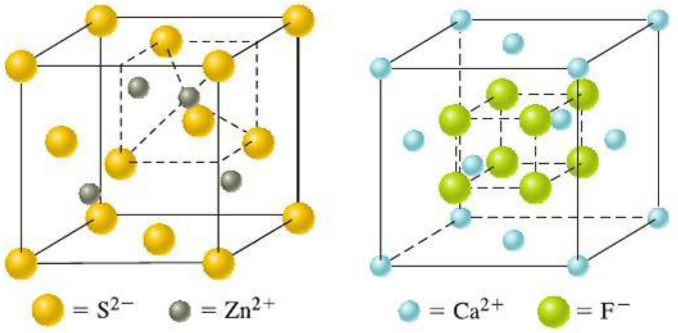
$$\begin{aligned}\text{Length} &= (r_{Cl^-}) + (r_{Na^+}) + (r_{Na^+}) + (r_{Cl^-})\\ &= 2(r_{Na^+}) + 2(r_{Cl^-})\\ &= (2 \times 99) + (2 \times 181) = 560\text{ pm}\end{aligned}$$

Assess

As we saw earlier, we need to remember the atomic arrangement of the unit cell to determine its the geometric relationships.

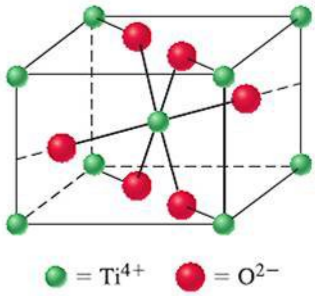
PRACTICE EXAMPLE A: The ionic radius of Cs^+ is 167 pm. Use Figure 12-49 and information in Examples 12-9 and 12-11 to determine the length of the unit cell of CsCl.

PRACTICE EXAMPLE B: Use the length of the unit cell of NaCl obtained in Example 12-11, together with the molar mass of NaCl and the Avogadro constant, to estimate the density of NaCl.



(a) Unit cell of ZnS, the zinc blend structure

(b) Unit cell of CaF_2, the fluorite structure



(c) Unit cell of TiO_2, the rutile structure

◀ FIGURE 12-50
Some unit cells of greater complexity

We expect from the radius ratio inequalities above that the Cs^+ ion will occupy a cubic hole in a simple cubic lattice of Cl^- ions. This unit cell is in accord with the one-to-one ratio of Cs^+ to Cl^- ions since there is one Cs^+ in the center of the unit cell and $8 \times (\frac{1}{8})$ Cl^- ions at the corners.

Ionic compounds of the type $M^{2+}X^{2-}$ (for example, MgO, BaS, CaO) may form crystals of the NaCl type. However, if the cation is small enough, as in the case of Zn^{2+}, it can occupy the tetrahedral holes. The radius ratio for ZnS is 0.35, so to satisfy the stoichiometry only half of the tetrahedral holes (there are eight of them) are occupied, to correspond to the four S^{2-} forming the face-centered cubic array (Fig. 12-50a). For substances with the formulas MX_2 or M_2X, the crystal structures are more complex. Because the cations and anions occur in unequal numbers, the crystals have *two* coordination numbers, one for the cation and another for the anion.

CaF_2 (the fluorite structure) has twice as many fluoride ions as calcium ions (Fig. 12-50b). The coordination number of Ca^{2+} is *eight*, and that of F^- is *four.* This is easiest to see by looking at the Ca^{2+} ion in the middle of a face. There are four F^- ions within the unit cell that are nearest neighbors. In addition, the four F^- ions in the next unit cell (the one that shares the face-centered Ca^{2+} ion) are also nearest neighbors. This gives a coordination number of eight for the Ca^{2+}. The F^- ions each have one corner Ca^{2+} ion and three face-centered Ca^{2+} ions as nearest neighbors, giving a coordination number of four. In TiO_2 (the rutile structure, Figure 12-50c), Ti^{4+} has a coordination number of *six* and O^{2-}, *three.* In this structure, two of the O^{2-} ions are within the interior of the cell, two are in the top face, and two in the bottom face of the cell. Ti^{4+} ions are at the corners and the center of the cell.

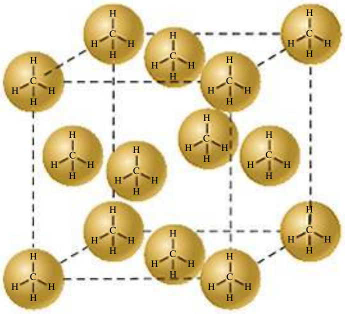
12-9 CONCEPT ASSESSMENT

Buckminsterfullerene C_{60} crystallizes in a face-centered cubic array. If potassium atoms fill all the tetrahedral and octahedral holes, what is the formula of the resulting compound?

TABLE 12.7 Characteristics of Crystalline Solids

Types	Structural Particles	Strongest Contributing Forces[a]	Typical Properties	Examples
Metallic	Cations and delocalized electrons	Metallic bonds	Hardness varies from soft to very hard; melting point varies from low to very high; lustrous; ductile; malleable; very good conductors of heat and electricity	Na, Mg, Al, Fe, Sn, Cu, Ag, W
Ionic	Cations and anions	Electrostatic attractions	Hard; moderate to very high melting points; nonconductors as solids, but good electric conductors as liquids; many are soluble in polar solvents such as water	NaCl, MgO, $NaNO_3$
Network covalent	Atoms	Covalent bonds	Most are very hard and either sublime or melt at very high temperatures; most are nonconductors of electricity	C(diamond), C(graphite), SIC, AlN, SiO_2
Molecular *Nonpolar*	Atoms or nonpolar molecules	Dispersion forces	Soft; extremely low to moderate melting points (depending on molar mass); sublime in some cases; soluble in some nonpolar solvents	He, Ar, H_2, CO_2, CCl_4, CH_4, I_2
Polar	Polar molecules	Dispersion forces and dipole–dipole attractions	Low to moderate melting points; soluble in some polar and some nonpolar solvents	$(CH_3)_2O$, $CHCl_3$, HCl
Hydrogen-Bonded	Molecules with H bonded to N, O, or F	Hydrogen bonds	Low to moderate melting points; soluble in some hydrogen-bonded solvents and some polar solvents	H_2O, NH_3

[a] Generally speaking, more than one type of force contributes. For each case above, we have listed only the strongest of all the contributing forces.



▲ **A sketch of the unit cell of methane**
The unit cell of methane is a face-centered cubic array of CH_4 molecules. In the diagram, the spheres containing the methane molecules are meant to emphasize the fcc array of molecules.

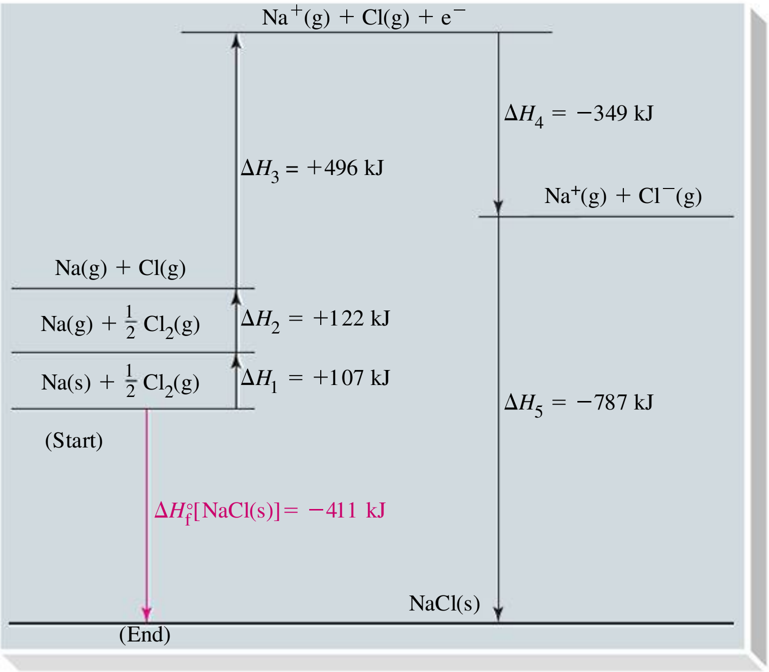
Types of Crystalline Solids: A Summary

In this section, we have emphasized crystal structures composed of metal atoms and those composed of ions. But the structural particles of crystalline solids can be atoms, ions, or molecules. To picture a crystal structure having molecules as its structural units, consider solid methane, CH_4. The crystal structure is fcc, which means that the unit cell has a CH_4 molecule at each corner and at the center of each face. Each CH_4 molecule occupies a volume equivalent to a sphere with a radius of 228 pm. Substances that adopt fcc structures are relatively uncommon. Most complex molecules adopt less symmetric unit cells, but a further discussion of this matter is beyond the scope of this text.

The intermolecular forces operating among the structural units of a crystal may be metallic bonds, interionic attractions, van der Waals forces, hydrogen bonds, or covalent bonds. Table 12.7 lists the basic types of crystalline solids, the intermolecular forces within them, some of their characteristic properties, and examples of each.

12-7 Energy Changes in the Formation of Ionic Crystals

The concept of lattice energy, which we introduced qualitatively in Section 12-5, is most useful when stated in quantitative terms. It is difficult, however, to calculate a lattice energy directly. The problem is that oppositely charged ions attract one another and like-charged ions repel one another, and these interactions must be considered at the same time. More commonly, lattice energy is determined *indirectly* through an application of Hess's law known as the Born–Fajans–Haber cycle, named after its originators Max Born, Kasimir Fajans, and Fritz Haber. The crux of the method is to design a sequence of steps in



◀ FIGURE 12-51
Enthalpy diagram for the formation of an ionic crystal
Shown here is a five-step sequence for the formation of one mole of NaCl(s) from its elements in their standard states. The sum of the five enthalpy changes gives $\Delta H^\circ_f[\text{NaCl(s)}]$. The equivalent one-step reaction for the formation of NaCl(s) directly from Na(s) and $Cl_2(g)$ is shown in color. (The vertical arrows representing ΔH values are not to scale.)

which enthalpy changes are known for all the steps but one—the step in which a crystal lattice is formed from gaseous ions.

Figure 12-51 illustrates a five-step method for finding the lattice energy of NaCl.

◀ NaCl has a lattice energy of about $\frac{1}{4}$ that of MgO. This is because the coulombic attraction between the ions is proportional to $(-1)(+1)$ in the former and $(-2)(+2)$ in the latter.

Step 1. Sublime one mole of solid Na.

Step 2. Dissociate 0.5 mole of $Cl_2(g)$ into one mole of Cl(g).

Step 3. Ionize one mole of Na(g) to $Na^+(g)$.

Step 4. Convert one mole of Cl(g) to $Cl^-(g)$.

Step 5. Allow the $Na^+(g)$ and $Cl^-(g)$ to form one mole of NaCl(s).

The overall change in these five steps is the same as the reaction in which NaCl(s) is formed from its elements in their standard states—that is, $\Delta H_{\text{overall}} = \Delta H^\circ_f[\text{NaCl(s)}]$. From Appendix D, we see that $\Delta H^\circ_f[\text{NaCl(s)}] = -411\ \text{kJ mol}^{-1}$, so in the following setup, the lattice energy of NaCl is the only unknown.

$$\textbf{1.}\quad \text{Na(s)} \longrightarrow \cancel{\text{Na(g)}} \qquad \Delta H_1 = \Delta H_{\text{sublimation}} = +107\ \text{kJ}$$

$$\textbf{2.}\quad \frac{1}{2}\text{Cl}_2\text{(g)} \longrightarrow \cancel{\text{Cl(g)}} \qquad \Delta H_2 = \frac{1}{2}\text{Cl—Cl bond energy} = +122\ \text{kJ}$$

$$\textbf{3.}\quad \cancel{\text{Na(g)}} \longrightarrow \cancel{\text{Na}^+\text{(g)}} + \cancel{e^-} \qquad \Delta H_3 = \text{1st ioniz. energy} = +496\ \text{kJ}$$

$$\textbf{4.}\quad \cancel{\text{Cl(g)}} + \cancel{e^-} \longrightarrow \cancel{\text{Cl}^-\text{(g)}} \qquad \Delta H_4 = \text{electron affinity of Cl} = -349\ \text{kJ}$$

$$\textbf{5.}\quad \cancel{\text{Na}^+\text{(g)}} + \cancel{\text{Cl}^-\text{(g)}} \longrightarrow \text{NaCl(s)} \qquad \Delta H_5 = \text{lattice energy of NaCl} = ?$$

$$\textit{overall:}\qquad \text{Na(s)} + \frac{1}{2}\text{Cl}_2\text{(g)} \longrightarrow \text{NaCl(s)}$$

$$\Delta H_{\text{overall}} = -411\ \text{kJ} = \Delta H_1 + \Delta H_2 + \Delta H_3 + \Delta H_4 + \Delta H_5$$

$$-411\ \text{kJ} = 107\ \text{kJ} + 122\ \text{kJ} + 496\ \text{kJ} - 349\ \text{kJ} + \Delta H_5$$

$$\Delta H_5 = \text{lattice energy} = (-411 - 107 - 122 - 496 + 349)\ \text{kJ} = -787\ \text{kJ}$$

◀ A commonly used convention defines lattice energy in terms of the breakup of a crystal rather than its formation. By that convention, all lattice energies are positive quantities and $\Delta H_5 = -(\text{lattice energy})$.

One way to use the concept of lattice energy is in making predictions about the possibility of synthesizing ionic compounds. In Example 12-12, we predict the likelihood of obtaining the compound MgCl(s) by evaluating its enthalpy of formation.

EXAMPLE 12-12 Relating Enthalpy of Formation, Lattice Energy, and Other Energy Quantities

With the following data, calculate ΔH_f° per mol MgCl(s): Enthalpy of sublimation of 1 mol Mg(s): +146 kJ; enthalpy of dissociation of $\frac{1}{2}$ mol $Cl_2(g)$: +122 kJ; first ionization energy of 1 mol Mg(g): +738 kJ; electron affinity of 1 mol Cl(g): −349 kJ; lattice energy of 1 mol MgCl(s): −676 kJ.

Analyze

We begin this problem by drawing an enthalpy diagram for the formation of an ionic solid, MgCl(s). From the diagram we find that the lattice energy (ΔH_5) is known, and the unknown is $\Delta H_{\text{overall}}$, which is the enthalpy of formation of MgCl(s).

Solve

The various reactions are given as part of the example:

$$\begin{aligned}
\text{Mg(s)} &\longrightarrow \cancel{\text{Mg(g)}} && \Delta H_1 = +146\text{ kJ}\\
\tfrac{1}{2}\text{Cl}_2(\text{g}) &\longrightarrow \cancel{\text{Cl(g)}} && \Delta H_2 = +122\text{ kJ}\\
\cancel{\text{Mg(g)}} &\longrightarrow \cancel{\text{Mg}^+(\text{g})} + \cancel{e^-} && \Delta H_3 = +738\text{ kJ}\\
\cancel{\text{Cl(g)}} + \cancel{e^-} &\longrightarrow \cancel{\text{Cl}^-(\text{g})} && \Delta H_4 = -349\text{ kJ}\\
\cancel{\text{Mg}^+(\text{g})} + \cancel{\text{Cl}^-(\text{g})} &\longrightarrow \cancel{\text{MgCl(s)}} && \Delta H_5 = -676\text{ kJ}
\end{aligned}$$

$$\textit{overall:}\quad \text{Mg(s)} + \frac{1}{2}\text{Cl}_2(\text{g}) \longrightarrow \text{MgCl(s)}$$

$$\begin{aligned}
\Delta H_{\text{overall}} &= \Delta H_f^\circ[\text{MgCl(s)}] = \Delta H_1 + \Delta H_2 + \Delta H_3 + \Delta H_4 + \Delta H_5\\
&= 146\text{ kJ} + 122\text{ kJ} + 738\text{ kJ} - 349\text{ kJ} - 676\text{ kJ} = -19\text{ kJ}
\end{aligned}$$

Assess

These types of problems are another form of Hess's law. The enthalpy diagram is just a way for us to keep the equations straight.

PRACTICE EXAMPLE A: The enthalpy of sublimation of cesium is 78.2 kJ mol^{-1}, and $\Delta H_f^\circ[\text{CsCl(s)}] = -442.8$ kJ mol^{-1}. Use these values, together with other data from the text, to calculate the lattice energy of CsCl(s).

PRACTICE EXAMPLE B: Given the following data, together with data included in Example 12-12, calculate ΔH_f° per mol $CaCl_2(s)$: Enthalpy of sublimation of Ca(s), +178.2 kJ mol^{-1}; first ionization energy of Ca(g), +590 kJ mol^{-1}; second ionization energy of Ca(g), +1145 kJ mol^{-1}; lattice energy of $CaCl_2(s)$, −2223 kJ mol^{-1}.

Example 12-12 suggests that we can obtain MgCl(s) as a stable compound—it has a slightly negative enthalpy of formation. Why have we been writing $MgCl_2$ all this time instead of MgCl? You might think that because MgCl has a Mg-to-Cl ratio of 1 : 1 and $MgCl_2$ has a ratio of 1 : 2, MgCl should form if Mg(s) reacts with a limited amount of $Cl_2(g)$. But this is not the case. No matter how limited the amount of $Cl_2(g)$ available, the only compound that forms is $MgCl_2$. To understand this, repeat the calculation of Example 12-12 for the formation of $MgCl_2(s)$, and you will obtain an enthalpy of formation that is very much more negative than that for MgCl(s) (see Exercise 87). Even though the energy requirement to produce Mg^{2+} is larger than to produce Mg^+, the lattice energy is very much greater for $MgCl_2(s)$ than for MgCl(s). This is because the *doubly* charged Mg^{2+}ions exert a much stronger force on Cl^- ions than do *singly* charged Mg^+ ions. The reaction between Mg and Cl atoms does not stop at MgCl but continues on to the more stable $MgCl_2$.

Is $NaCl_2$ a stable compound? Here, the answer is no. The additional lattice energy associated with $NaCl_2$ over NaCl is not nearly enough to compensate for the very high second ionization energy of sodium (see Exercise 114).

MasteringCHEMISTRY www.masteringchemistry.com

The acronym LCD, which stands for liquid crystal display, needs little introduction. Using the word liquid to describe crystals appears contradictory based upon the material in this chapter. For a discussion of the properties and uses of materials that we call liquid crystals, go to the Focus On feature for Chapter 12, Liquid Crystals, on the MasteringChemistry website.

Summary

12-1 Intermolecular Forces—The intermolecular forces that occur between molecules are collectively known as **van der Waals forces**. The most common intermolecular forces of attraction are those between instantaneous and induced dipoles (**dispersion forces**, or **London forces**). The magnitudes of dispersion forces depend on how easily electron displacements within molecules cause a temporary imbalance of electron charge distribution, that is, on the **polarizability** of the molecule. In polar substances, there are also dipole–dipole forces. Some hydrogen-containing substances exhibit significant intermolecular attractions called **hydrogen bonds,** in which H atoms bonded to highly electronegative atoms—N, O, or F—in a molecule are simultaneously attracted to other highly electronegative atoms in the same molecule or in different molecules. Hydrogen bonding has a profound effect on physical properties, such as boiling points (Fig. 12-5) and is a vital intermolecular force in living systems.

12-2 Some Properties of Liquids—**Surface tension**, the energy required to extend the surface of a liquid, and **viscosity,** a liquid's resistance to flow, are properties related to intermolecular forces. Familiar phenomena such as drop shape, meniscus formation, and capillary action depend on surface tension. Specifically, these phenomena are influenced by the balance between **cohesive forces**, intermolecular forces between molecules in a liquid, and **adhesive forces**, intermolecular forces between liquid molecules and a surface. **Vapor pressure,** the pressure exerted by a vapor in equilibrium with a liquid, is a measure of the volatility of a liquid and is related to the strength of intermolecular forces. The conversion of a liquid to a vapor is called **vaporization** or **evaporation**; the reverse process is called **condensation**. The dependence of vapor pressure on temperature is represented by a **vapor pressure curve** (Fig. 12-18) and can be expressed in the Clausius–Clapeyron equation (Equation 12.2). When the pressure exerted by the escaping molecules from the surface of the liquid equals the pressure exerted by the molecules in the atmosphere, **boiling** is said to occur. The **normal boiling point** is the temperature at which the vapor pressure of the liquid equals 1 atm. The **critical point** is the condition of temperature and pressure at which a liquid and its vapor become indistinguishable (Fig. 12-22).

12-3 Some Properties of Solids—When crystalline solids are heated, a temperature is reached where the solid state is converted to a liquid—**melting** occurs. The temperature at which this occurs is the **melting point**. When liquids are cooled, the crystalline material will form during the process of **freezing**, and the temperature at which this occurs is the **freezing point**. Under certain conditions solids can directly convert into vapor by the process of **sublimation**. The reverse process is called **deposition**. Among the properties of a solid affected by intermolecular forces are its sublimation (vapor) pressure and its melting point.

12-4 Phase Diagrams—A **phase diagram** (Figs. 12-24 to 12-28) is a graphical plot of conditions under which solids, liquids, and gases (vapors) exist, as single phases or as two or more phases in equilibrium with one another. Significant points on a phase diagram are the **triple point** (where all three phases coexist), melting point, boiling point, and critical point, beyond which a supercritical fluid is possible. Some substances can exist in different forms in the solid state; such behavior is called **polymorphism** (Fig. 12-28).

12-5 Network Covalent Solids and Ionic Solids—In **network covalent solids**, chemical bonds extend throughout a crystalline structure. For these substances, the chemical bonds are themselves intermolecular forces. **Lattice energy** is the energy released when separated gaseous ions come together to form one mole of an ionic solid.

12-6 Crystal Structures—Some crystal structures can be described in terms of the packing of spheres. Depending on the way in which the spheres are packed, different **unit cells** are obtained (Fig. 12-37). The hexagonal unit cell is obtained with **hexagonal closest packed (hcp)** spheres; a **face-centered cubic (fcc)** unit cell is obtained with **cubic closest packed** spheres (Figs. 12-38 and 12-39). A **body-centered cubic (bcc)** (Fig. 12-38) unit cell is found in some cases where spheres are not packed as closely as in the hcp and fcc structures. The dimensions of the unit cell can be determined by X-ray diffraction, and these dimensions can be used in calculating atomic radii and densities. An important consideration with ionic crystals is that the ions are not all of the same size or charge. Ionic crystals can often be viewed as an array of anions with the cations fitting in the holes within the anion array.

12-7 Energy Changes in the Formation of Ionic Crystals—Lattice energies of ionic crystals can be related to certain atomic and thermodynamic properties by means of the Born–Fajans–Haber cycle (Fig. 12-51).

Integrative Example

Use data from the table of physical properties of hydrazine, N_2H_4, to calculate the partial pressure of $N_2H_4(g)$ when a container filled with an equilibrium mixture of $N_2H_4(g)$ and $N_2H_4(l)$ at 25.0 °C is cooled to the temperature of an ice–water bath.

Property	Value
Freezing point	2.0 °C
Boiling point	113.5 °C
Critical temperature	380 °C
Critical pressure	145.4 atm
Enthalpy of fusion	$12.66\ \text{kJ mol}^{-1}$
Heat capacity of liquid	$98.84\ \text{J mol}^{-1}\ {}^{\circ}\text{C}^{-1}$
Density of liquid at 25.0 °C	$1.0036\ \text{g mL}^{-1}$
Vapor pressure at 25.0 °C	14.4 Torr

Analyze

At a temperature below its freezing point of 2.0 °C, the hydrazine will be present as a solid in equilibrium with its vapor. We are seeking the sublimation pressure of $N_2H_4(s)$ at the melting point of ice, 0 °C. At its freezing point of 2.0 °C, the hydrazine coexists in three phases—liquid, solid, and vapor. We must first determine the vapor pressure of hydrazine at 2.0 °C. Then we can then use the Clausius–Clapeyron equation (12.2) to calculate the vapor (sublimation) pressure at 0 °C. Our principal task will be to identify the data needed to apply the Clausius–Clapeyron equation, three times in all, as detailed in the stepwise solution to the problem.

Solve

To determine a value of ΔH_{vap}, choose the vapor pressure data at 25.0 °C for T_1 and P_1 and at the normal boiling point for T_2 and P_2 for substitution into equation (12.2).

$$\ln\frac{P_2}{P_1} = -\frac{\Delta H_{\text{vap}}}{R}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)$$

$$\ln\frac{760\ \text{Torr}}{14.4\ \text{Torr}} = -\frac{\Delta H_{\text{vap}}}{8.3145\ \text{J mol}^{-1}\ \text{K}^{-1}} \times \left(\frac{1}{386.7\ \text{K}}-\frac{1}{298.2\ \text{K}}\right) = 3.967$$

$$\Delta H_{\text{vap}} = -\frac{8.3145\ \text{J mol}^{-1}\ \text{K}^{-1} \times 3.967}{(0.002586 - 0.003353)\ \text{K}^{-1}} = 4.30 \times 10^4\ \text{J mol}^{-1}$$

Return to the Clausius–Clapeyron equation (12.2) by using the value of ΔH_{vap} just obtained. Also use the same data as in the first calculation for T_1 and P_1, but now with $T_2 = 2.0 + 273.15 = 275.2\ K$ and P_2 as an unknown. Solve the equation for P_2.

$$\ln\frac{P_2}{14.4} = -\frac{4.30 \times 10^4\ \text{J mol}^{-1}}{8.3145\ \text{J mol}^{-1}\ \text{K}^{-1}} \times \left(\frac{1}{275.2\ \text{K}}-\frac{1}{298.2\ \text{K}}\right)$$

$$= -5.17 \times 10^3 \times (2.80 \times 10^{-4}) = -1.45$$

$$P_2/14.4 = e^{-1.45} = 0.235$$

$$P_2 = 0.235 \times 14.4 = 3.38\ \text{Torr}$$

We now have the triple point data for hydrazine. The triple point temperature is 2.0 °C (275.2 K) and the triple point pressure is 3.38 Torr. In our final application of equation (12.2), we use those data as T_2 and P_2. The temperature T_1 is 0 °C (273.2 K) and the unknown sublimation pressure is P_1. The enthalpy change needed in this final calculation must be the enthalpy of sublimation, which is

$$\Delta H_{\text{sub}} = \Delta H_{\text{fus}} + \Delta H_{\text{vap}}$$

$$= \left(12.66\frac{\text{kJ}}{\text{mol}} \times \frac{1000\ \text{J}}{1\ \text{kJ}}\right) + 4.30 \times 10^4\ \text{J mol}^{-1} = 5.57 \times 10^4\ \text{J mol}^{-1}$$

Finally, we substitute these data into equation (12.2) and solve for P_1, the sublimation pressure of hydrazine at 0 °C.

$$\ln\frac{3.38\text{ Torr}}{P_1} = -\frac{5.57\times10^4\text{ J mol}^{-1}}{8.3145\text{ J mol}^{-1}\text{ K}^{-1}}\times\left(\frac{1}{275.2}-\frac{1}{273.2}\right)\text{K}^{-1}$$

$$\ln\frac{3.38\text{ Torr}}{P_1} = -6.70\times10^3\times(-2.66\times10^{-5}) = 0.178$$

$$\frac{3.38\text{ Torr}}{P_1} = e^{0.178} = 1.19$$

$$P_1 = \frac{3.38\text{ Torr}}{1.19} = 2.84\text{ Torr}$$

Assess

Observe that, compared with the vapor pressure at 25 °C (14.4 Torr), the calculated triple point pressure (3.38 Torr) is smaller; and the sublimation pressure at 0 °C (2.84 Torr) is smaller still. This is certainly the trend expected for the three values. In the three situations in which equation (12.2) is used, the first one is the most subject to error because the difference between T_2 and T_1 is 89 °C, while in the other two it is 23 °C and 2 °C, respectively. Both ΔH_{vap} and ΔH_{sub} are undoubtedly temperature-dependent.

PRACTICE EXAMPLE A: The normal boiling point of isooctane (a gasoline component with a high octane rating) is 99.2 °C, and its ΔH_{vap} is 35.76 kJ mol^{-1}. Because isooctane and water have nearly identical boiling points, will they have nearly equal vapor pressures at room temperature? If not, which would you expect to be more volatile? Explain.

PRACTICE EXAMPLE B: We cannot measure the second electron affinity of oxygen directly:

$$O^-(g) + e^- \longrightarrow O^{2-}(g) \quad EA_2 = ?$$

The O^{2-} ion can exist in the solid state, however, where the high energy requirement for its formation is offset by the large lattice energies of ionic oxides.

(a) Show that EA_2 can be calculated from the enthalpy of formation and lattice energy of MgO(s), the enthalpy of sublimation of Mg(s), the ionization energies of Mg, the bond energy of O_2, and the EA_1 for O(g).

(b) The lattice energy of MgO is −3925 kJ mol^{-1}. Combine this with other values in the text to estimate EA_2 for oxygen.

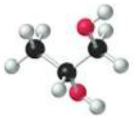
MasteringCHEMISTRY

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

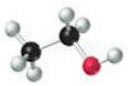
Exercises

Intermolecular Forces

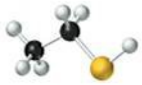
1. For each of the following substances describe the importance of dispersion (London) forces, dipole–dipole interactions, and hydrogen bonding: **(a)** HCl; **(b)** Br_2; **(c)** ICl; **(d)** HF; **(e)** CH_4.
2. When another atom or group of atoms is substituted for one of the hydrogen atoms in benzene, C_6H_6, the boiling point changes. Explain the order of the following boiling points: C_6H_6, 80 °C; C_6H_5Cl, 132 °C; C_6H_5Br, 156 °C; C_6H_5OH, 182 °C.
3. Arrange the liquids represented by the following molecular models in the expected order of increasing viscosity at 25 °C.



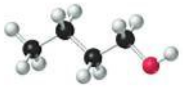
(a)



(b)

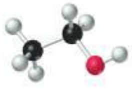


(c)



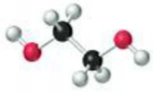
(d)

4. Arrange the liquids represented by the following molecular models in the expected order of increasing normal boiling point.

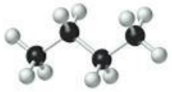


(a)

(b)



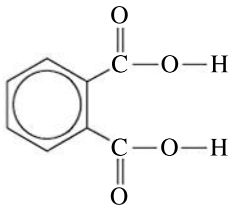
(c)



(d)

5. One of the following substances is a liquid at room temperature and the others are gaseous: CH_3OH; C_3H_8; N_2; N_2O. Which do you think is the liquid? Explain.

6. In which of the following compounds do you think that intramolecular hydrogen bonding is an important factor: **(a)** $CH_3CH_2CH_2CH_3$; **(b)** $HOOCCH_2CH_2CH_2CH_2COOH$; **(c)** CH_3COOH; **(d)** *ortho*-phthalic acid? Explain.

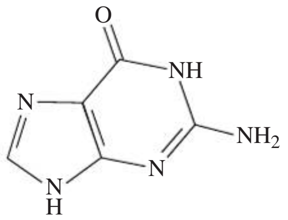


ortho-Phthalic acid

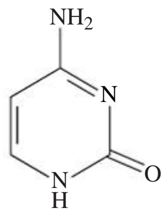
7. How many water molecules can hydrogen bond to methanol?

8. What is the maximum number of hydrogen bonds that can form between two acetic acid molecules?

9. In DNA the nucleic acid bases form hydrogen bonds between them, which are responsible for the formation of the double-stranded helix. Arrange the bases guanine and cytosine to give the maximum number of hydrogen bonds.



Guanine



Cytosine

10. Water molecules will form small, stable clusters. Draw one possible water cluster by using six water molecules and maximizing the number of hydrogen bonds for each water molecule.

Surface Tension and Viscosity

11. Silicone oils, such as $H_3C[SiO(CH_3)_2]_nSi(CH_3)$, are used in water repellents for treating tents, hiking boots, and similar items. Explain how silicone oils function.

12. Surface tension, viscosity, and vapor pressure are all related to intermolecular forces. Why do surface tension and viscosity decrease with temperature, whereas vapor pressure increases with temperature?

13. Is there any scientific basis for the colloquial expression "slower than molasses in January"? Explain.

14. A television commercial claims that a product makes water "wetter." Can there be any basis to this claim? Explain.

15. Rank the following in order of increasing surface tension (at room temperature): **(a)** CH_3OH; **(b)** CCl_4; **(c)** $CH_3CH_2OCH_2CH_3$.

16. Would you predict the surface tension of t-butyl alcohol, $(CH_3)_3COH$, to be greater than or less than that of n-butyl alcohol, $CH_3CH_2CH_2CH_2OH$? Explain.

17. Butanol and pentane have approximately the same mass, however, the viscosity (at 20 °C) of butanol is $\eta = 2.948$ cP, and the viscosity of pentane is $\eta = 0.240$ cP. Explain this difference.

18. Carbon tetrachloride (CCl_4) and mercury have similar viscosities at 20 °C. Explain.

Vaporization

19. As a liquid evaporated from an open container, its temperature was observed to remain roughly constant. When the same liquid evaporated from a thermally insulated container (a vacuum bottle or Dewar flask), its temperature was observed to drop. How would you account for this difference?

20. Explain why vaporization occurs only at the surface of a liquid until the boiling point temperature is reached. That is, why does vapor not form throughout the liquid at all temperatures?

21. The enthalpy of vaporization of benzene, $C_6H_6(l)$, is $33.9\ \mathrm{kJ\,mol^{-1}}$ at 298 K. How many liters of $C_6H_6(g)$, measured at 298 K and 95.1 mmHg, are formed when 1.54 kJ of heat is absorbed by $C_6H_6(l)$ at a constant temperature of 298 K?

22. A vapor volume of 1.17 L forms when a sample of liquid acetonitrile, CH_3CN, absorbs 1.00 kJ of heat at its normal boiling point (81.6 °C and 1 atm). What is ΔH_{vap} in kilojoules per mole of CH_3CN?

23. Use data from the Integrative Example (page 546) to determine how much heat is required to convert 25.00 mL of liquid hydrazine at 25.0 °C to hydrazine vapor at its normal boiling point.

24. How much heat is required to raise the temperature of 215 g $CH_3OH(l)$ from 20.0 to 30.0 °C and then vaporize it at 30.0 °C? Use data from Table 12.3 and a molar heat capacity of $CH_3OH(l)$ of $81.1\ \mathrm{J\ mol^{-1}K^{-1}}$.

25. How many liters of $CH_4(g)$, measured at 23.4 °C and 768 mmHg, must be burned to provide the heat needed to vaporize 3.78 L of water at 100 °C? $\Delta H_{combustion} = -8.90 \times 10^2\ \mathrm{kJ\,mol^{-1}}\ CH_4$. For $H_2O(l)$ at 100 °C, $d = 0.958\ \mathrm{g\,cm^{-3}}$, and $\Delta H_{vap} = 40.7\ \mathrm{kJ\,mol^{-1}}$.

26. A 50.0 g piece of iron at 152 °C is dropped into 20.0 g $H_2O(l)$ at 89 °C in an open, thermally insulated container. How much water would you expect to vaporize, assuming no water splashes out? The specific heats of iron and water are 0.45 and $4.21\ \mathrm{J\,g^{-1}\,°C^{-1}}$, respectively, and $\Delta H_{vap} = 40.7\ \mathrm{kJ\,mol^{-1}}\,H_2O$.

Vapor Pressure and Boiling Point

27. From Figure 12-18, estimate (a) the vapor pressure of C_6H_7N at 100 °C; (b) the normal boiling point of C_7H_8.

28. Use data in Figure 12-20 to estimate **(a)** the normal boiling point of aniline; **(b)** the vapor pressure of diethyl ether at 25 °C.

29. Equilibrium is established between $Br_2(l)$ and $Br_2(g)$ at 25.0 °C. A 250.0 mL sample of the vapor weighs 0.486 g. What is the vapor pressure of bromine at 25.0 °C, in millimeters of mercury?

30. The density of acetone vapor in equilibrium with liquid acetone, $(CH_3)_2CO$, at 32 °C is 0.876 g L^{-1}. What is the vapor pressure of acetone at 32 °C, expressed in kilopascals?

31. A double boiler is used when a careful control of temperature is required in cooking. Water is boiled in an outside container to produce steam, and the steam condenses on the outside walls of an inner container in which cooking occurs. (A related laboratory device is called a steam bath.) **(a)** How is heat energy conveyed to the food to be cooked in a double boiler? **(b)** What is the maximum temperature that can be reached in the inside container?

32. One popular demonstration in chemistry labs is performed by boiling a small quantity of water in a metal can (such as a used soda can), picking up the can with tongs and quickly submerging it upside down in cold water. The can collapses with a loud and satisfying pop. Give an explanation of this crushing of the can. (Note: If you try this demonstration, do not heat the can over an open flame.)

33. Pressure cookers achieve a high cooking temperature to speed the cooking process by heating a small amount of water under a constant pressure. If the pressure is set at 2 atm, what is the boiling point of the water? Use information from Table 12.4.

34. Use data from Table 12.4 to estimate **(a)** the boiling point of water in Santa Fe, New Mexico, if the prevailing atmospheric pressure is 640 mmHg; **(b)** the prevailing atmospheric pressure at Lake Arrowhead, California, if the observed boiling point of water is 94 °C.

35. A 25.0 L volume of He(g) at 30.0 °C is passed through 6.220 g of liquid aniline $(C_6H_5NH_2)$ at 30.0 °C. The liquid remaining after the experiment weighs 6.108 g. Assume that the He(g) becomes saturated with aniline vapor and that the total gas volume and temperature remain constant. What is the vapor pressure of aniline at 30.0 °C?

36. A 7.53 L sample of $N_2(g)$ at 742 mmHg and 45.0 °C is bubbled through $CCl_4(l)$ at 45.0 °C. Assuming the gas becomes saturated with $CCl_4(g)$, what is the volume of the resulting gaseous mixture, if the total pressure remains at 742 mmHg and the temperature remains at 45 °C? The vapor pressure of CCl_4 at 45 °C is 261 mmHg.

37. Some vapor pressure data for Freon-12, CCl_2F_2, once a common refrigerant, are −12.2 °C, 2.0 atm; 16.1 °C, 5.0 atm; 42.4 °C, 10.0 atm; 74.0 °C, 20.0 atm. Also, bp = −29.8 °C, $T_c = 111.5$ °C, $P_c = 39.6$ atm. Use these data to plot the vapor pressure curve of Freon-12. What approximate pressure would be required in the compressor of a refrigeration system to convert Freon-12 vapor to liquid at 25.0 °C?

38. A 10.0 g sample of liquid water is sealed in a 1515 mL flask and allowed to come to equilibrium with its vapor at 27 °C. What is the mass of $H_2O(g)$ present when equilibrium is established? Use vapor pressure data from Table 12.4.

The Clausius–Clapeyron Equation

39. Cyclohexanol has a vapor pressure of 10.0 mmHg at 56.0 °C and 100.0 mmHg at 103.7 °C. Calculate its enthalpy of vaporization, ΔH_{vap}.

40. The vapor pressure of methyl alcohol is 40.0 mmHg at 5.0 °C. Use this value and other information from the text to estimate the normal boiling point of methyl alcohol.

41. The normal boiling point of acetone, an important laboratory and industrial solvent, is 56.2 °C and its ΔH_{vap} is 25.5 kJ mol^{-1}. At what temperature does acetone have a vapor pressure of 375 mmHg?

42. The vapor pressure of trichloromethane (chloroform) is 40.0 Torr at −7.1 °C. Its enthalpy of vaporization is 29.2 kJ mol^{-1}. Calculate its normal boiling point.

43. Benzaldehyde, C_6H_5CHO, has a normal boiling point of 179.0 °C and a critical point at 422 °C and 45.9 atm. Estimate its vapor pressure at 100.0 °C.

44. With reference to Figure 12-20, which is the more volatile liquid, benzene or toluene? At approximately what temperature does the less volatile liquid have the same vapor pressure as the more volatile one at 65 °C?

Critical Point

45. Which substances listed in Table 12.5 can exist as liquids at room temperature (about 20.0 °C)? Explain.

46. Can SO_2 be maintained as a liquid under a pressure of 100 atm at 0 °C? Can liquid methane be obtained under the same conditions?

Melting and Freezing

47. The normal melting point of copper is 1357 K, and ΔH_{fus} of Cu is 13.05 kJ mol^{-1}. **(a)** How much heat, in kilojoules, is evolved when a 3.78 kg sample of molten Cu freezes? **(b)** How much heat, in kilojoules, must be absorbed at 1357 K to melt a bar of copper that is 75 cm × 15 cm × 12 cm? (Assume $d = 8.92$ g/cm^3 for Cu.)

48. An ice calorimeter measures quantities of heat by the quantity of ice melted. How many grams of ice would be melted by the heat released in the complete combustion of 1.35 L of propane gas, $C_3H_8(g)$, measured at 25.0 °C and 748 mmHg? [*Hint*: What is the standard molar enthalpy of combustion of $C_3H_8(g)$?]

States of Matter and Phase Diagrams

49. An 80.0 g piece of dry ice, $CO_2(s)$, is placed in a 0.500 L container, and the container is sealed. If this container is held at 25 °C, what state(s) of matter must be present? [*Hint*: Refer to Table 12.5 and Figure 12-28.]

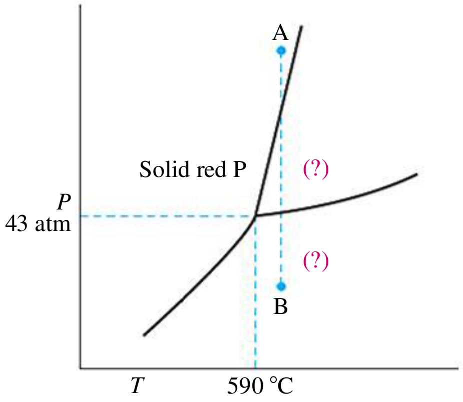
50. Sketch a plausible phase diagram for hydrazine (N_2H_4) from the following data: triple point (2.0 °C and 3.4 mmHg), the normal melting point (2 °C), the normal boiling point (113.5 °C), and the critical point (380 °C and 145 atm). The density of the liquid is less than that of the solid. Label significant data points on this diagram. Are there any features of the diagram that remain uncertain? Explain.

51. Shown here is a portion of the phase diagram for phosphorus.

(a) Indicate the phases present in the regions labeled with a question mark.

(b) A sample of solid red phosphorus cannot be melted by heating in a container open to the atmosphere. Explain why this is so.

(c) Trace the phase changes that occur when the pressure on a sample is reduced from point A to B, at constant temperature.



52. Describe what happens to the following samples in situations like those pictured in Figure 12-31. Be as specific as you can about the temperatures and pressures at which changes occur.

(a) A sample of water is heated from −20 to 200 °C at a constant pressure of 600 Torr.

(b) The pressure on a sample of iodine is increased from 90 mmHg to 100 atm at a constant temperature of 114 °C.

(c) A sample of carbon dioxide at 35 °C is cooled to −100 °C at a constant pressure of 50 atm. [*Hint:* Refer also to Table 12.5.]

53. A 0.240 g sample of $H_2O(l)$ is sealed into an evacuated 3.20 L flask. What is the pressure of the vapor in the flask if the temperature is **(a)** 30.0 °C; **(b)** 50.0 °C; **(c)** 70.0 °C?

54. A 2.50 g sample of $H_2O(l)$ is sealed in a 5.00 L flask at 120.0 °C.

(a) Show that the sample exists completely as vapor.

(b) Estimate the temperature to which the flask must be cooled before liquid water condenses.

55. Use appropriate phase diagrams and data from Table 12.5 to determine whether any of the following is likely to occur naturally at or near Earth's surface anywhere on Earth: **(a)** $CO_2(s)$; **(b)** $CH_4(l)$; **(c)** $SO_2(g)$; **(d)** $I_2(l)$; **(e)** $O_2(l)$. Explain.

56. Trace the phase changes that occur as a sample of $H_2O(g)$, originally at 1.00 mmHg and −0.10 °C, is compressed at constant temperature until the pressure reaches 100 atm.

57. To an insulated container with 100.0 g $H_2O(l)$ at 20.0 °C, 175 g steam at 100.0 °C and 1.65 kg of ice at 0.0 °C are added.

(a) What mass of ice remains unmelted after equilibrium is established?

(b) What *additional* mass of steam should be introduced into the insulated container to just melt all of the ice?

58. A 54 cm^3 ice cube at −25.0 °C is added to a thermally insulated container with 400.0 mL $H_2O(l)$ at 32.0 °C. What will be the final temperature in the container and what state(s) of matter will be present? (Specific heats: $H_2O(s)$, $2.01\ J\,g^{-1}\,°C^{-1}$; $H_2O(l)$, $4.18\ J\,g\,°C^{-1}$. Densities: $H_2O(s)$, $0.917\ g/cm^3$; $H_2O(l)$, $0.998\ g/cm^3$. Also, ΔH_{fus} of ice $= 6.01\ kJ\,mol^{-1}$.)

59. You decide to cool a can of soda pop quickly in the freezer compartment of a refrigerator. When you take out the can, the soda pop is still liquid; but when you open the can, the soda pop immediately freezes. Explain why this happens.

60. Why is the triple point of water (ice–liquid–vapor) a better fixed point for establishing a thermometric scale than either the melting point of ice or the boiling point of water?

Network Covalent Solids

61. Based on data presented in the text, would you expect diamond or graphite to have the greater density? Explain.

62. Diamond is often used as a cutting medium in glass cutters. What property of diamond makes this possible? Could graphite function as well?

63. Silicon carbide, SiC, crystallizes in a form similar to diamond, whereas boron nitride, BN, crystallizes in a form similar to graphite.

(a) Sketch the SiC structure as in Figure 12-32(b).

(b) Propose a bonding scheme for BN.

64. Are the fullerenes network covalent solids? What makes them different from diamond and graphite? It has been shown that carbon can form chains in which every other carbon atom is bonded to the next carbon atom by a triple bond. Is this allotrope of carbon a network covalent solid? Explain.

Ionic Bonding and Properties

65. The melting points of NaF, NaCl, NaBr, and NaI are 988, 801, 755, and 651 °C, respectively. Are these data consistent with ideas developed in Section 12-5? Explain.

66. Use Coulomb's law (see Appendix B) to verify the conclusion concerning the relative strengths of the attractive forces in the ion pairs Na^+Cl^- and $Mg^{2+}O^{2-}$ presented in Figure 12-36.

67. The hardness of crystals is rated based on Mohs hardness values. The higher the Mohs value, the harder the material is to scratch. Which crystal will have the highest Mohs value: NaF, NaCl, or KCl?

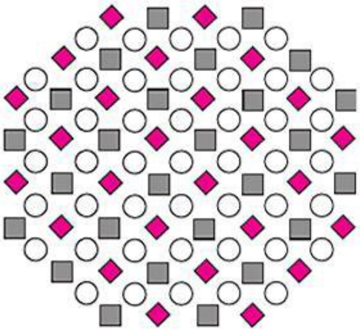
68. Will the mineral villaumite (NaF) or periclase (MgO) have a higher Mohs hardness value (see Exercise 67)?

Crystal Structures

69. Explain why there are *two* arrangements for the closest packing of spheres rather than a single one.

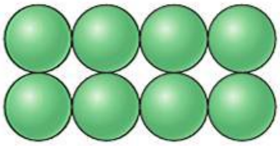
70. Argon, copper, sodium chloride, and carbon dioxide all crystallize in the fcc structure. How can this be when their physical properties are so different?

71. Consider the two-dimensional lattice shown here.



(a) Identify a unit cell.
(b) How many of each of the following elements are in the unit cell: ◆, ■, and ○?
(c) Indicate some simpler units than the unit cell, and explain why they cannot function as a unit cell.

72. As we saw in Section 12-6, stacking spheres always leaves open space. Consider the corresponding situation in two dimensions: Squares can be arranged to cover all the area, but circles cannot. For the arrangement of circles pictured here, what percentage of the area remains uncovered?



73. Tungsten has a body-centered cubic crystal structure. Using a metallic radius of 139 pm for the W atom, calculate the density of tungsten.

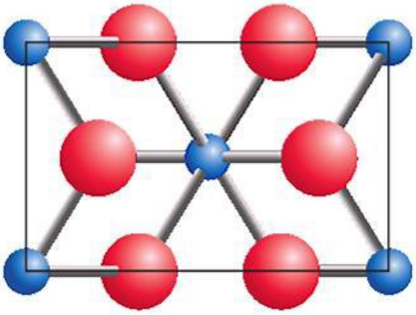
74. Magnesium crystallizes in the hcp arrangement shown in Figure 12-41. The dimensions of the unit cell are height, 520 pm; length on an edge, 320 pm. Calculate the density of Mg(s), and compare with the measured value of 1.738 g/cm^3.

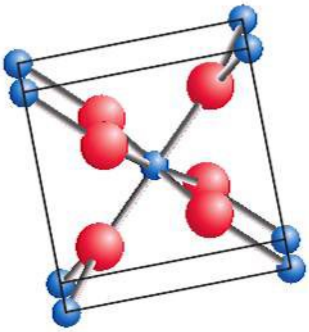
75. Polonium (Po) is the largest member of group 16 and is the only element known to take on the simple cubic crystal system. The distance between nearest neighbor Po atoms in this structure is 335 pm.
(a) What is the diameter of a Po atom?
(b) What is the density of Po metal?
(c) At what angle (in degrees) to the parallel faces of the Po unit cells would first-order diffraction be observed when using X-rays of wavelength 1.785×10^{-10} m?

76. Germanium has a cubic unit cell with a side edge of 565 pm. The density of germanium is 5.36 g/cm^3. What is the crystal system adopted by germanium?

77. Silicon tetrafluoride molecules are arranged in a body-centered cubic unit cell. How many silicon atoms are in the unit cell?

78. Two views, a top and side view, for the unit cell for rutile (TiO_2) are shown here. **(a)** How many titanium atoms (blue) are in this unit cell? **(b)** How many oxygen atoms (red) are in this unit cell?





Ionic Crystal Structures

79. Show that the unit cells for CaF_2 and TiO_2 in Figure 12-50 are consistent with their formulas.

80. Using methods similar to Examples 12-10 and 12-11, calculate the density of CsCl. Use 169 pm as the radius of Cs^+.

81. The crystal structure of magnesium oxide, MgO, is of the NaCl type (Fig. 12-48). Use this fact, together with ionic radii from Figure 9-8, to establish the following.
(a) the coordination numbers of Mg^{2+} and O^{2-};
(b) the number of formula units in the unit cell;
(c) the length and volume of a unit cell;
(d) the density of MgO.

82. Potassium chloride has the same crystal structure as NaCl. Careful measurement of the internuclear distance between K^+ and Cl^- ions gave a value of 314.54 pm. The density of KCl is $1.9893\ g/cm^3$. Use these data to evaluate the Avogadro constant, N_A.

83. Use data from Figure 9-9 to predict the type of cubic unit cell adopted by **(a)** CaO; **(b)** CuCl; **(c)** LiO_2 (the radius of the O_2^- ion is 128 pm).

84. Use data from Figure 9-9 to predict the type of cubic unit cell adopted by **(a)** BaO; **(b)** CuI; **(c)** LiS_2. (The radii of Ba^{2+} and S_2^- ions are 135 and 198 pm, respectively.)

Lattice Energy

85. *Without doing calculations*, indicate how you would expect the lattice energies of LiCl(s), KCl(s), RbCl(s), and CsCl(s) to compare with the value of $-787\ kJ\ mol^{-1}$ determined for NaCl(s) on page 543. [*Hint:* Assume that the enthalpies of sublimation of the alkali metals are comparable in value. What atomic properties from Chapter 9 should you compare?]

86. Determine the lattice energy of KF(s) from the following data: $\Delta H_f^\circ[KF(s)] = -567.3\ kJ\ mol^{-1}$; enthalpy of sublimation of K(s), $89.24\ kJ\ mol^{-1}$; enthalpy of dissociation of $F_2(g)$, $159\ kJ\ mol^{-1}\ F_2$; I_1 for K(g), $418.9\ kJ\ mol^{-1}$; EA for F(g), $-328 kJ\ mol^{-1}$.

87. Refer to Example 12-12. Together with data given there, use the data here to calculate ΔH_f° for 1 mol $MgCl_2(s)$. Explain why you would expect $MgCl_2$ to be a much more stable compound than MgCl. (Second ionization energy of Mg, $I_2 = 1451\ kJ\ mol^{-1}$; lattice energy of $MgCl_2(s) = -2526\ kJ\ mol^{-1}\ MgCl_2$.)

88. In ionic compounds with certain metals, hydrogen exists as the hydride ion, H^-. Determine the electron affinity of hydrogen; that is, ΔH for the process $H(g) + e^- \rightarrow H^-(g)$. To do so, use data from Section 12-7; the bond energy of $H_2(g)$ from Table 10.3; $-812\ kJ\ mol^{-1}$ NaH for the lattice energy of NaH(s); and $-57\ kJ\ mol^{-1}$ NaH for the enthalpy of formation of NaH(s).

Integrative and Advanced Exercises

89. When a wax candle is burned, the fuel consists of *gaseous* hydrocarbons appearing at the end of the candle wick. Describe the phase changes and processes by which the solid wax is ultimately consumed.

90. The normal boiling point of water is 100.00 °C and the enthalpy of vaporization at this temperature is $\Delta H_{vap} = 40.657\ kJ\ mol^{-1}$. What would be the boiling point of water if it were based on a pressure of 1 bar instead of the standard atm?

91. A supplier of cylinder gases warns customers to determine how much gas remains in a cylinder by weighing the cylinder and comparing this mass to the original mass of the full cylinder. In particular, the customer is told not to try to estimate the mass of gas available from the measured gas pressure. Explain the basis of this warning. Are there cases where a measurement of the gas pressure *can* be used as a measure of the remaining available gas? If so, what are they?

92. Use the following data and data from Appendix D to determine the quantity of heat needed to convert 15.0 g of solid mercury at −50.0 °C to mercury vapor at 25 °C. Specific heats: Hg(s), $24.3\ J\ mol^{-1}\ K^{-1}$; Hg(l), $28.0\ J\ mol^{-1}\ K^{-1}$. Melting point of Hg(s), −38.87 °C. Heat of fusion, $2.33\ kJ\ mol^{-1}$.

93. To vaporize 1.000 g water at 20 °C requires 2447 J of heat. At 100 °C, 10.00 kJ of heat will convert 4.430 g $H_2O(l)$ to $H_2O(g)$. Do these observations conform to your expectations? Explain.

94. Estimate how much heat is absorbed when 1.00 g of Instant Car Kooler vaporizes. Comment on the effectiveness of this spray in cooling the interior of a car. Assume the spray is 10% $C_2H_5OH(aq)$ by mass, the temperature is 55 °C, the heat capacity of air is $29\ J\ mol^{-1}\ K^{-1}$, and use ΔH_{vap} data from Table 12.3.

95. Because solid *p*-dichlorobenzene, $C_6H_4Cl_2$, sublimes rather easily, it has been used as a moth repellent. From the data given, estimate the sublimation pressure of $C_6H_4Cl_2(s)$ at 25 °C. For $C_6H_4Cl_2$; mp = 53.1 °C; vapor pressure of $C_6H_4Cl_2(l)$ at 54.8 °C is 10.0 mmHg; $\Delta H_{fus} = 17.88\ kJ\ mol^{-1}$; $\Delta H_{vap} = 72.22\ kJ\ mol^{-1}$.

96. A 1.05 mol sample of $H_2O(g)$ is compressed into a 2.61 L flask at 30.0 °C. Describe the point(s) in Figure 12-30 representing the final condition.

97. One handbook lists the sublimation pressure of *solid* benzene as a function of *Kelvin* temperature, T, as $\log P(\text{mmHg}) = 9.846 - 2309/T$. Another handbook lists the vapor pressure of *liquid* benzene as a function of *Celsius* temperature, t, as $\log P(\text{mmHg}) = 6.90565 - 1211.033/(220.790 + t)$. Use these equations to estimate the normal melting point of benzene, and compare your result with the listed value of 5.5 °C.

98. By the method used to graph Figure 12-20, plot ln P versus $1/T$ for liquid white phosphorus, and estimate

(a) its normal boiling point and **(b)** its enthalpy of vaporization, ΔH_{vap}, in kJ mol^{-1}. Vapor pressure data: 76.6 °C, 1 mmHg; 128.0 °C, 10 mmHg; 166.7 °C, 40 mmHg; 197.3 °C, 100 mmHg; 251.0 °C, 400 mmHg.

99. Assume that a skater has a mass of 80 kg and that his skates make contact with 2.5 cm^2 of ice. **(a)** Calculate the pressure in atm exerted by the skates on the ice. **(b)** If the melting point of ice decreases by 1.0 °C for every 125 atm of pressure, what would be the melting point of the ice under the skates?

100. Estimate the boiling point of water in Leadville, Colorado, elevation 3170 m. To do this, use the barometric formula relating pressure and altitude: $P = P_0 \times 10^{-Mgh/2.303\,RT}$ (where P = pressure in atm; $P_0 = 1$ atm; g = acceleration due to gravity; molar mass of air, $M = 0.02896$ kg mol^{-1}; $R = 8.3145$ J mol^{-1} K^{-1}; and T is the Kelvin temperature). Assume the air temperature is 10.0 °C and that $\Delta H_{\text{vap}} = 41$ kJ mol^{-1} H_2O.

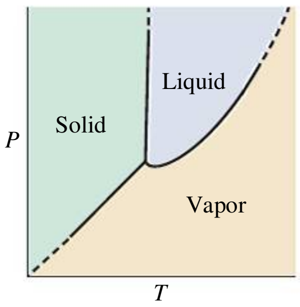
101. Inspection of the straight-line graphs in Figure 12-20 suggests that the graphs for benzene and water intersect at a point that falls off the page. At this point, the two liquids have the same vapor pressure. Estimate the temperature and the vapor pressure at this point by a calculation based on data obtainable from the graphs.

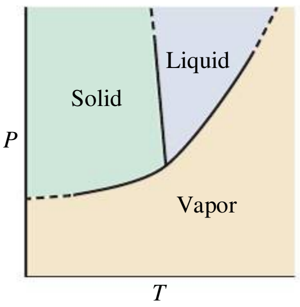
102. A cylinder containing 151 lb Cl_2 has an inside diameter of 10 in. and a height of 45 in. The gas pressure is 100 psi (1 atm = 14.7 psi) at 20 °C. Cl_2 melts at −103 °C, boils at −35 °C, and has its critical point at 144 °C and 76 atm. In what state(s) of matter does the Cl_2 exist in the cylinder?

103. In acetic acid vapor, some molecules exist as monomers and some as dimers (see Figure 12-9). If the density of the vapor at 350 K and 1 atm is 3.23 g/L, what percentage of the molecules must exist as dimers? Would you expect this percent to increase or decrease with temperature?

104. A 685 mL sample of Hg(l) at 20 °C is added to a large quantity of liquid N_2 kept at its boiling point in a thermally insulated container. What mass of N_2(l) is vaporized as the Hg is brought to the temperature of the liquid N_2? For the specific heat of Hg(l) from 20 to −39 °C use 0.138 J g^{-1} °C^{-1}, and for Hg(s) from −39 to −196 °C, 0.126 J g^{-1} °C^{-1}. The density of Hg(l) is 13.6 g/mL, its melting point is −39 °C, and its enthalpy of fusion is 2.30 kJ mol^{-1}. The boiling point of N_2(l) is −196 °C, and its ΔH_{vap} is 5.58 kJ mol^{-1}.

105. Sketched here are two hypothetical phase diagrams for a substance, but neither of these diagrams is possible. Indicate what is wrong with each of them.



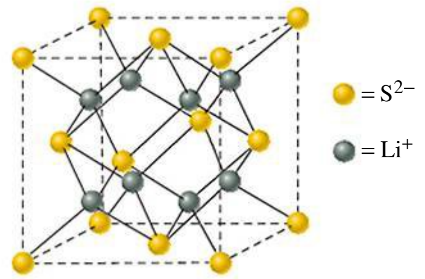


106. A chemistry handbook lists the following equation for the vapor pressure of NH_3(l) as a function of temperature. What is the normal boiling point of NH_3(l)?

$$\log_{10} P(\text{mmHg}) = 9.95028 - 0.003863T - \frac{1473.17}{T}$$

107. The triple point temperature of bismuth is 544.5 K and the normal boiling point is 1832 K. Imagine that a 1.00 mol sample of bismuth is heated at a constant rate of 1.00 kJ min^{-1} in an apparatus in which the sample is maintained under a constant pressure of 1 atm. In the manner shown in Figure 12-24 and as much to scale as possible, that is in terms of times and temperatures, sketch the heating curve that would be obtained in heating the sample from 300 K to 2000 K. Use the following data. $\Delta H_{\text{fus}} = 10.9$ kJ mol^{-1} Bi(s); $\Delta H_{\text{vap}} = 151.5$ kJ mol^{-1} Bi(l); average molar heat capacities, in J mol^{-1} K^{-1}, 28 for Bi(s), 31 for Bi(l), and 21 for Bi(g). [*Hint:* Under the conditions described, no vapor appears until the normal boiling point is reached.]

108. The crystal structure of lithium sulfide (Li_2S), is pictured here. The length of the unit cell is 5.88×10^2 pm. For this structure, determine



(a) the coordination numbers of Li^+ and S^{2-}
(b) the number of formula units in the unit cell
(c) the density of Li_2S

109. Refer to Figure 12-44 and Figure 12-48. Suppose that the two planes of ions pictured in Figure 12-44 correspond to the top and middle planes of ions in the NaCl unit cell in Figure 12-48. If the X-rays used have a wavelength of 154.1 pm, at what angle θ would the diffracted beam have its greatest intensity? [*Hint:* Use n=1 in equation (12.5).]

110. Use the analyses of a bcc structure on page 534 and the fcc structure in Exercise 139 to determine the percent voids in the packing-of-spheres arrangement found in the fcc crystal structure.

111. One way to describe ionic crystal structures is in terms of cations filling voids among closely packed anions. Show that in order for cations to fill the tetrahedral voids in a close packed arrangement of anions, the radius ratio of cation, r_c, to anion, r_a, must fall between the following limits $0.225 < r_c : r_a < 0.414$.

112. Use the unit cell of diamond in Figure 12-32(b) and a carbon-to-carbon bond length of 154.45 pm, together with other relevant data from the text, to calculate the density of diamond.

113. The enthalpy of formation of NaI(s) is −288 kJ mol^{-1}. Use this value, together with other data in the text, to calculate the lattice energy of NaI(s). [*Hint:* Use data from Appendix D also.]

114. Show that the formation of $NaCl_2(s)$ is very unfavorable; that is, $\Delta H_f^\circ[NaCl_2(s)]$ is a large *positive* quantity. To do this, use data from Section 12-7 and assume that the lattice energy for $NaCl_2$ would be about the same as that of $MgCl_2$, $-2.5 \times 10^3\ kJ\ mol^{-1}$.

115. A crystalline solid contains three types of ions, Na^+, O^{2-}, and Cl^-. The solid is made up of cubic unit cells that have O^{2-} ions at each corner, Na^+ ions at the center of each face, and Cl^- ions at the center of the cells. What is the chemical formula of the compound? What are the coordination numbers for the O^{2-} and Cl^- ions? If the length of one edge of the unit cell is a, what is the shortest distance from the center of a Na^+ ion to the center of an O^{2-} ion? Similarly, what is the shortest distance from the center of a Cl^- ion to the center of an O^{2-} ion?

116. A certain mineral has a cubic unit cell with calcium at each corner, oxygen at the center of each face, and titanium at its body center. What is the formula of the mineral? An alternate way of drawing the unit cell has calcium at the center of each cubic unit cell. What are the positions of titanium and oxygen in such a representation of the unit cell? How many oxygen atoms surround a particular titanium atom in either representation?

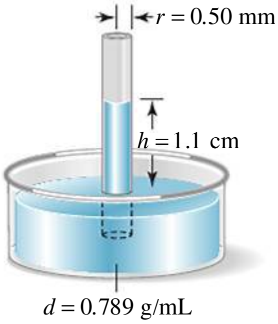
117. Calculate the radius ratio (r_+/r_-) for CaF_2. Suggest an alternative structure to that shown in Figure 12-50(b) that better conforms to the radius ratio you compute.

118. In some barbecue grills the electric lighter consists of a small hammer-like device striking a small crystal, which generates voltage and causes a spark between wires that are attached to opposite surfaces of the crystal. The phenomenon of causing an electric potential through mechanical stress is known as the piezoelectric effect. One type of crystal that exhibits the piezoelectric effect is lead zirconate titanate. In this perovskite crystal structure, a titanium(IV) ion sits in the middle of a tetragonal unit cell with dimensions of $0.403\ nm \times 0.398\ nm \times 0.398\ nm$. At each corner is a lead(II) ion, and at the center of each face is an oxygen anion. Some of the Ti(IV) are replaced by Zr(IV). This substitution, along with Pb(II), results in the piezoelectic behavior.

(a) How many oxygen ions are in the unit cell?
(b) How many lead(II) ions are in the unit cell?
(c) How many titanium(IV) ions are in the unit cell?
(d) What is the density of the unit cell?

Feature Problems

119. In a capillary rise experiment, the height (h) to which a liquid rises depends on the density (d) and surface tension (γ) of the liquid and the radius of the capillary (r). The equation relating these quantities and the acceleration due to gravity (g) is $h = 2\gamma/dgr$. The sketch provides data obtained with ethanol. What is the surface tension of ethanol?



120. We have learned that the enthalpy of vaporization of a liquid is generally a function of temperature. If we wish to take this temperature variation into account, we cannot use the Clausius–Clapeyron equation in the form given in the text (that is, equation 12.2). Instead, we must go back to the differential equation upon which the Clausius–Clapeyron equation is based and reintegrate it into a new expression. Our starting point is the following equation describing the rate of change of vapor pressure with temperature in terms of the enthalpy of vaporization, the difference in molar volumes of the vapor (V_g), and liquid (V_l), and the temperature.

$$\frac{dP}{dT} = \frac{\Delta H_{vap}}{T(V_g - V_l)}$$

Because in most cases the volume of one mole of vapor greatly exceeds the molar volume of liquid, we can treat the V_l term as if it were zero. Also, unless the vapor pressure is unusually high, we can treat the vapor as if it were an ideal gas; that is, for one mole of vapor, $PV = RT$. Make appropriate substitutions into the above expression, and separate the P and dP terms from the T and dT terms. The appropriate substitution for ΔH_{vap} means expressing it as a function of temperature. Finally, integrate the two sides of the equation between the limits P_1 and P_2 on one side and T_1 and T_2 on the other.

(a) Derive an equation for the vapor pressure of $C_2H_4(l)$ as a function of temperature, if $\Delta H_{vap} = 15{,}971 + 14.55\,T - 0.160\,T^2$ (in $J\ mol^{-1}$).

(b) Use the equation derived in (a), together with the fact that the vapor pressure of $C_2H_4(l)$ at 120 K is 10.16 Torr, to determine the normal boiling point of ethylene.

121. All solids contain defects or imperfections of structure or composition. Defects are important because they influence properties, such as mechanical strength. Two common types of defects are a missing ion in an otherwise perfect lattice, and the slipping of an ion from its normal site to a hole in the lattice.

The holes discussed in this chapter are often called *interstitial sites*, since the holes are in fact interstices in the array of spheres. The two types of defects described here are called *point defects* because they occur within specific sites. In the 1930s, two solid-state physicists, W. Schottky and J. Fraenkel, studied the two types of point defects: A Schottky defect corresponds to a missing ion in a lattice, while a Fraenkel defect corresponds to an ion that is displaced into an interstitial site.

(a) An example of a Schottky defect is the absence of a Na^+ ion in the NaCl structure. The absence of a Na^+ ion means that a Cl^- ion must also be absent to preserve electrical neutrality. If one NaCl unit is missing per unit cell, does the overall stoichiometry change, and what is the change in density?

(b) An example of a Fraenkel defect is the movement of a Ag^+ ion to a tetrahedral interstitial site from its normal octahedral site in AgCl, which has a structure like NaCl. Does the overall stoichiometry of the compound change, and do you expect the density to change?

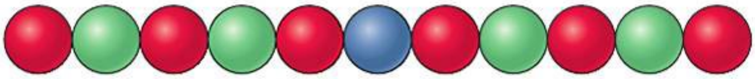
(c) Titanium monoxide (TiO) has a sodium chloride-like structure. X-ray diffraction data show that the edge length of the unit cell is 418 pm. The density of the crystal is 4.92 g/cm^3 Do the data indicate the presence of vacancies? If so, what type of vacancies?

122. In an ionic crystal lattice each cation will be attracted by anions next to it and repulsed by cations near it. Consequently the coulomb potential leading to the lattice energy depends on the type of crystal. To get the total lattice energy you must sum all of the electrostatic interactions on a given ion. The general form of the electrostatic potential is

$$V = \frac{Q_1 Q_2 e^2}{d_{12}}$$

where Q_1 and Q_2 are the charges on ions 1 and 2, d_{12} is the distance between them in the crystal lattice. and e is the charge on the electron.

(a) Consider the linear "crystal" shown below.



The distance between the centers of adjacent spheres is R. Assume that the blue sphere and the green spheres are cations and that the red spheres are anions. Show that the total electrostatic energy is

$$V = -\frac{Q^2 e^2}{d} \times \ln 2$$

(b) In general, the electrostatic potential in a crystal can be written as

$$V = -k_M \frac{Q^2 e^2}{R}$$

where k_M is a geometric constant, called the Madelung constant, for a particular crystal system under consideration. Now consider the NaCl crystal structure and let R be the distance between the centers of sodium and chloride ions. Show that by considering three layers of nearest neighbors to a central chloride ion, k_M is given by

$$k_M = \left(6 - \frac{12}{\sqrt{2}} + \frac{8}{\sqrt{3}} - \frac{6}{\sqrt{4}} \cdots\right)$$

(c) Carry out the same calculation for the CsCl structure. Are the Madelung constants the same?

123. Plot the following data first as boiling point versus polarizability, and then as boiling point versus molecular mass. What conclusions can you draw from these plots?

Compound	Polarizability, 10^{-25} cm^3	Mass, amu	Boiling Point, K
H_2	7.90	2.0158	20.35
N_2	17.6	28.0134	77.35
O_2	16.0	31.9988	90.188
Cl_2	46.1	70.906	238.25
HF	24.6	20.01	292.69
HCl	26.3	36.46	188.25
HBr	36.1	80.92	206.15
HI	54.4	127.91	237.77
N_2O	30.0	44.01	184.65
CO	19.5	28.01	81.65
SO_2	37.2	64.06	263.15
H_2S	37.8	34.08	212.45
CS_2	87.4	76.14	319.45
NH_3	22.6	17.03	239.8
HCN	25.9	27.03	299.15
CH_4	26.0	16.04	109.15
C_2H_6	44.7	30.07	184.55
$CH_2{=}CH_2$	42.6	28.05	169.45
$CH{=}CH$	33.3	26.01	189.15
C_3H_8	62.9	44.11	231.05
C_6H_6	103	78.12	353.25
CH_3Cl	45.6	50.94	248.95
CH_2Cl_2	64.8	84.93	313.15
$CHCl_3$	82.3	119.38	334.85
CCl_4	105	153.81	349.95
CH_3OH	32.3	32.04	338.15

124. The Born–Fajans–Haber cycle uses thermodynamic cycles to determine lattice energy. An alternative to the Born–Fajans–Haber method is one based on fundamental principles. Because the dominant interactions in an ionic crystal are Coulomb interactions, we can use the theory of electrostatics to calculate the lattice energy. Kapustinskii used these ideas and proposed the following equation:

$$U = \frac{120{,}250\, v\, Z^+ Z^-}{r_0}\left(1 - \frac{34.5}{r_0}\right)(\text{kJ mol}^{-1})$$

where the number of ions per formula unit is given by v and r_0 is equal to the sum of the ionic radii, $r_+ + r_-$(pm). Use the equation to complete the following table:

Compound	Lattice Energy, KJ mol^{-1}	r_-, pm	r_+, pm
NaCl		181	99
LaF_3		133	117
Na_2SO_4	−3389		99

Self-Assessment Exercises

125. In your own words, define or explain the following terms or symbols: **(a)** ΔH_{vap}; **(b)** T_c; **(c)** instantaneous dipole; **(d)** coordination number; **(e)** unit cell.

126. Briefly describe each of the following phenomena or methods: **(a)** capillary action; **(b)** polymorphism; **(c)** sublimation; **(d)** supercooling; **(e)** determining the freezing point of a liquid from a cooling curve.

127. Explain the important distinctions between each pair of terms: **(a)** adhesive and cohesive forces; **(b)** vaporization and condensation; **(c)** triple point and critical point; **(d)** face-centered and body-centered cubic unit cell; **(e)** tetrahedral and octahedral hole.

128. The magnitude of one of the following properties must always increase with temperature; that one is **(a)** surface tension; **(b)** density; **(c)** vapor pressure; **(d)** ΔH_{vap}.

129. Of the compounds HF, CH_4, CH_3OH, N_2H_4, and $CHCl_3$, hydrogen bonding is an important intermolecular force in **(a)** none of these; **(b)** two of these; **(c)** three of these; **(d)** all but one of these; **(e)** all of these.

130. A metal that crystallizes in the body-centered cubic (bcc) structure has a crystal coordination number of **(a)** 6; **(b)** 8; **(c)** 12; **(d)** any even number between 4 and 12.

131. A unit cell of an ionic crystal **(a)** shares some ions with other unit cells; **(b)** is the same as the formula unit; **(c)** is any portion of the crystal that has a cubic shape; **(d)** must contain the same number of cations and anions.

132. If the triple point pressure of a substance is greater than 1 atm, which two of the following conclusions are valid?

(a) The solid and liquid states of the substance cannot coexist at equilibrium.

(b) The melting point and boiling point of the substance are identical.

(c) The liquid state of the substance cannot exist.

(d) The liquid state cannot be maintained in a beaker open to air at 1 atm pressure.

(e) The melting point of the solid must be greater than 0 °C.

(f) The gaseous state at 1 atm pressure cannot be condensed to the solid at the triple point temperature.

133. In each of the following pairs, which would you expect to have the higher boiling point? **(a)** C_7H_{16} or $C_{10}H_{22}$; **(b)** C_3H_8 or $(CH_3)_2O$; **(c)** CH_3CH_2SH or CH_3CH_2OH.

134. One of the substances is out of order in the following list based on increasing boiling point. Identify it, and put it in its proper place: N_2, O_3, F_2, Ar, Cl_2. Explain your reasoning.

135. Arrange the following substances in the expected order of increasing melting point: KI, Ne, K_2SO_4, C_3H_8, CH_3CH_2OH, MgO, $CH_2OHCHOHCH_2OH$.

136. Is it possible to obtain a sample of ice from liquid water without ever putting the water in a freezer or other enclosure at a temperature below 0 °C? If so, how might this be done?

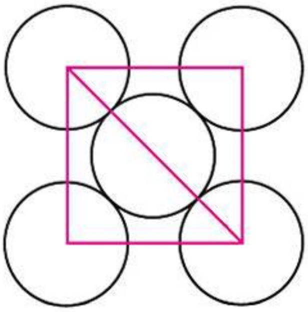
137. The phenomena in Figure 12-22 will be seen at the critical temperature only if the proper amount of liquid is placed in the sealed tube initially. Why should this be the case? What would you expect to see if too little liquid was present initially? If too much liquid was present?

138. The following data are given for CCl_4. Normal melting point, −23 °C; normal boiling point, 77 °C; density of liquid 1.59 g/mL; $\Delta H_{fus} = 3.28\ \text{kJ mol}^{-1}$; vapor pressure at 25 °C, 110 Torr.

(a) What phases—solid, liquid, and/or gas—are present if 3.50 g CCl_4 is placed in a closed 8.21 L container at 25 °C?

(b) How much heat is required to vaporize 2.00 L of $CCl_4(l)$ at its normal boiling point?

139. The fcc unit cell is a cube with atoms at each of the corners and in the center of each face, as shown here. Copper has the fcc crystal structure. Assume an atomic radius of 128 pm for a Cu atom.



(a) What is the length of the unit cell of Cu?

(b) What is the volume of the unit cell?

(c) How many atoms belong to the unit cell?

(d) What percentage of the volume of the unit cell is occupied?

(e) What is the mass of a unit cell of copper?

(f) Calculate the density of copper.

140. Of the following liquids at 20 °C, which has the smallest surface tension? **(a)** CH_3OH; **(b)** CH_3CH_2OH; **(c)** $CH_3CH_2CH_2OH$; **(d)** $CH_3CH_2CH_2CH_2OH$.

141. Of the following liquids at 20 °C, which has the smallest viscosity? **(a)** Dodecane, $C_{12}H_{26}$; **(b)** n-nonane, C_9H_{20}; **(c)** n-heptane C_7H_{16}; **(d)** n-pentane C_5H_{12}.

142. Would you expect an ionic solid or a network covalent solid to have the higher melting point?

143. In the lithium iodide crystal, the Li–I distance is 3.02 Å. Calculate the iodide radius, assuming that the iodide ions are in contact.

144. Which of the following phase transitions is most likely to occur when the pressure on a metallic solid increases? **(a)** bcc to sc; **(b)** fcc to sc; **(c)** bcc to fcc; **(d)** fcc to sc.

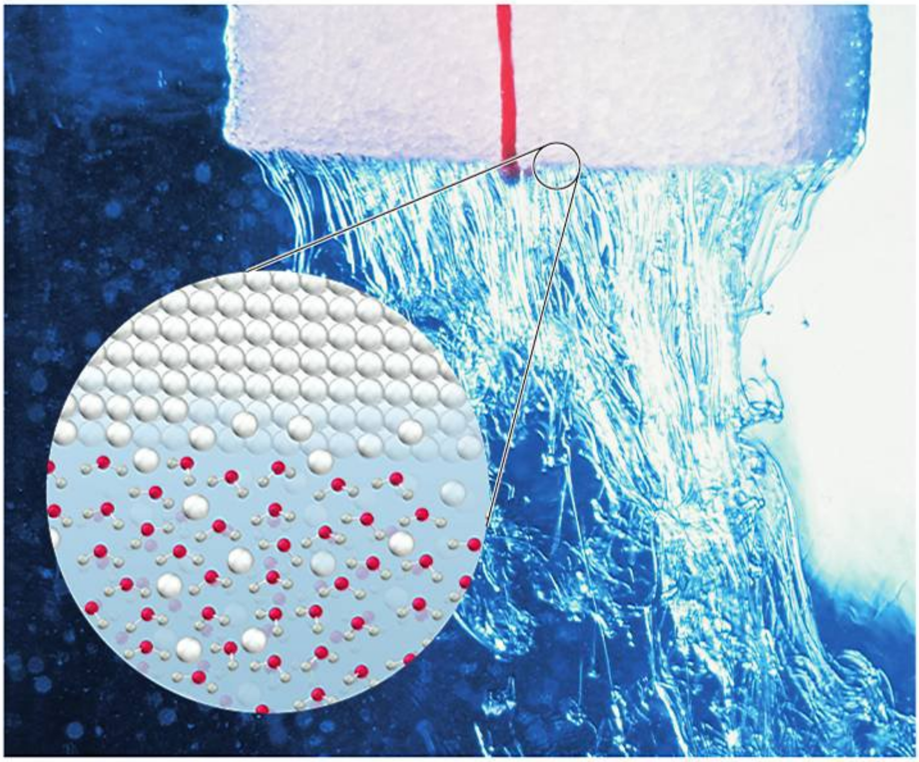
145. Construct a concept map representing the different types of intermolecular forces and their origin.

146. Construct a concept map using the ideas of packing of spheres and the structure of metal and ionic crystals.

147. Construct a concept map showing the ideas contained in a phase diagram.

13

Solutions and Their Physical Properties



The dissolving of a cube of sugar (sucrose) is seen here as swirls of a higher-density sucrose solution falling through the lower-density water.

Residents of cold climate regions know they must add antifreeze to the water in the cooling system of an automobile in the winter. The antifreeze–water mixture has a much lower freezing point than does pure water. In this chapter we will learn why.

To restore body fluids to a dehydrated individual by intravenous injection, pure water cannot be used. A solution with just the right value of a physical property known as osmotic pressure is necessary, and this requires a solution of a particular concentration of solutes. Again, in this chapter we will learn why.

Altogether, we will explore several solution properties whose values depend on solution concentration. Our emphasis will be on describing solution phenomena and their applications and explaining these phenomena at the molecular level.

CONTENTS

13-1 Types of Solutions: Some Terminology
13-2 Solution Concentration
13-3 Intermolecular Forces and the Solution Process
13-4 Solution Formation and Equilibrium
13-5 Solubilities of Gases
13-6 Vapor Pressures of Solutions
13-7 Osmotic Pressure
13-8 Freezing-Point Depression and Boiling-Point Elevation of Nonelectrolyte Solutions
13-9 Solutions of Electrolytes
13-10 Colloidal Mixtures

13-1 Types of Solutions: Some Terminology

In Chapters 1 and 4 we learned that a solution is a *homogeneous mixture*. It is *homogeneous* because its composition and properties are uniform, and it is a *mixture* because it contains two or more substances in proportions that can be varied. The **solvent** is the component that is present in the greatest quantity or that determines the state of matter in which a solution exists. Other solution components, called **solutes**, are said to be dissolved in the solvent. A *concentrated* solution has a relatively large quantity of dissolved solute(s), and a *dilute* solution has only a small quantity. Consider solutions containing sucrose (cane sugar) as one of the solutes in the solvent water: Pancake syrup is a concentrated solution, whereas a sweetened cup of coffee is much more dilute.

Although liquid solutions are most common, solutions can exist in gaseous and solid states as well. For instance, the U.S. five-cent coin, the nickel, is a solid solution of 75% Cu and 25% Ni. Solid solutions with a metal as the solvent are also called *alloys*.* Table 13.1 lists a few common solutions.

13-2 Solution Concentration

In Chapters 4 and 5 we learned that to describe a solution fully we must know its *concentration*—a measure of the quantity of solute in a given quantity of solvent (or solution). The concentration unit we stressed in those chapters was molarity. In this section, we describe several methods of expressing concentration, each of which serves a different purpose.

Mass Percent, Volume Percent, and Mass/Volume Percent

If we dissolve 5.00 g NaCl in 95.0 g H_2O, we get 100.0 g of a solution that is 5.00% NaCl, by *mass*. Mass percent is widely used in industrial chemistry. Thus, we might read that the action of 78% $H_2SO_4(aq)$ on phosphate rock $[3\,Ca_3(PO_4)_2 \cdot CaF_2]$ produces 46% $H_3PO_4(aq)$.

Because liquid volumes are so easily measured, some solutions are prepared on a *volume* percent basis. For example, a handbook lists a freezing point of −15.6 °C for a methyl alcohol–water antifreeze solution that is 25.0%

TABLE 13.1 Some Common Solutions

Solution	Components
Gaseous solutions	
Air	N_2, O_2, and several others
Natural gas	CH_4, C_2H_6, and several others
Liquid solutions	
Seawater	H_2O, NaCl, and many others
Vinegar	H_2O, CH_3COOH (acetic acid)
Soda pop	H_2O, CO_2, $C_{12}H_{22}O_{11}$ (sucrose), and several others
Solid solutions	
Yellow brass	Cu, Zn
Palladium–Hydrogen	Pd, H_2

---

*The term *alloy* can also apply to certain heterogeneous mixtures, such as the common two-phase solid mixture of lead and tin known as *solder*, or to intermetallic compounds, such as the silver–tin compound Ag_3Sn that, in the past, was mixed with mercury in *dental amalgam*.

CH_3OH, by volume. Such a solution could be prepared by dissolving 25.0 mL $CH_3OH(l)$ with water until the total solution volume is 100.0 mL.

Another possibility is to express the *mass* of solute and *volume* of solution. An aqueous solution with 0.9 g NaCl in 100.0 mL of solution is said to be 0.9% NaCl (*mass/volume*). Mass/ volume percent is extensively used in the medical and pharmaceutical fields.

Parts per Million, Parts per Billion, and Parts per Trillion

In solutions where the mass or volume percent of a component is very low, we often switch to other units to describe solution concentration. For example, 1 mg solute/L solution amounts to only 0.001 g/L. A solution that is this dilute will have the same density as water, approximately 1 g/mL; therefore, the solution concentration is 0.001 g solute/1000 g solution, which is the same as 1 g solute/1,000,000 g solution. We can describe the solute concentration more succinctly as 1 *part per million* **(ppm)**. For a solution with only 1 μg solute/L solution, the situation is 1×10^{-6} g solute/1000 g solution, or 1.0 g solute/ 1×10^{9} g solution. Here, the solute concentration is 1 *part per billion* **(ppb)**. If the solute concentration is only 1 μg solute/L solution, the concentration is 1 *part per trillion* **(ppt)**.

◀ A part per billion: The average head of hair has 10,000 hairs. Therefore, 1 part per billion is one hair out of 100,000 people.

Because these terms are widely used in environmental reporting, they may be more familiar than other units that chemists use. For example, a consumer in California might read in an annual water quality report from the municipal water department that the maximum contaminant level allowed for nitrate ion is 45 ppm and for carbon tetrachloride, 0.5 ppb.

KEEP IN MIND

that 1 ppm = 1 mg/L, 1 ppb = 1 μg/L, and 1 ppt = 1 ng/L.

Mole Fraction and Mole Percent

To relate certain physical properties (such as vapor pressure) to solution concentration, we need a unit in which all solution components are expressed on a mole basis. We can do this with the mole fraction. The *mole fraction* of component *i*, designated x_i, is the fraction of all the molecules in a solution that are of type *i*. The mole fraction of component *j* is x_j, and so on. The mole fraction of a solution component is defined as

$$x_i = \frac{\text{amount of component } i \text{ (in moles)}}{\text{total amount of all solution components (in moles)}}$$

The sum of the mole fractions of all the solution components is 1.

$$x_i + x_j + x_k + \cdots = 1$$

The *mole percent* of a solution component is the percent of all the molecules in solution that are of a given type. Mole percents are mole fractions multiplied by 100%.

13-1 CONCEPT ASSESSMENT

In one mole of a solution with a mole fraction of 0.5 water, how many water molecules would there be?

Molarity

In Chapters 4 and 5 we introduced molarity to provide a conversion factor relating the amount of solute and the volume of solution. We used it in various stoichiometric calculations. As we learned at that time,

$$\text{molarity } (M) = \frac{\text{amount of solute (in moles)}}{\text{volume of solution (in liters)}}$$

Molality

Suppose we prepare a solution at 20 °C by using a volumetric flask calibrated at 20 °C. Then suppose we warm this solution to 25 °C. As the temperature increases from 20 to 25 °C, the amount of solute remains constant, but the solution volume increases slightly (by about 0.1%). The number of moles of solute per liter—the molarity—*decreases* slightly (by about 0.1%). This temperature dependence of molarity can be a problem in experiments demanding a high precision. That is, the solution might be used at a temperature different from the one at which it was prepared, and so its molarity is not exactly the one written on the label. A concentration unit that is *independent* of temperature, and also proportional to mole fraction in dilute solutions, is **molality** (m)—the number of moles of solute per kilogram of *solvent* (not of solution). A solution in which 1.00 mol of urea, $CO(NH_2)_2$, is dissolved in 1.00 kg of water is described as a 1.00 molal solution and designated as 1.00 m $CO(NH_2)_2$. Molality is defined as

▶ Molal units, being the number of moles per kg of solvent, are independent of temperature in contrast to molar units, being the number of moles per liter.

$$\text{molality } (m) = \frac{\text{amount of solute (in moles)}}{\text{mass of solvent (in kilograms)}}$$

The concentration of a solution is expressed in several different ways in Example 13-1. The calculation in Example 13-2 is perhaps more typical: A concentration is converted from one unit (molarity) to another (mole fraction).

EXAMPLE 13-1 Expressing a Solution Concentration in Various Units

An ethanol–water solution is prepared by dissolving 10.00 mL of ethanol, CH_3CH_2OH (d = 0.789 g/mL), in a sufficient volume of water to produce 100.0 mL of a solution with a density of 0.982 g/mL (Fig. 13-1). What is the concentration of ethanol in this solution expressed as **(a)** volume percent; **(b)** mass percent; **(c)** mass/volume percent; **(d)** mole fraction; **(e)** mole percent; **(f)** molarity; **(g)** molality?

Analyze

Each part of this problem uses an equation presented in the text. Expressing concentrations in these different units will illustrate the similarities and differences among volume percent, mass percent, mass/volume percent, mole fraction, mole percent, molarity, and molality.

Solve

(a) Volume percent ethanol

$$\text{volume percent ethanol} = \frac{10.00 \text{ mL ethanol}}{100.0 \text{ mL solution}} \times 100\% = 10.00\%$$

(b) Mass percent ethanol

$$\text{mass ethanol} = 10.00 \text{ mL ethanol} \times \frac{0.789 \text{ g ethanol}}{1.00 \text{ mL ethanol}}$$

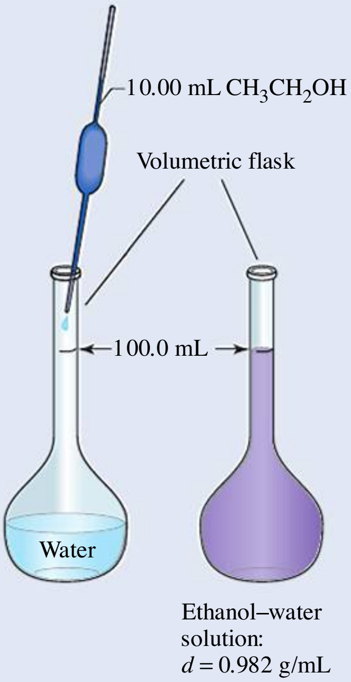
$$= 7.89 \text{ g ethanol}$$

$$\text{mass soln} = 100.0 \text{ mL soln} \times \frac{0.982 \text{ g soln}}{1.0 \text{ mL solution}} = 98.2 \text{ g soln}$$

$$\text{mass percent ethanol} = \frac{7.89 \text{ g ethanol}}{98.2 \text{ g solution}} \times 100\% = 8.03\%$$

(c) Mass/volume percent ethanol

$$\text{mass/volume percent ethanol} = \frac{7.89 \text{ g ethanol}}{100.0 \text{ mL solution}} \times 100\% = 7.89\%$$



▲ FIGURE 13-1
Preparation of an ethanol–water solution—Example 13-1 illustrated
A 10.00 mL sample of CH_3CH_2OH is added to some water in the volumetric flask. The solution is mixed, and more water is added to bring the total volume to 100.0 mL.

(d) Mole fraction of ethanol
Convert the mass of ethanol from part (b) to an amount in moles.

$$\begin{aligned} ?\ \text{mol } CH_3CH_2OH &= 7.89\ \text{g } CH_3CH_2OH \times \frac{1\ \text{mol } CH_3CH_2OH}{46.07\ \text{g } CH_3CH_2OH} \\ &= 0.171\ \text{mol } CH_3CH_2OH \end{aligned}$$

Determine the mass of water present in 100.0 mL of solution.

$$98.2\ \text{g soln} - 7.89\ \text{g ethanol} = 90.3\ \text{g water}$$

Convert the mass of water to the number of moles present.

$$?\ \text{mol } H_2O = 90.3\ \text{g } H_2O \times \frac{1\ \text{mol } H_2O}{18.02\ \text{g } H_2O} = 5.01\ \text{mol } H_2O$$

$$x_{CH_3CH_2OH} = \frac{0.171\ \text{mol } CH_3CH_2OH}{0.171\ \text{mol } CH_3CH_2OH + 5.01\ \text{mol } H_2O} = \frac{0.171}{5.18} = 0.0330$$

(e) Mole percent ethanol

$$\text{mole percent } CH_3CH_2OH = x_{CH_3CH_2OH} \times 100\% = 0.0330 \times 100\% = 3.30\%$$

(f) Molarity of ethanol
Divide the number of moles of ethanol from part (d) by the solution volume, 100.0 mL = 0.1000 L.

$$\text{molarity} = \frac{0.171\ \text{mol } CH_3CH_2OH}{0.1000\ \text{L soln}} = 1.71\ \text{M } CH_3CH_2OH$$

(g) Molality of ethanol
First, convert the mass of water present in 100.0 mL of solution [from part (d)] to the unit kg.

$$?\ \text{kg } H_2O = 90.3\ \text{g } H_2O \times \frac{1\ \text{kg } H_2O}{1000\ \text{g } H_2O} = 0.0903\ \text{kg } H_2O$$

Use this result and the number of moles of CH_3CH_2OH from part (d) to establish the molality.

$$\text{molality} = \frac{0.171\ \text{mol } CH_3CH_2OH}{0.0903\ \text{kg } H_2O} = 1.89\ m\ CH_3CH_2OH$$

Assess

For the same solution, the volume percent, mass percent, and mass/volume percent are not necessarily the same. Molarity and molality are also not the same values, because molarity is based on the volume of solution and molality is based on the mass of the solvent.

PRACTICE EXAMPLE A: A solution that is 20.0% ethanol, by volume, is found to have a density of 0.977 g/mL. Use this fact, together with data from Example 13-1, to determine the mass percent ethanol in the solution.

PRACTICE EXAMPLE B: A 11.3 mL sample of CH_3OH ($d = 0.793$ g/mL) is dissolved in enough water to produce 75.0 mL of a solution with a density of 0.980 g/mL. What is the solution concentration expressed as **(a)** mole fraction H_2O; **(b)** molarity of CH_3OH; **(c)** molality of CH_3OH?

EXAMPLE 13-2 Converting Molarity to Mole Fraction

Laboratory ammonia is 14.8 M NH_3(aq) with a density of 0.8980 g/mL. What is x_{NH_3} in this solution?

Analyze

In this problem we note that no volume of solution is stated, suggesting that our calculation can be based on any fixed volume of our choice. A convenient volume to work with is one liter. We need to determine the number of moles of NH_3 and of H_2O in one liter of the solution.

(continued)

Solve

Find the number of moles of NH_3 by using the definition of molarity.

$$\text{moles of } NH_3 = 1.00\text{ L} \times \frac{14.8\text{ mol } NH_3}{1\text{ L}} = 14.8\text{ mol } NH_3$$

For moles of H_2O, first find mass of the solution by using solution density.

$$\text{mass of soln} = 1000.0\text{ mL soln} \times \frac{0.8980\text{ g soln}}{1.0\text{ mL solution}} = 898.0\text{ g soln}$$

Then use moles of NH_3 and molar mass to find the mass of NH_3.

$$\text{mass of } NH_3 = 14.8\text{ mol } NH_3 \times \frac{17.03\text{ g } NH_3}{1\text{ mol } NH_3} = 252\text{ g } NH_3$$

Find the mass of H_2O by subtracting the mass of NH_3 from the solution mass.

$$\text{mass of } H_2O = 898.0\text{ g soln} - 252\text{ g } NH_3 = 646\text{ g } H_2O$$

Find moles of H_2O by multiplying by the inverse of the molar mass for H_2O.

$$\text{moles of } H_2O = 646\text{ g } H_2O \times \frac{1\text{ mol } H_2O}{18.02\text{ g } H_2O} = 35.8\text{ mol } H_2O$$

Find the mole fraction of ammonia x_{NH_3} by dividing moles NH_3 by the total number of moles of NH_3 and H_2O in the solution.

$$x_{NH_3} = \frac{14.8\text{ mol } NH_3}{14.8\text{ mol } NH_3 + 35.8\text{ mol } H_2O} = 0.292$$

Assess

By using the solution concentration definitions, we were able to convert from one concentration unit to another. This skill is used frequently by chemists.

PRACTICE EXAMPLE A: A 16.00% aqueous solution of glycerol, $HOCH_2CH(OH)CH_2OH$, by mass, has a density of 1.037 g/mL. What is the mole fraction of glycerol in this solution?

PRACTICE EXAMPLE B: A 10.00% aqueous solution of sucrose, $C_{12}H_{22}O_{11}$, by mass, has a density of 1.040 g/mL. What is **(a)** the molarity; **(b)** the molality; and **(c)** the mole fraction of $C_{12}H_{22}O_{11}$, in this solution?

13-2 CONCEPT ASSESSMENT

Which of the several concentration units described in Section 13-2 are temperature-dependent and which are not? Explain.

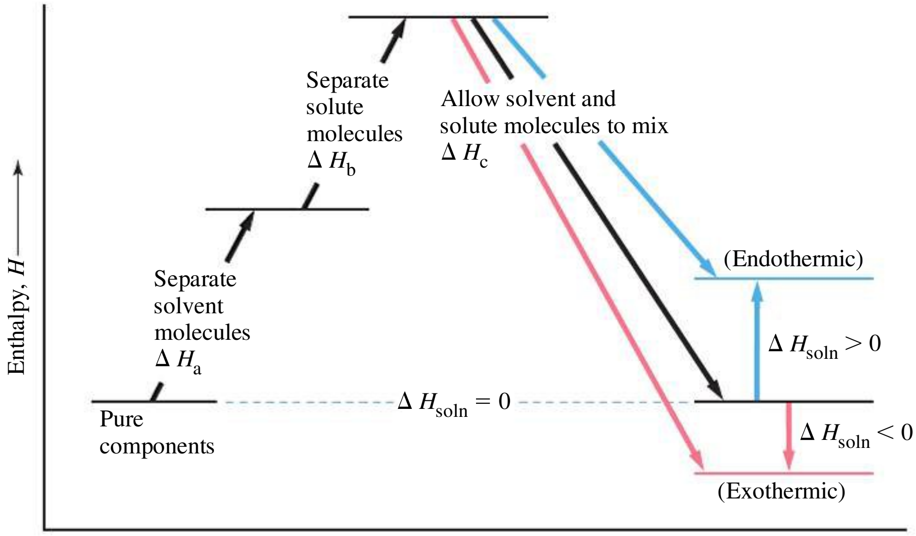
13-3 Intermolecular Forces and the Solution Process

If there is even a little water in the fuel tank of an automobile, the engine will misfire. This problem would not occur if water were soluble in gasoline. Why does water not form solutions with gasoline? We can often understand a process if we analyze its energy requirements; this approach can help us to explain why some substances mix to form solutions and others do not. In this section, we focus on the behavior of molecules in solution, specifically on intermolecular forces and their contribution to the energy required for the dissolution process.

Enthalpy of Solution

In the formation of some solutions, heat is given off to the surroundings; in other cases, heat is absorbed. An enthalpy of solution, ΔH_{soln}, can be rather easily measured—for example, in the coffee-cup calorimeter of Figure 7-6—but why should some solution processes be exothermic, whereas others are endothermic?

Let's think in terms of a three-step approach to ΔH_{soln}. First, solvent molecules must be separated from one another to make room for the solute molecules. Some energy is required to overcome the forces of attraction between solvent molecules. As a result, this step should be an endothermic one: $\Delta H > 0$. Second, the solute molecules must be separated from one another.



Enthalpy, H
Separate solute molecules ΔH_b
Allow solvent and solute molecules to mix ΔH_c
Separate solvent molecules ΔH_a
Pure components
$\Delta H_{soln} = 0$
(Endothermic)
$\Delta H_{soln} > 0$
$\Delta H_{soln} < 0$
(Exothermic)

▲ FIGURE 13-2
Enthalpy diagram for solution formation
The solution process can be endothermic (blue arrow), exothermic (red arrow), or has $\Delta H_{soln} = 0$ (black arrow), depending on the magnitude of the enthalpy change in the mixing step.

This step, too, will take energy and should be endothermic. Finally, we can imagine that we allow the separated solvent and solute molecules to be attracted to one another. These attractions will bring the molecules closer together and energy should be released. This is an exothermic step: $\Delta H < 0$. The enthalpy of solution is the sum of the three enthalpy changes just described, and depending on their relative values, ΔH_{soln} is either positive (endothermic) or negative (exothermic). This three-step process is summarized by equation (13.1) and Figure 13-2.

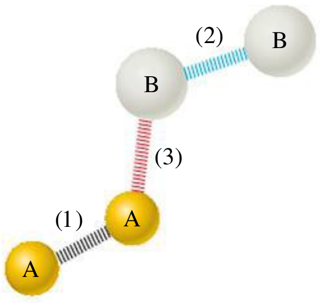
$$\begin{array}{lllll}
\textbf{(a)} & \text{pure solvent} & \longrightarrow & \text{separated solvent molecules} & \Delta H_a > 0 \\
\textbf{(b)} & \text{pure solute} & \longrightarrow & \text{separated solute molecules} & \Delta H_b > 0 \\
\textbf{(c)} & \text{separated solvent} & & & \\
 & \text{and solute molecules} & \longrightarrow & \text{solution} & \Delta H_c < 0 \\
\hline
\multicolumn{2}{l}{\textit{Overall:}\ \text{pure solvent} + \text{pure solute}} & \longrightarrow & \text{solution} &
\end{array}$$

$$\Delta H_{soln} = \Delta H_a + \Delta H_b + \Delta H_c \qquad \textbf{(13.1)}$$

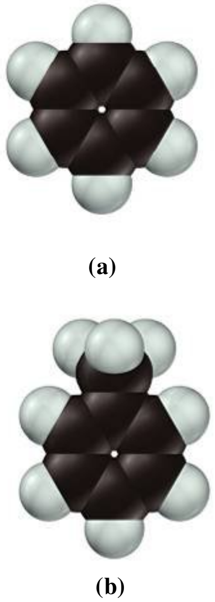
Intermolecular Forces in Mixtures

We see from equation (13.1) that the magnitude and sign of ΔH_{soln} depends on the values of the three terms ΔH_a, ΔH_b, and ΔH_c. These, in turn, depend on the strengths of the *three* kinds of intermolecular forces of attraction represented in Figure 13-3. Four possibilities for the relative strengths of these intermolecular forces are described in the discussion that follows.

1. If the intermolecular forces of attraction shown in Figure 13-3 are of the same type and of equal strength, the solute and solvent molecules mix randomly. A homogeneous mixture or solution results. Because properties of solutions of this type can generally be predicted from the properties of the pure components, they are called **ideal solutions**. There is no overall enthalpy change in the formation of an ideal solution from its components, and $\Delta H_{soln} = 0$. This means that ΔH_c in equation (13.1) is



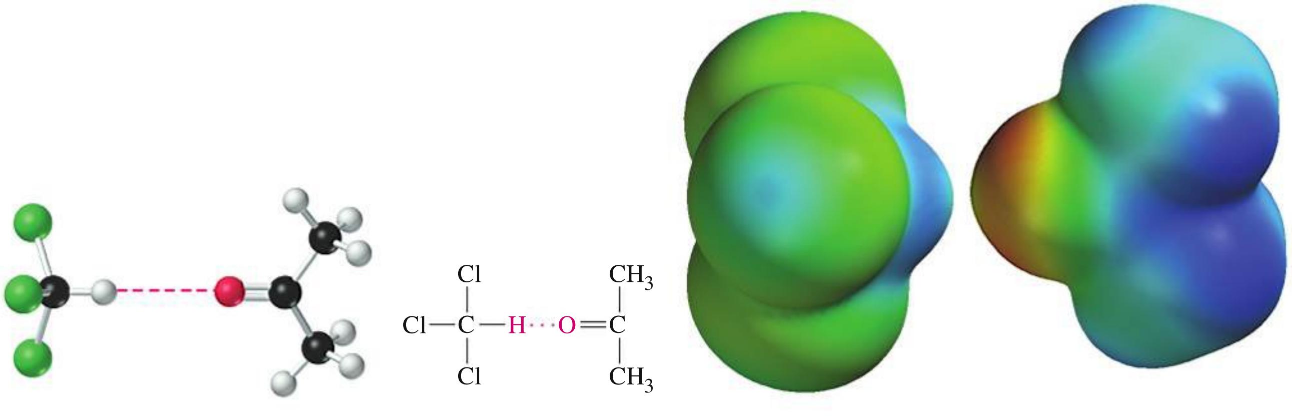
▲ FIGURE 13-3
Intermolecular forces in a solution
The intermolecular forces of attraction, represented here by dashed lines, are between: (1) solvent molecules, A–A; (2) solute molecules, B–B; and (3) solvent and solute molecules, A–B.



▲ FIGURE 13-4
Two components of a nearly ideal solution
Think of the —CH_3 group in toluene **(b)** as a small "bump" on the planar benzene ring **(a)**. Substances with similar molecular structures have similar intermolecular forces of attraction.

equal in magnitude and opposite in sign to the sum of ΔH_a and ΔH_b. Many mixtures of liquid hydrocarbons fit this description, or very nearly so (Fig. 13-4).

2. If forces of attraction between unlike molecules *exceed* those between like molecules, a solution also forms. The properties of such solutions generally cannot be predicted, however, and they are called *nonideal solutions*. Interactions between solute and solvent molecules (ΔH_c) release more heat than the heat absorbed to separate the solvent and solute molecules ($\Delta H_a + \Delta H_b$). The solution process is exothermic ($\Delta H_{soln} < 0$). Solutions of acetone and chloroform fit this type. As suggested by Figure 13-5, weak hydrogen bonding occurs between the two kinds of molecules, but the conditions for hydrogen bonding are not met in either of the pure liquids alone.*
3. If forces of attraction between solute and solvent molecules are *somewhat weaker* than between molecules of the same kind, complete mixing may still occur, but the solution formed is *nonideal*. The solution has a higher enthalpy than the pure components, and the solution process is endothermic. This type of behavior is observed in mixtures of carbon disulfide (CS_2), a nonpolar liquid, and acetone, a polar liquid. In these mixtures, the acetone molecules are attracted to other acetone molecules by dipole–dipole interactions and hence show a preference for other acetone molecules as neighbors. A possible explanation of how a solution process can be endothermic and still occur is found on page 567.
4. Finally, if forces of attraction between unlike molecules are *much weaker* than those between like molecules, the components remain segregated in a *heterogeneous mixture*. Dissolution does not occur to any significant extent. In a mixture of water and octane (a constituent of gasoline), strong hydrogen bonds hold water molecules together in clusters. The nonpolar octane molecules cannot exert a strong attractive force on the water molecules, and the two liquids do not mix. Thus, we now have an answer to the question posed at the beginning of this section of why water does not dissolve in gasoline or vice versa.



▲ FIGURE 13-5
Intermolecular force between unlike molecules leading to a nonideal solution
The interaction between these molecules is illustrated by using three different representations: ball and stick, line representation, and electrostatic potential maps. Hydrogen bonding between $CHCl_3$ (chloroform) and $(CH_3)_2CO$ (acetone) molecules produces forces of attraction between unlike molecules that exceed those between like molecules.

---

*In most cases, H atoms bonded to C atoms cannot participate in hydrogen bonding. In a molecule like $CHCl_3$, however, the three Cl atoms have a strong electron-withdrawing effect on electrons in the C—H bond ($\mu = 1.01$ D). The H atom is then attracted to a lone pair of electrons on the O atom of $(CH_3)_2CO$ (but not to Cl atoms in other $CHCl_3$ molecules).

As an oversimplified summary of the four cases described in the preceding paragraphs, we can say that "like dissolves like." That is, substances with similar molecular structures are likely to exhibit similar intermolecular forces of attraction and to be soluble in one another. Substances with dissimilar structures are likely not to form solutions. Of course, in many cases, parts of the structures may be similar and parts may be dissimilar. Then it is a matter of trying to establish which are the more important parts, a matter we explore in Example 13-3.

◀ Remember that "like dissolves like."

EXAMPLE 13-3 Using Intermolecular Forces to Predict Solution Formation

Predict whether or not a solution will form in each of the following mixtures and whether the solution is likely to be ideal: **(a)** ethyl alcohol, CH_3CH_2OH, and water; **(b)** the hydrocarbons hexane, $CH_3(CH_2)_4CH_3$, and octane, $CH_3(CH_2)_6CH_3$; **(c)** octanol, $CH_3(CH_2)_6CH_2OH$, and water.

Analyze

Keep in mind that ideal or nearly ideal solutions are not too common. They require the solvent and solute(s) to be quite similar in structure.

(a) If we think of water as H—OH, ethyl alcohol is similar to water. (Just substitute the group CH_3CH_2— for one of the H atoms in water.) Both molecules meet the requirements of hydrogen bonding as an important intermolecular force. The strengths of the hydrogen bonds between like molecules and between unlike molecules are likely to differ, however.

(b) In hexane, the carbon chain is six atoms long, and in octane it is eight. Both substances are virtually nonpolar, and intermolecular attractive forces (of the dispersion type) should be quite similar both in the pure liquids and in the solution.

(c) At first sight, this case may seem similar to (a), with the substitution of a hydrocarbon group for a H atom in H—OH. Here, however, the carbon chain is *eight* members long. This long carbon chain is much more important than the terminal —OH group in establishing the physical properties of octanol. Viewed from this perspective, octanol and water are quite *dissimilar*.

Solve

(a) We expect ethyl alcohol and water to form *nonideal* solutions.

(b) We expect a solution to form, and it should be nearly *ideal*.

(c) We do not expect a solution to form.

Assess

In these types of problems a strong understanding of both molecular structure and intermolecular forces is required. Keep in mind the statement "like dissolves like."

In our answer to part (c), we observed that octanol does not form a solution; however, alcohols, such as butyl alcohol, $CH_3CH_2CH_2CH_2OH$, have a limited solubility in water (9 grams per 100 grams of water). The aqueous solubilities of alcohols fall off fairly rapidly as the hydrocarbon chain length increases beyond four.

PRACTICE EXAMPLE A: Which of the following organic compounds do you think is most readily soluble in water? Explain.

(a) Toluene

(b) Oxalic acid

(c) Benzaldehyde

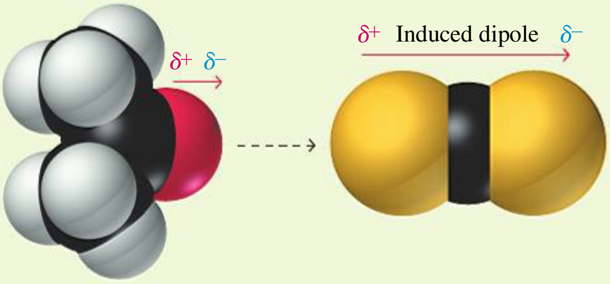
PRACTICE EXAMPLE B: In which solvent is solid iodine likely to be more soluble, water or carbon tetrachloride? Explain.

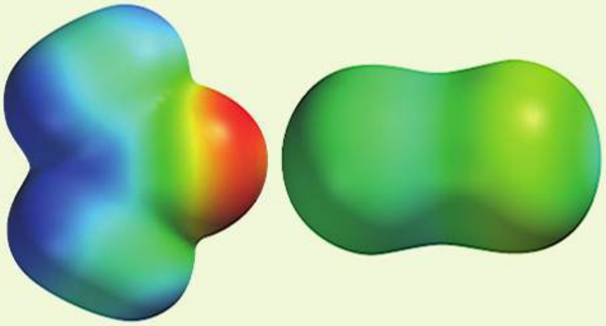
▲ Remember that "like dissolves like"

13-1 ARE YOU WONDERING...

What is the nature of the intermolecular forces in a mixture of carbon disulfide and acetone?

Carbon disulfide is a nonpolar molecule, and so in the pure substance the only intermolecular forces are weak London dispersion forces; carbon disulfide is a volatile liquid. Acetone is a polar molecule, and in the pure substance dipole–dipole forces are strong. Acetone is somewhat less volatile than carbon disulfide. In a solution of acetone in carbon disulfide (case 3 on page 564), the dipoles of acetone molecules polarize carbon disulfide molecules, giving rise to *dipole–induced dipole* interactions.



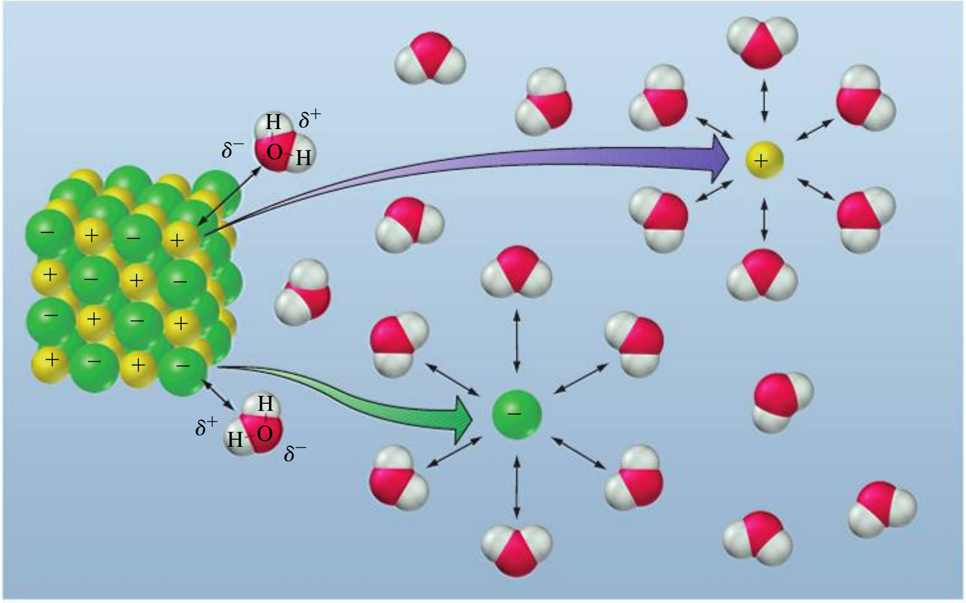


The dipole–induced dipole forces between acetone and carbon disulfide molecules are weaker than the dipole–dipole interactions among acetone molecules, causing the acetone molecules to be relatively less stable in their solutions with carbon disulfide than they are in pure acetone. As a result, acetone–carbon disulfide mixtures are nonideal solutions.

Formation of Ionic Solutions

To assess the energy requirements for the formation of aqueous solutions of ionic compounds, we turn to the process pictured in Figure 13-6. Water dipoles are shown clustered around ions at the surface of a crystal. The negative ends of water dipoles are pointed toward the positive ions, and the positive ends of water dipoles toward negative ions. The interaction between an ion and a dipole is an intermolecular force known as an ion–dipole force. If these ion–dipole forces of attraction are strong enough to overcome the interionic forces of attraction in the crystal, dissolving will occur. Moreover, these ion–dipole forces also persist in the solution. An ion surrounded by a cluster of water molecules is said to be *hydrated*. Energy is *released* when ions become hydrated. The greater the hydration energy compared with the energy needed to separate ions from the ionic crystal, the more likely that the ionic solid will dissolve in water.

We can again use a *hypothetical* three-step process to describe the dissolution of an ionic solid. The energy requirement to dissociate a mole of an ionic solid into separated gaseous ions, an endothermic process, is the *negative of* the



▲ FIGURE 13-6
An ionic crystal dissolving in water
Clustering of water dipoles around the surface of the ionic crystal and the formation of hydrated ions in solution are the key factors in the dissolution process.

lattice energy. Energy is released in the next two steps—hydration of the gaseous cations and anions. The enthalpy of solution is the sum of these three ΔH values, described below for NaCl.

◀ We discussed lattice energy in Section 12-7.

$$\mathrm{NaCl(s)} \longrightarrow \mathrm{Na^+(g)} + \mathrm{Cl^-(g)} \qquad \Delta H_1 = (-\text{lattice energy of NaCl}) > 0$$

$$\mathrm{Na^+(g)} \xrightarrow{H_2O} \mathrm{Na^+(aq)} \qquad \Delta H_2 = (\text{hydration energy of Na}^+) < 0$$

$$\mathrm{Cl^-(g)} \xrightarrow{H_2O} \mathrm{Cl^-(aq)} \qquad \Delta H_3 = (\text{hydration energy of Cl}^-) < 0$$

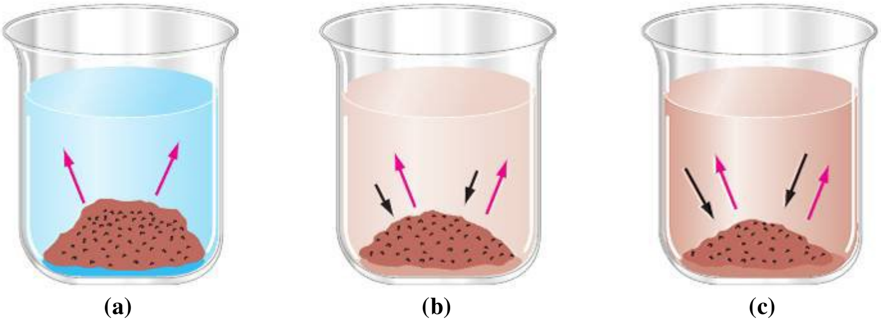
$$\mathrm{NaCl(s)} \xrightarrow{H_2O} \mathrm{Na^+(aq)} + \mathrm{Cl^-(aq)} \qquad \Delta H_{\text{soln}} = \Delta H_1 + \Delta H_2 + \Delta H_3 \approx +5\ \text{kJ/mol}$$

The dissolution of sodium chloride in water is *endothermic*, and this is also the case for the vast majority (about 95%) of soluble ionic compounds. Why does NaCl dissolve in water if the process is endothermic? It might appear that an endothermic process would not occur because of the increase in enthalpy. Because NaCl does actually dissolve in water, there must be another factor involved. In fact, *two* factors must be considered in determining whether a process will occur spontaneously. Enthalpy change is only one of them. The other factor, called *entropy* (see page 821), concerns the natural tendency for microscopic particles—atoms, ions, or molecules—to spread themselves out in the space available to them. The dispersed condition of the microscopic particles in NaCl(aq) compared with pure NaCl(s) and $H_2O(l)$ offsets the +5 kJ/mol increase in enthalpy in the solution process. In summary, if the hypothetical three-step process for solution formation is *exothermic*, we expect dissolution to occur; but we also expect a solution to form for an endothermic solution process, as long as ΔH_{soln} is not too large.

◀ A common misconception is that an endothermic process cannot be spontaneous.

13-4 Solution Formation and Equilibrium

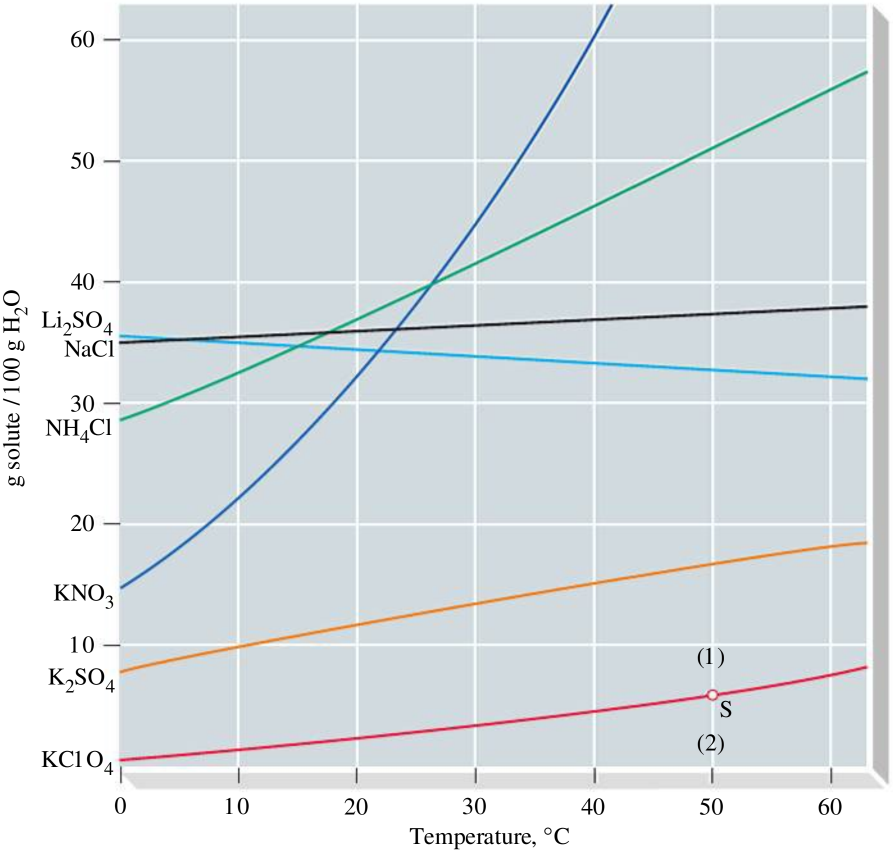
In the previous section, we described what happens at the molecular (microscopic) level when solutions form. In this section, we will describe solution formation in terms of phenomena that we can actually observe, that is, a macroscopic view.



▲ FIGURE 13-7
Formation of a saturated solution
The lengths of the arrows represent the rate of dissolution (↑) and the rate of crystallization (↓). **(a)** When solute is first placed in the solvent, only dissolution occurs. **(b)** After a time, the rate of crystallization becomes significant. **(c)** The solution is saturated when the rates of dissolution and crystallization become equal.

Figure 13-7 suggests what happens when a solid solute and liquid solvent are mixed. At first, only dissolution occurs, but soon the reverse process of crystallization becomes increasingly important; and some dissolved atoms, ions, or molecules return to the undissolved state. When dissolution and crystallization occur at the same rate, the solution is in a state of dynamic equilibrium. The quantity of dissolved solute remains constant with time, and the solution is said to be a **saturated solution**. The concentration of the saturated solution is called the **solubility** of the solute in the given solvent. Solubility varies with temperature, and a solubility–temperature graph is called a *solubility curve*. Some typical solubility curves are shown in Figure 13-8.

If, in preparing a solution, we start with less solute than would be present in the saturated solution, the solute completely dissolves, and the solution is



▶ FIGURE 13-8
Aqueous solubility of several salts as a function of temperature
Solubilities can be expressed in many ways: molarities, mass percent, or, as in this figure, grams of solute per 100 g H_2O. For each solubility curve (as shown here for $KClO_4$), points on the curve (S) represent saturated solutions. Regions above the curve (1) correspond to supersaturated solutions and below the curve (2), to unsaturated solutions.

an **unsaturated solution**. But suppose we prepare a saturated solution at one temperature and then change the temperature to a value at which the solubility is lower (this generally means a lower temperature). Usually, the excess solute crystallizes from solution, but occasionally all the solute may remain in solution. In these cases, because the quantity of solute is greater than in a saturated solution, the solution is said to be a **supersaturated solution**. A supersaturated solution is unstable, and if a few crystals of solute are added to serve as particles on which crystallization can occur, the excess solute crystallizes. Figure 13-8 shows how unsaturated and supersaturated solutions can be represented with a solubility curve.

Solubility as a Function of Temperature

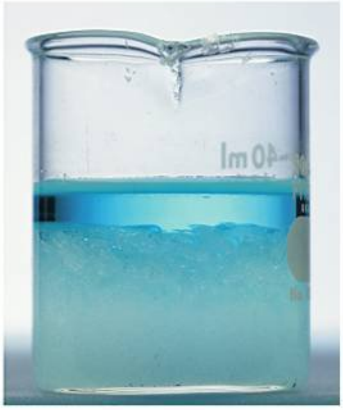
As a general observation, the solubilities of ionic substances (about 95% of them) *increase* with increasing temperature. Exceptions to this generalization tend to be found among compounds containing the anions SO_3^{2-}, SO_4^{2-}, AsO_4^{3-}, and PO_4^{3-}.

In Chapter 15 we will learn to predict how an equilibrium condition changes with such variables as temperature and pressure by using an idea known as *Le Châtelier's principle*. One statement of the principle is that heat added to a system at equilibrium stimulates the heat-absorbing, or endothermic, reaction. This suggests that when $\Delta H_{\text{soln}} > 0$, raising the temperature stimulates dissolving and *increases* the solubility of the solute. Conversely, if $\Delta H_{\text{soln}} < 0$ (exothermic), the solubility *decreases* with increasing temperature. In this case, crystallization—being endothermic—is favored over dissolving.

We must be careful in applying the relationship we just described. The particular value of ΔH_{soln} that establishes whether solubility increases or decreases with increased temperature is that associated with dissolving a small quantity of solute in a solution that is already very nearly saturated. In some cases, this heat effect is altogether different from what is observed when a solute is added to the pure solvent. For example, when NaOH is dissolved in water, there is a sharp increase in temperature—*an exothermic* process. This fact suggests that the solubility of NaOH in water should decrease as the temperature is raised. What is observed, though, is that the solubility of NaOH in water *increases* with increased temperature. This is because when a small quantity of NaOH is added to a solution that is already nearly saturated, heat is *absorbed*, not evolved.*

Fractional Crystallization

Compounds synthesized in chemical reactions are generally impure, but the fact that the solubilities of most solids increase with increased temperature provides the basis for one simple method of purification. Usually, the impure solid consists of a high proportion of the desired compound and lesser proportions of the impurities. Suppose that both the compound and its impurities are soluble in a particular solvent and that we prepare a concentrated solution at a high temperature. Then we let the concentrated solution cool. At lower temperatures, the solution becomes saturated in the desired compound. The excess compound crystallizes from solution. The impurities remain in solution because the temperature is still too high for these to crystallize.[†] This method of purifying a solid, called **fractional crystallization**, or **recrystallization**, is pictured in Figure 13-9. Example 13-4 illustrates how solubility curves can be used to predict the outcome of a fractional crystallization.



▲ FIGURE 13-9
Recrystallization of KNO_3
Colorless crystals of KNO_3 separated from an aqueous solution of KNO_3 and $CuSO_4$ (an impurity). The pale blue color of the solution is produced by Cu^{2+}, which remains in solution.

---

*The solid in equilibrium with saturated NaOH(aq) over a range of temperatures around 25 °C is $NaOH \cdot H_2O(s)$. It is actually the temperature dependence of the solubility of this hydrate that we have been discussing.

[†] This is the usual behavior, but at times, one or more impurities may form a solid solution with the compound being recrystallized. In these cases simple recrystallization does not work as a method of purification.

EXAMPLE 13-4 Applying Solubility Data in Fractional Crystallization

A solution is prepared by dissolving 95 g NH_4Cl in 200.0 g H_2O at 60 °C. **(a)** What mass of NH_4Cl will recrystallize when the solution is cooled to 20 °C? **(b)** How might we improve the yield of NH_4Cl?

Analyze

We need to know the solubility of NH_4Cl at 20°C and at 95 °C. We obtain the required data from Figure 13-8, which shows the solubility of several salts as a function of temperature.

Solve

(a) Using Figure 13-8, we estimate that the solubility of NH_4Cl at 20 °C is 37 g NH_4Cl/100 g H_2O. The quantity of NH_4Cl in the saturated solution at 20 °C is

$$200.0\ \text{g H}_2\text{O} \times \frac{37\ \text{g NH}_4\text{Cl}}{100\ \text{g H}_2\text{O}} = 74\ \text{g NH}_4\text{Cl}$$

The mass of NH_4Cl recrystallized is $95 - 74 = 21$ g NH_4Cl.

(b) The yield of NH_4Cl in (a) is rather poor—21 g out of 95 g, or 22%. We can do better: (1) The solution at 60 °C, although concentrated, is not saturated. Using Figure 13-8, we estimate that a saturated solution at 60 °C has 55 g NH_4Cl/100 g H_2O. Thus, the 95 g NH_4Cl requires less than 200.0 g H_2O to make a saturated solution. At 20 °C, a smaller quantity of saturated solution would contain less NH_4Cl than in (a), and the yield of recrystallized NH_4Cl would be greater. (2) Instead of cooling the solution to 20 °C, we might cool it to 0 °C. Here the solubility of NH_4Cl is less than at 20 °C, and more solid would recrystallize. (3) Still another possibility is to start with a solution at a temperature higher than 60 °C, say closer to 100 °C. The mass of water needed for the saturated solution would be less than at 60 °C. Note that options (1) and (3) both require changing the conditions by using a different amount of water from that originally specified.

Assess

The amount of dissolved salt can be increased by increasing the volume of solvent or by increasing the temperature. Keep in mind that fractional crystallization works best when the quantities of impurities are small and the solubility curve of the desired solute rises steeply with temperature.

PRACTICE EXAMPLE A: Calculate the quantity of NH_4Cl that would be obtained if suggestions (1) and (2) in Example 13-4 (b) were followed. [*Hint*: Use data from Figure 13-8. What mass of water is needed to produce a saturated solution containing 95 g NH_4Cl at 60 °C?]

PRACTICE EXAMPLE B: Use Figure 13-8 to examine the solubility curves for the three potassium salts: $KClO_4$, K_2SO_4, and KNO_3. If saturated solutions of these salts at 40 °C are cooled to 20 °C, rank the salts in order of highest percent yield for the recrystallization.

13-5 Solubilities of Gases

Why does a freshly opened can of soda pop fizz, and why does the soda go flat after a time? To answer questions like these requires an understanding of the solubilities of gases. As discussed in this section, the effect of temperature on the solubility of gases is generally different from that on solid solutes. Additionally, the pressure of a gas strongly affects its solubility.

Effect of Temperature

We cannot make an all-inclusive generalization about the effect of temperature on the solubilities of gases in solvents. It is certainly true, though, that the solubilities of most gases in water *decrease* with an increase in temperature. This is true of $N_2(g)$ and $O_2(g)$—the major components of air—and of air itself (Fig. 13-10). This fact helps to explain why many types of fish can survive only in cold water. There is not enough dissolved air (oxygen) in warm water to sustain them.

For solutions of gases in organic solvents, the situation is often the reverse of that just described; that is, gases may become more soluble at higher temperatures. The solubility behavior of the noble gases in water is more complex. The solubility of each gas decreases with an increase in temperature, reaching a minimum at a certain temperature; then the solubility trend reverses direction, with the gas becoming more soluble with an increase in temperature. For example, for helium at 1 atm pressure, this minimum solubility in water comes at 35 °C.

Effect of Pressure

Pressure affects the solubility of a gas in a liquid much more than does temperature. The English chemist William Henry (1775–1836) found that *the solubility of a gas increases with increasing pressure.* A mathematical statement of **Henry's law** is

$$C = k \times P_{\text{gas}} \tag{13.2}$$

In this equation, C represents the solubility of a gas in a particular solvent at a fixed temperature, P_{gas} is the partial pressure of the gas above the solution, and k is a proportionality constant. To evaluate the proportionality constant k, we need to have one measurement of the solubility of the gas at a known pressure and temperature. For example, the aqueous solubility of $N_2(g)$ at 0 °C and 1.00 atm is 23.54 mL N_2 per liter. The Henry's law constant, k, is

$$k = \frac{C}{P_{\text{gas}}} = \frac{23.54 \text{ mL N}_2/\text{L}}{1.00 \text{ atm}}$$

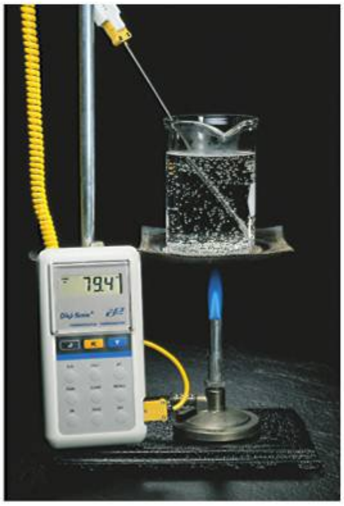
Suppose we want to increase the solubility of the $N_2(g)$ to a value of 100.0 mL N_2 per liter. Equation (13.2) suggests that to do so, we must increase the pressure of $N_2(g)$ above the solution. That is,

$$P_{N_2} = \frac{C}{k} = \frac{100.0 \text{ mL N}_2/\text{L}}{(23.54 \text{ mL N}_2/\text{L})/1.00 \text{ atm}} = 4.25 \text{ atm}$$

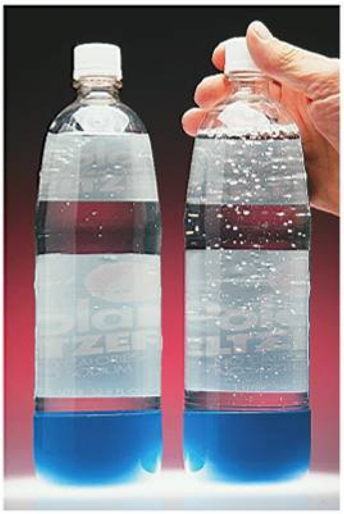
At times, we are required to change the units used to express a gas solubility at the same time that the pressure is changed. This variation is illustrated in Example 13-5.

We can rationalize Henry's law as follows: In a saturated solution, the rate of evaporation of gas molecules from solution and the rate of condensation of gas molecules into the solution are equal. Both of these rates depend on the number of molecules per unit volume. With increasing pressure on the system, the number of molecules per unit volume in the gaseous state increases (through an increase in the gas pressure), and the number of molecules per unit volume must also increase in the solution (through an increase in concentration). Figure 13-11 illustrates this rationalization.

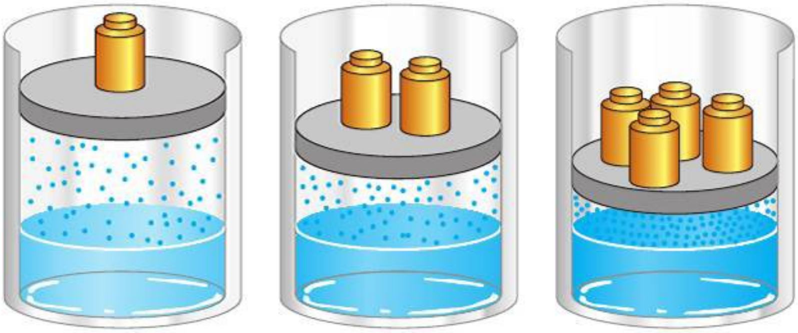
We see a practical application of Henry's law in carbonated beverages. The dissolved gas is carbon dioxide, and the higher the gas pressure maintained above the soda pop, the more CO_2 that dissolves. When a bottle of soda is opened, some gas is released. As the gas pressure above the solution drops, dissolved CO_2 is expelled, usually fast enough to cause fizzing. In sparkling wines, the dissolved CO_2 is also under pressure, but rather than being added artificially as in soda pop, the CO_2 is produced by a fermentation process within the bottle.



▲ FIGURE 13-10
Effect of temperature on the solubilities of gases
Dissolved air is released as water is heated, even at temperatures well below the boiling point.



▲ The unopened bottle of soda water is under a high pressure of $CO_2(g)$. When a similar bottle is opened, the pressure quickly drops and some of the $CO_2(g)$ is released from solution (bubbles).



◀ FIGURE 13-11
Effect of pressure on the solubility of a gas
The concentration of dissolved gas (suggested by the depth of color) is proportional to the pressure of the gas above the solution (suggested by the density of the dots).

EXAMPLE 13-5 Using Henry's Law

At 0 °C and an O_2 pressure of 1.00 atm, the aqueous solubility of $O_2(g)$ is 48.9 mL O_2 per liter. What is the molarity of O_2 in a saturated water solution when the O_2 is under its normal partial pressure in air, 0.2095 atm?

Analyze

Think of this as a two-part problem. (1) Determine the molarity of the saturated O_2 solution at 0 °C and 1 atm. (2) Use Henry's law in the manner just outlined.

Solve

Determine the molarity of O_2 at 0 °C when $P_{O_2} = 1$ atm.

$$\text{molarity} = \frac{0.0489 \text{ L } O_2 \times \dfrac{1 \text{ mol } O_2}{22.4 \text{ L } O_2 \text{ (STP)}}}{1 \text{ L soln}} = 2.18 \times 10^{-3} \text{ M } O_2$$

Evaluate the Henry's law constant.

$$k = \frac{C}{P_{\text{gas}}} = \frac{2.18 \times 10^{-3} \text{ M } O_2}{1.00 \text{ atm}}$$

Apply Henry's law.

$$C = k \times P_{\text{gas}} = \frac{2.18 \times 10^{-3} \text{ M } O_2}{1.00 \text{ atm}} \times 0.2095 \text{ atm} = 4.57 \times 10^{-4} \text{ M } O_2$$

Assess

When working problems involving gaseous solutes in a solution in which the solute is at very low concentration, use Henry's law.

PRACTICE EXAMPLE A: Use data from Example 13-5 to determine the partial pressure of O_2 above an aqueous solution at 0 °C known to contain 5.00 mg O_2 per 100.0 mL of solution.

PRACTICE EXAMPLE B: A handbook lists the solubility of carbon monoxide in water at 0 °C and 1 atm pressure as 0.0354 mL CO per milliliter of H_2O. What pressure of CO(g) must be maintained above the solution to obtain 0.0100 M CO?

▲ To avoid the painful and dangerous condition of the bends, divers must not surface too quickly from great depths.

Deep-sea diving provides us with still another example of Henry's law. Divers must carry a supply of air to breathe while underwater. If they are to stay submerged for any period of time, they must breathe compressed air. High-pressure air, however, is much more soluble in the blood and other body fluids than is air at normal pressures. When a diver returns to the surface, excess dissolved $N_2(g)$ is released as tiny bubbles from body fluids. When the ascent to the surface is made too quickly, N_2 diffuses out of the blood too quickly, causing severe pain in the limbs and joints, probably by interfering with the nervous system. This dangerous condition, known as "the bends," can be avoided if the diver ascends very slowly or spends time in a decompression chamber. Another effective method is to substitute a helium–oxygen mixture for compressed air. Helium is less soluble in blood than is nitrogen.

Henry's law (equation 13.2) fails for gases at high pressures; it also fails if the gas ionizes in water or reacts with water. For example, at 20 °C and with $P_{HCl} = 1$ atm, a saturated solution of HCl(aq) is about 20 M. But to prepare 10 M HCl, we do not need to maintain $P_{HCl} = 0.5$ atm above the solution, nor is $P_{HCl} = 0.05$ atm above 1 M HCl. We cannot even detect HCl(g) above 1 M HCl by its odor. The reason we cannot is that HCl ionizes in aqueous solutions, and in dilute solutions there are almost no molecules of HCl.

$$HCl(g) \xrightarrow{H_2O} H^+(aq) + Cl^-(aq)$$

Henry's law applies only to equilibrium between molecules of a gas and the same *molecules* in solution.

13-3 CONCEPT ASSESSMENT

Do you think that Henry's law works better for solutions of HCl(g) in benzene, C_6H_6, than it does for solutions of HCl(g) in water? If so, why?

13-6 Vapor Pressures of Solutions

Separating compounds from one another is a task that chemists commonly face. If the compounds are volatile liquids, this separation often can be achieved by *distillation*. To understand how distillation works, we need to know something about the vapor pressures of solutions. This knowledge will also enable us to deal with other important solution properties, such as boiling points, freezing points, and osmotic pressures.

To simplify the following discussion we will consider only solutions with two components, solvent A and solute B. In the 1880s, the French chemist F. M. Raoult found that a dissolved solute *lowers* the vapor pressure of the solvent. **Raoult's law** states that the partial pressure exerted by solvent vapor above an ideal solution, P_A, is the product of the mole fraction of solvent in the solution, x_A, and the vapor pressure of the pure solvent at the given temperature, P_A°.

$$P_A = x_A P_A^\circ \qquad (13.3)$$

Equation (13.3) relates to Raoult's observation that a dissolved solute lowers the vapor pressure of the solvent because if $x_A + x_B = 1.00$, x_A must be less than 1.00, and P_A must be smaller than P_A°. Strictly speaking, Raoult's law applies only to ideal solutions and to all volatile components of the solutions. However, even in nonideal solutions, the law often works reasonably well for the *solvent* in *dilute* solutions, for example, solutions in which $x_{solv} > 0.98$. A more detailed discussion of Raoult's law requires the notion of entropy, which was briefly mentioned on page 567. Rather than attempt the explanation now, however, we will wait until Section 19-3, after we have said more about entropy.

13-4 CONCEPT ASSESSMENT

An alternative statement of Raoult's law is that the fractional lowering of the vapor pressure of the solvent, $(P_A^\circ - P_A)/P_A^\circ$, is equal to the mole fraction of solute(s), x_B. Show that this statement is equivalent to equation (13.3).

Liquid–Vapor Equilibrium: Ideal Solutions

The results of Examples 13-6 and 13-7, together with similar data for other benzene–toluene solutions, are plotted in Figure 13-12. This figure consists of four lines—three straight and one curved—spanning the entire concentration range.

The red line shows how the vapor pressure of benzene varies with the solution composition. Because benzene in benzene–toluene solutions obeys Raoult's law, the red line has the equation $P_{benz} = x_{benz}P_{benz}^\circ$. The blue line shows how the vapor pressure of toluene varies with solution composition and indicates that toluene also obeys Raoult's law. The dashed black line shows how the *total* vapor pressure varies with the solution composition. Can you see that each pressure on this black line is the sum of the pressures on the two straight lines that lie below it? Thus, point 3 represents the total vapor pressure (point 1 + point 2) of a benzene–toluene solution in which $x_{benz} = 0.500$ (see Example 13-6).

EXAMPLE 13-6 Predicting Vapor Pressures of Ideal Solutions

The vapor pressures of pure benzene and pure toluene at 25 °C are 95.1 and 28.4 mmHg, respectively. A solution is prepared in which the mole fractions of benzene and toluene are both 0.500. What are the partial pressures of the benzene and toluene above this solution? What is the total vapor pressure?

Analyze

We saw in Figure 13-4 that benzene–toluene solutions should be ideal. We expect Raoult's law to apply to both solution components.

Solve

$$\begin{aligned} P_{\text{benz}} &= x_{\text{benz}}P^{\circ}_{\text{benz}} = 0.500 \times 95.1\ \text{mmHg} = 47.6\ \text{mmHg} \\ P_{\text{tol}} &= x_{\text{tol}}P^{\circ}_{\text{tol}} = 0.500 \times 28.4\ \text{mmHg} = 14.2\ \text{mmHg} \\ P_{\text{total}} &= P_{\text{benz}} + P_{\text{tol}} = 47.6\ \text{mmHg} + 14.2\ \text{mmHg} = 61.8\ \text{mmHg} \end{aligned}$$

Assess

In this example we assumed these to be ideal solutions, which allowed us to use Raoult's law. We observe that the vapor pressure of each component is lowered because of the presence of the other component.

PRACTICE EXAMPLE A: The vapor pressure of pure hexane and pentane at 25 °C are 149.1 mmHg and 508.5 mmHg, respectively. If a hexane–pentane solution has a mole fraction of hexane of 0.750, what are the vapor pressures of hexane and pentane above the solution? What is the total vapor pressure?

PRACTICE EXAMPLE B: Calculate the vapor pressures of benzene, C_6H_6, and toluene, C_7H_8, and the total pressure at 25 °C above a solution with equal *masses* of the two liquids. Use the vapor pressure data given in Example 13-6.

EXAMPLE 13-7 Calculating the Composition of Vapor in Equilibrium with a Liquid Solution

What is the composition of the vapor in equilibrium with the benzene–toluene solution of Example 13-6?

Analyze

We are being asked to find the mole fraction of benzene and of toluene in the vapor. From Example 13-6 we know the vapor pressure of pure benzene and pure toluene. We have already calculated the partial vapor pressures; now we need to apply the definition of mole fraction.

Solve

The ratio of each partial pressure to the total pressure is the mole fraction of that component in the vapor. (This is another application of equation 6.17.) The mole-fraction composition of the vapor is

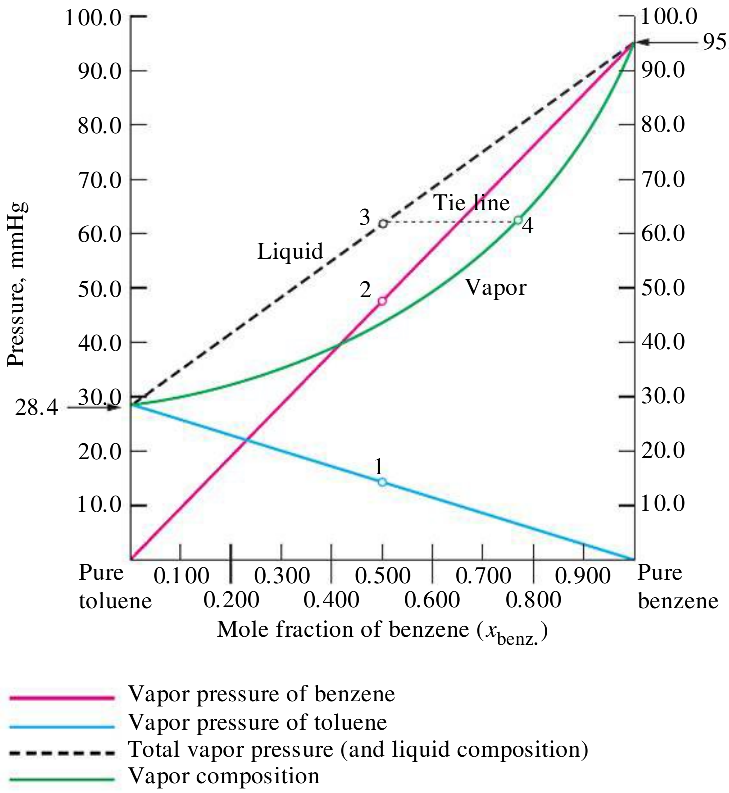
$$\begin{aligned} x_{\text{benz}} &= \frac{P_{\text{benz}}}{P_{\text{total}}} = \frac{47.6\ \text{mmHg}}{61.8\ \text{mmHg}} = 0.770 \\ x_{\text{tol}} &= \frac{P_{\text{tol}}}{P_{\text{total}}} = \frac{14.2\ \text{mmHg}}{61.8\ \text{mmHg}} = 0.230 \end{aligned}$$

Assess

The mole fraction of benzene in the vapor is 0.770, whereas in the liquid the mole fraction of benzene is 0.5. For toluene the mole fraction in the vapor is 0.230, whereas in the liquid the mole fraction of toluene is 0.5. This difference in mole-fraction vapor composition caused by the difference in vapor pressures of the two components is the central concept of fractional distillation, which is discussed next.

PRACTICE EXAMPLE A: What is the composition of the vapor in equilibrium with the hexane–pentane solution described in Practice Example 13-6A?

PRACTICE EXAMPLE B: What is the composition of the vapor in equilibrium with the benzene–toluene solution described in Practice Example 13-6B?



◀ FIGURE 13-12
Liquid–vapor equilibrium for benzene–toluene mixtures at 25 °C
In this diagram, partial pressures and the total pressure of the vapor are plotted as a function of the solution and vapor compositions.

As we calculated in Example 13-7, the vapor in equilibrium with a solution in which $x_{benz} = 0.500$ is richer still in benzene. The vapor has $x_{benz} = 0.770$ (point 4). The line joining points 3 and 4 is called a *tie line*. Imagine establishing a series of tie lines throughout the composition range. The vapor ends of these tie lines can be joined to form the green curve in Figure 13-12. From the relative placement of the liquid and vapor curves, we see that for ideal solutions of two components, *the vapor phase is richer in the more volatile component than is the liquid phase.*

13-5 CONCEPT ASSESSMENT

Describe a case in which the liquid and vapor curves in a diagram such as Figure 13-12 would converge into a single curve. Is such a case likely to exist?

Fractional Distillation

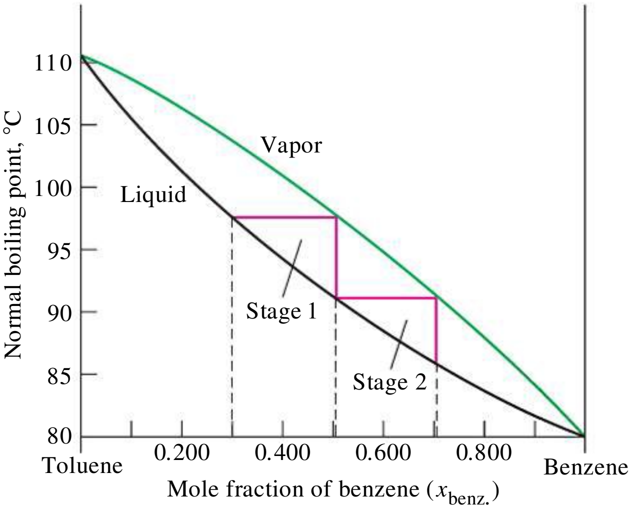
Let's look at liquid–vapor equilibrium in benzene–toluene mixtures in a somewhat different way. Instead of plotting vapor pressures as a function of the solution and vapor compositions, let's plot normal boiling temperature—the temperature at which the *total* vapor pressure of the solution is 1 atm. The resulting graph is shown in Figure 13-13. This graph is useful in explaining **fractional distillation**, a procedure for separating volatile liquids from one another.

Notice that the graph starts at a high temperature—110.6 °C, the boiling point of toluene—and ends at a lower temperature—80.0 °C, the boiling point of benzene. This is the reverse of the situation in Figure 13-12. Also, the vapor curve lies above the liquid curve in Figure 13-13, not below, as is the case in Figure 13-12.

Figure 13-13 indicates that a benzene–toluene solution with $x_{benz} = 0.30$ boils at a temperature of 98.6 °C and is in equilibrium with a vapor in which $x_{benz} = 0.51$. Imagine extracting some of this vapor and cooling it to the point where it condenses to a liquid. The new liquid will have $x_{benz} = 0.51$ and represents the conclusion of stage 1 in Figure 13-13. Now imagine repeating the

KEEP IN MIND

that the placement of the two curves in liquid–vapor equilibrium diagrams is such that the vapor is richer in the more volatile component than is the liquid. The more volatile component is the one with the higher vapor pressure or lower boiling point.



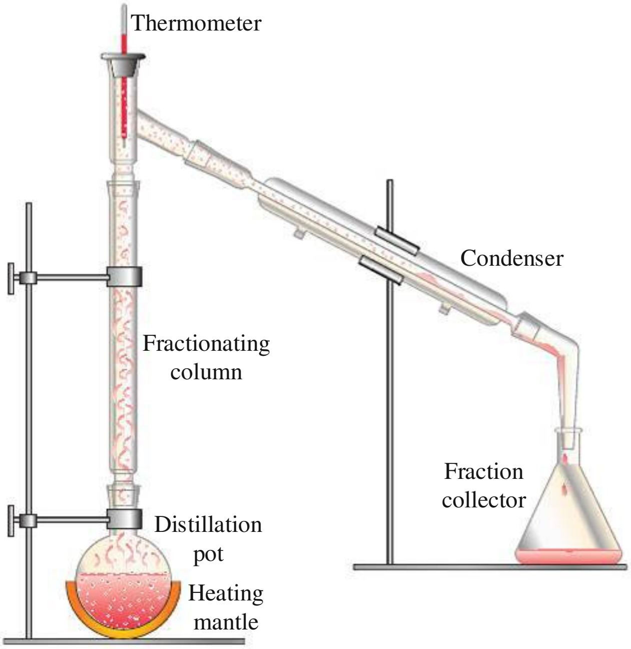
▶ FIGURE 13-13
Liquid–vapor equilibrium for benzene–toluene mixtures at 1 atm
In this diagram, the normal boiling points of solutions are plotted as a function of solution and vapor compositions.

process, that is, vaporizing a solution with $x_{\text{benz}} = 0.51$ and condensing the vapor. The new liquid at the end of stage 2 has $x_{\text{benz}} = 0.71$. By repeating the cycle, the vapor becomes progressively richer in benzene. As pictured in Figure 13-14, boiling solutions in equilibrium with vapor can be spread out over a long column, called a *fractionating column*, in which the equilibrium temperatures range from lowest at the top of the column to highest at the bottom. The most volatile component in the solution emerges from the top of the column as a vapor that is condensed to a liquid and removed. The least volatile component concentrates in the pot at the bottom of the column. Fractional distillation of a solution of many volatile components, such as petroleum, can be carried out in such a way that the components are withdrawn from the top of the column and condensed, one by one.

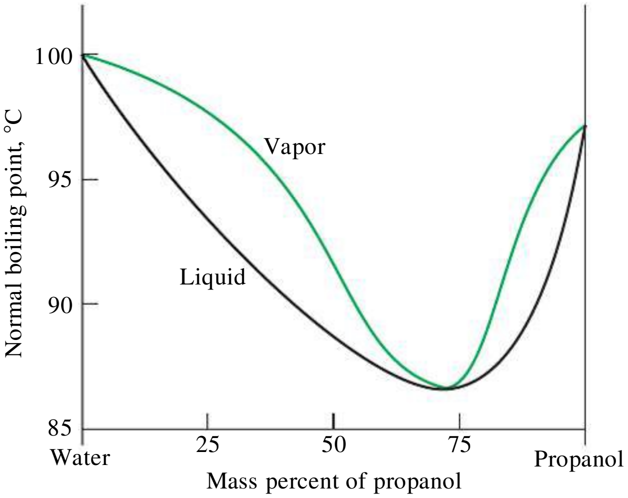
▲ Fractional distillation is used in many industrial processes.

Liquid–Vapor Equilibrium: Nonideal Solutions

We cannot construct a liquid–vapor equilibrium diagram for nonideal solutions in the simple manner illustrated in Figure 13-12. For example, vapor pressures in acetone–chloroform solutions are *lower* than we would predict for ideal solutions and boiling temperatures are correspondingly *higher*. In acetone–carbon disulfide solutions, conversely, vapor pressures are higher



▶ FIGURE 13-14
Fractional distillation
The fractionating column is packed with glass beads or stainless steel turnings. Initially, as vapor rises from the pot and encounters these cooler objects, it condenses to a liquid. As the beads or turnings heat up, the liquid–vapor equilibrium front moves progressively up the column. Soon, liquid–vapor equilibrium occurs throughout the column, but with the equilibrium temperature changing continuously from the hottest regions at the bottom of the column to the coolest at the top. The vapor emerging from the top of the column is condensed to a liquid in the water-cooled condenser. The first fraction collected contains the most volatile component (lowest boiling point). Later fractions are less volatile liquids. The least volatile (highest boiling point) components remain as a residue in the distillation pot.



◀ FIGURE 13-15
A minimum boiling-point azeotrope
A solution of propanol in water having 71.69% $CH_3CH_2CH_2OH$ by mass—an azeotrope—has a lower boiling point than any other solution of these two components. In fractional distillation, solutions having less than 71.69% of the alcohol yield the azeotrope and water as ultimate products. Solutions with more than 71.69% of the alcohol yield the azeotrope and propanol. In each case, the azeotrope is drawn off through the condenser (Fig. 13-14), and the other component remains in the pot.

than predicted and boiling temperatures are correspondingly lower. In Figure 13-5, we saw that the forces of attraction between unlike molecules are greater than those between like molecules in acetone–chloroform mixtures. It is not unreasonable to expect the components in such solutions to show a reduced tendency to vaporize and to have lower-than-predicted vapor pressures. With acetone–carbon disulfide solutions, the situation is the reverse: Forces of attraction between unlike molecules are weaker than between like molecules. This leads to greater tendencies for vaporization and higher vapor pressures than predicted by Raoult's law.

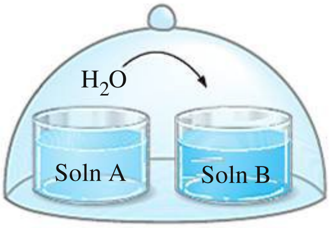
If the departures from ideal solution behavior are sufficiently great, some solutions may have vapor pressures that pass through either a maximum or a minimum in vapor-pressure-composition graphs. Correspondingly, their boiling points pass through either a minimum or maximum in boiling-point-composition graphs. The solutions corresponding to these maxima or minima boil at a constant temperature and produce a vapor having the *same* composition as the liquid. These solutions are called **azeotropes**. The boiling-point diagram of a minimum boiling-point azeotrope is illustrated in Figure 13-15.

One of the most familiar azeotropes consists of 96.0% ethanol (C_2H_5OH) and 4.0% water, by mass, and has a boiling point of 78.174 °C. Pure ethanol has a boiling point of 78.3 °C. Dilute ethanol–water solutions can be distilled to produce the azeotrope, but the remaining water cannot be removed by ordinary distillation. As a result, most ethanol used in the laboratory or in industry is only 96.0% C_2H_5OH. To obtain absolute, or 100%, C_2H_5OH requires special measures.

13-7 Osmotic Pressure

In the previous section our primary emphasis was on solutions containing a volatile solvent and volatile solute. Another common type of solution is one with a volatile solvent, such as water, but one or more *nonvolatile* solutes, such as glucose, sucrose, or urea. Raoult's law still applies to the solvent in such solutions—the vapor pressure of the solvent is lowered.

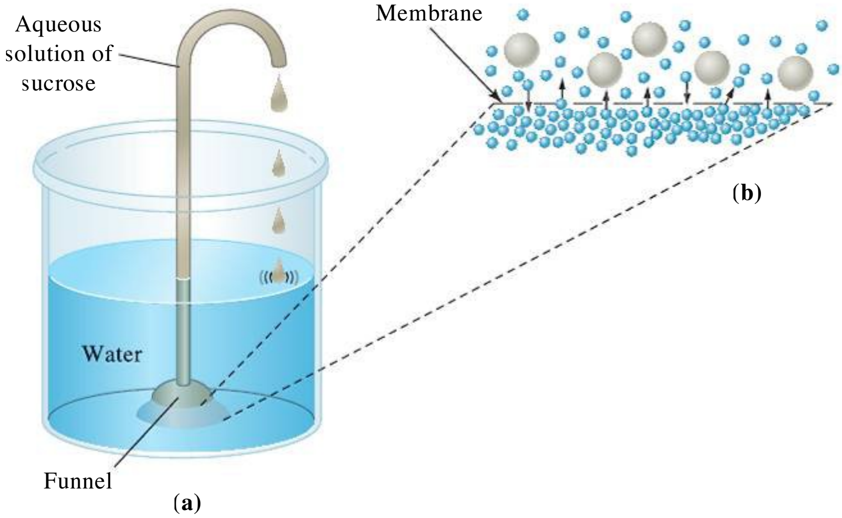
Figure 13-16(a) pictures two aqueous solutions of a nonvolatile solute within the same enclosure. They are labeled A and B. The curved arrow indicates that water vaporizes from A and condenses into B. What is the driving force behind this? It must be that the vapor pressure of H_2O above A is greater than that above B. Solution A is more dilute; it has a higher mole fraction of H_2O. How long will this transfer of water continue? Solution A becomes more concentrated as it loses water, and solution B becomes more dilute as it gains water. When the mole fraction of H_2O is the same in both solutions, the *net* transfer of H_2O stops.



(a)

(b)

▲ FIGURE 13-16
Observing the direction of flow of water vapor
(a) Water passes, as vapor, from the more dilute solution (higher mole fraction of H_2O) to the more concentrated solution. **(b)** Water vapor in air condenses onto solid calcium chloride hexahydrate, $CaCl_2 \cdot 6\,H_2O$. The liquid water dissolves some of the solid. The eventual result could be an unsaturated solution.



▲ FIGURE 13-17
Osmosis
(a) Water molecules pass through pores in the membrane and create a pressure within the funnel that causes the sucrose solution to rise, overflow, and fall into the pure water. After a time, the solution inside the funnel becomes more dilute and the pure water in the beaker becomes a sucrose solution. Liquid flow stops when the compositions of the solutions separated by the membrane have become nearly equal. **(b)** Enlarged cross-section of the membrane demonstrating its semi-permeable properties: water molecules (represented as small blue spheres) freely cross the membrane, while the sucrose molecule (represented as large gray spheres) cannot cross the membrane.

A related phenomenon occurs when $CaCl_2 \cdot 6\,H_2O(s)$ is exposed to air (Fig. 13-16b). Water vapor from the air condenses on the solid, and the solid begins to dissolve, a phenomenon known as *deliquescence*. For a solid to deliquesce, the partial pressure of water vapor in the air must be greater than the vapor pressure of water above a saturated aqueous solution of the solid. This requirement is often met for certain solids under conditions of appropriate relative humidity. The deliquescence of $CaCl_2 \cdot 6\,H_2O$ occurs when the relative humidity exceeds 32%. (Relative humidity is described in Focus On 6: Earth's Atmosphere.)

▶ Semipermeable membranes are materials containing submicroscopic holes, such as a pig's bladder, parchment, or cellophane. The holes permit the passage of solvent molecules but not those of the solute.

Like the case just described, Figure 13-17 also pictures the flow of solvent molecules. Here, however, the flow is not through the vapor phase. An aqueous sucrose (sugar) solution in a long glass tube is separated from pure water by a semipermeable membrane (permeable to water only). Water molecules can pass through the membrane in either direction, and they do. But because the concentration of water molecules is greater in the pure water than in the solution, there is a net flow from the pure water into the solution. This net flow, called **osmosis**, causes the solution to rise in the tube. The more concentrated the sucrose solution, the higher the solution level rises.

13-6 CONCEPT ASSESSMENT

Describe the similarities and differences between the phenomena depicted in Figures 13-16(a) and 13-17.

Applying pressure to the sucrose solution slows down the net flow of water across the membrane into the solution. With a sufficiently high pressure, the net influx of water can be stopped altogether. The necessary pressure to stop osmotic flow is called the **osmotic pressure** of the solution. For a 20% sucrose solution, this pressure is about 15 atm. The magnitude of osmotic pressure depends only on the number of solute particles per unit volume of solution. It does not depend on the identity of the solute. Properties of this sort, whose values depend only on the concentration of solute particles in solution and *not* on what the solute is, are called **colligative properties**. The following equation works quite well for calculating osmotic pressures of *dilute* solutions of nonelectrolytes. The osmotic pressure is represented by the symbol π, R is the gas constant (0.08206 L atm mol^{-1} K^{-1}); and T is the Kelvin temperature. The term n represents the amount of solute (in moles), and V is the volume (in liters) of solution. Notice that this equation is similar to the equation for the ideal gas law. In this case, however, it is convenient to rearrange terms to yield equation (13.4). The ratio, n/V, then, is the *molarity* of the solution, represented by the symbol M.

◀ Vapor-pressure lowering, as expressed through Raoult's law for ideal solutions, is also a colligative property.

$$\pi V = nRT$$

$$\pi = \frac{n}{V}RT = M \times RT \qquad \textbf{(13.4)}$$

◀ The adjustment required to apply equation (13.4) to electrolyte solutions is discussed in Section 13-9.

The pressure difference of 18 mmHg that we calculate in Example 13-8 is easy to measure. (It corresponds to a solution height of about 25 cm.) This means that we can easily use the measurement of osmotic pressure for determining molar masses when we are dealing with very dilute solutions or solutes with high molar masses (or both). Example 13-9 shows how osmotic pressure measurements can be used to determine molar mass.

EXAMPLE 13-8 Calculating Osmotic Pressure

What is the osmotic pressure at 25 °C of an aqueous solution that is 0.0010 M $C_{12}H_{22}O_{11}$ (sucrose)?

Analyze

We just need to substitute the data into equation (13.4).

Solve

$$\pi = \frac{0.0010\ \text{mol} \times 0.08206\ \text{atm L mol}^{-1}\ \text{K}^{-1} \times 298\ \text{K}}{1\ \text{L}}$$

$$\pi = 0.024\ \text{atm (18 mmHg)}$$

Assess

At a very low concentration, there is an appreciable amount of osmotic pressure. This fact is used when measuring the molar mass of polymers and biopolymers.

PRACTICE EXAMPLE A: What is the osmotic pressure at 25 °C of an aqueous solution that contains 1.50 g $C_{12}H_{22}O_{11}$ in 125 mL of solution?

PRACTICE EXAMPLE B: What mass of urea [$CO(NH_2)_2$] would you dissolve in 225 mL of solution to obtain an osmotic pressure of 0.015 atm at 25 °C?

EXAMPLE 13-9 Establishing a Molar Mass from a Measurement of Osmotic Pressure

A 50.00 mL sample of an aqueous solution contains 1.08 g of human serum albumin, a blood-plasma protein. The solution has an osmotic pressure of 5.85 mmHg at 298 K. What is the molar mass of the albumin?

Analyze

We need to use osmotic pressure to determine the molar mass of a protein, human serum albumin, in a solution.

(continued)

Solve

Express osmotic pressure in atmospheres.

$$\pi = 5.85\ \text{mmHg} \times \frac{1\ \text{atm}}{760\ \text{mmHg}} = 7.70 \times 10^{-3}\ \text{atm}$$

Modify the basic equation for osmotic pressure, by showing moles of solute (n) as the mass of solute (m) divided by its molar mass (M), and solve for M.

$$\pi V = nRT \qquad \pi V = \frac{m}{M}RT \qquad M = \frac{mRT}{\pi V}$$

Obtain the value of M by substituting the given data into the last equation above, ensuring that units cancel to yield g/mol as the unit for M.

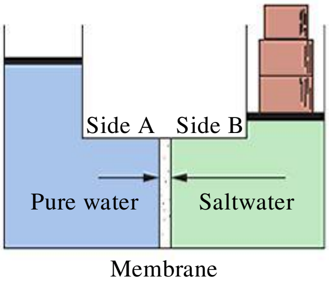
$$M = \frac{1.08\ \text{g} \times 0.08206\ \text{atm L mol}^{-1}\ \text{K}^{-1} \times 298\ \text{K}}{7.70 \times 10^{-3}\ \text{atm} \times 0.0500\ \text{L}} = 6.86 \times 10^{4}\ \text{g/mol}$$

Assess

Even though the solution is relatively dilute, knowing the osmotic pressure helped us determine the molar mass of human serum albumin.

PRACTICE EXAMPLE A: Creatinine is a by-product of nitrogen metabolism and can be used to provide an indication of renal function. A 4.04 g sample of creatinine is dissolved in enough water to make 100.0 mL of solution. The osmotic pressure of the solution is 8.73 mmHg at 298 K. What is the molar mass of creatinine?

PRACTICE EXAMPLE B: What would be the osmotic pressure of a solution containing 2.12 g of human serum albumin in 75.00 mL of water at 37.0 °C? Use the molar mass determined in Example 13-9.

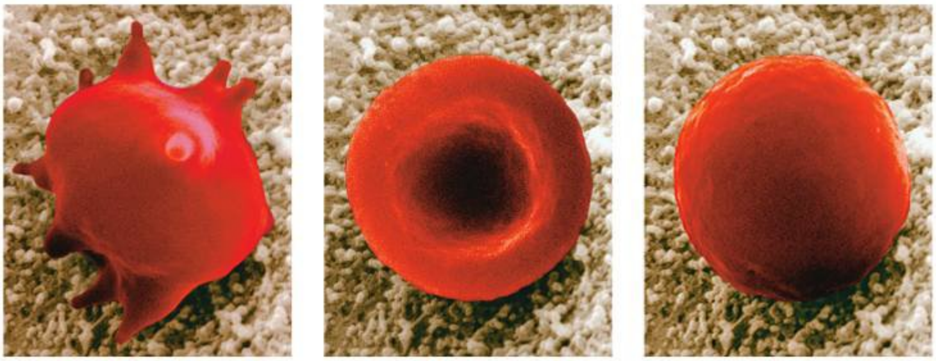


▲ FIGURE 13-18
Desalination of saltwater by reverse osmosis
The membrane is permeable to water but not to ions. The normal flow of water is from side A to side B. If a pressure is exerted on side B that exceeds the osmotic pressure of the saltwater, a net flow of water occurs in the *reverse* direction—from the saltwater to the pure water. The lengths of the arrows suggest the magnitudes of the flow of water molecules in each direction.

Practical Applications

Some of the best examples of osmosis are those associated with living organisms. For instance, if red blood cells are placed in pure water, the cells expand and eventually burst as a result of water that enters through osmosis. The osmotic pressure associated with the fluid inside the cell is equivalent to that of 0.92% (mass/volume) NaCl(aq). Thus, if cells are placed in a sodium chloride (saline) solution of this concentration, there is no net flow of water through the cell membrane, and the cell remains stable. Such a solution is said to be *isotonic*. If cells are placed in a solution with a concentration greater than 0.92% NaCl, water flows out of the cells, and the cells shrink. Such a solution is said to be *hypertonic*. If the NaCl concentration is less than 0.92%, the solution is *hypotonic*, and water flows into the cells. Fluids that are intravenously injected into patients to combat dehydration or to supply nutrients must be adjusted so that they are isotonic with blood. The osmotic pressure of the fluids must be the same as that of 0.92% (mass/volume) NaCl.

One recent application of osmosis goes to the very definition of osmotic pressure. Suppose in the device shown in Figure 13-18, we apply a pressure to the right side (side B) that is less than the osmotic pressure of the saltwater. The net flow of water molecules through the membrane will be from side A to side B, and ordinary osmosis occurs. If we apply a pressure greater than the



▶ A red blood cell in a hypertonic solution (left), an isotonic solution (center), and a hypotonic solution (right).

osmotic pressure to side B, we can cause a net flow of water in the *reverse* direction, from the saltwater into the pure water. This is the condition known as **reverse osmosis**. Reverse osmosis can be used in the *desalination* of seawater to supply drinking water for emergency situations or as an actual source of municipal water. Another application of reverse osmosis is the removal of dissolved materials from industrial or municipal wastewater before it is discharged into the environment.

SURVIVOR-35

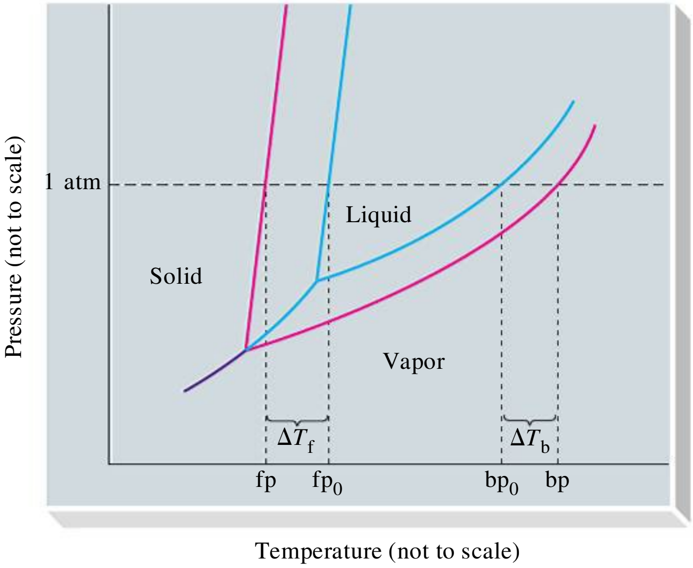
13-8 Freezing-Point Depression and Boiling-Point Elevation of Nonelectrolyte Solutions

In Section 13-6 we examined the lowering of the vapor pressure of a solvent produced by a dissolved solute. Vapor pressure lowering is not measured as frequently as certain properties directly related to it. In Figure 13-19 the blue curves represent the vapor pressure, fusion, and sublimation curves in the phase diagram for a pure solvent. The red curves represent the vapor pressure and fusion curves of the solvent in a solution. The sublimation curve for the solid solvent that freezes from the solution is shown in purple. Two assumptions are implicit in Figure 13-19. One is that the solute is nonvolatile, the other is that the solid that freezes from a solution is pure solvent. For many mixtures, these requirements are easily met.*

The vapor pressure curve of the solution (red) intersects the sublimation curve at a lower temperature than is the case for the pure solvent. The solid-liquid fusion curve, because it originates at the intersection of the sublimation and vapor pressure curves, is also displaced to lower temperatures. Now recall how we establish normal melting points and boiling points in a phase diagram. They are the temperatures at which a line at $P = 1$ atm intersects the fusion and vapor pressure curves, respectively. Four points of intersection are highlighted in Figure 13-19—the freezing points and the boiling points of the pure solvent and of the solvent in a solution. The freezing point of the solvent in solution is *depressed*, and the boiling point is *elevated*.

The extent to which the freezing point is lowered or the boiling point raised is proportional to the mole fraction of solute (just as is vapor pressure lowering).

◀ In Figure 13-19, the solid and vapor free energies do not change with the addition of a solute to the liquid phase. However, adding solute to the liquid does lower the free energy of the solution. Hence, to re-establish equilibrium, the S–L and the L–V curves shift to respectively lower and higher T. This can be thought of as an example of Le Châtelier's principle.



◀ FIGURE 13-19
Vapor-pressure lowering by a nonvolatlle solute
The normal freezing point and normal boiling point of the pure solvent are fp_0 and bp_0, respectively. The corresponding points for the solution are fp and bp. The freezing-point depression, ΔT_f, and the boiling-point elevation, ΔT_b, are indicated. Because the solute is assumed to be insoluble in the solid solvent, the sublimation curve of the solvent is unaffected by the presence of solute in the liquid solution phase. That is, the sublimation curve is the same for the two phase diagrams.

---

*Actually, the equation for freezing-point depression (13.5) applies even if the solute is volatile.

TABLE 13.2 Freezing-Point Depression and Boiling-Point Elevation Constants[a]

Solvent	Normal Freezing Point, °C	K_f, °C m^{-1}	Normal Boiling Point, °C	K_b, °C m^{-1}
Acetic acid	16.6	3.90	118	3.07
Benzene	5.53	5.12	80.10	2.53
Nitrobenzene	5.7	8.1	210.8	5.24
Phenol	41	7.27	182	3.56
Water	0.00	1.86	100.0	0.512

[a] Values correspond to freezing-point depressions and boiling-point elevations, in degrees Celsius, caused by 1 mol of solute particles dissolved in 1 kg of solvent in an ideal solution.

In *dilute* solutions, the solute mole fraction is proportional to its molality, and so we can write

$$\Delta T_f = -K_f \times m \qquad (13.5)$$

$$\Delta T_b = K_b \times m \qquad (13.6)$$

KEEP IN MIND

that freezing-point depression (ΔT_f) is defined as $T - T_f$, where T is the freezing point of the solution and T_f is the freezing point of the pure solvent, and similarly the boiling-point elevation (ΔT_b) is defined as $T - T_b$ where T_b is the boiling point of the pure solvent. So the need for the negative sign in equation (13.5) is evident.

In these equations, ΔT_f and ΔT_b are the freezing-point depression and boiling-point elevation, respectively; m is the solute molality; and K_f and K_b are proportionality constants. The value of K_f depends on the melting point, enthalpy of fusion, and molar mass of the solvent. The value of K_b depends on the boiling point, enthalpy of vaporization, and molar mass of the solvent. The units of K_f and K_b are °C m^{-1}, and you can think of their values as representing the freezing-point depression and boiling-point elevation for a 1 m solution. In practice, though, equations (13.5) and (13.6) often fail for solutions as concentrated as 1 m. Table 13.2 lists some typical values of K_f and K_b.

Historically, chemists have used the group of colligative properties—vapor pressure lowering, freezing-point depression, boiling-point elevation, and osmotic pressure—for molecular mass determinations. In Example 13-9, we showed how this could be accomplished with osmotic pressure. Example 13-10 shows how freezing-point depression can be used to determine a molar mass and, with other information, a molecular formula. To help you understand how this is done, we present a three-step procedure in the form of answers to three separate questions. In other cases, you should be prepared to work out your own procedure.

13-7 CONCEPT ASSESSMENT

In what important way would Figure 13-19 change if it were based on the phase diagram of water rather than for the general case shown? Would a boiling-point elevation and a freezing-point depression still be expected?

▶ The adjustment required to apply these equations to electrolyte solutions is discussed in Section 13-9.

Molar mass determination by freezing-point depression or boiling-point elevation has its limitations. Equations (13.5) and (13.6) apply only to dilute solutions of nonelectrolytes, usually much less than 1 m. This requires the use of special thermometers so that temperatures can be measured very precisely, say to ±0.001 °C. Because boiling points depend on barometric pressure, precise measurements require that pressure be held constant. As a consequence, boiling-point elevation is not much used. The precision of the freezing-point depression method can be improved by using a solvent with a larger K_f value

EXAMPLE 13-10 Establishing a Molecular Formula with Freezing-Point Data

Nicotine, extracted from tobacco leaves, is a liquid completely miscible with water at temperatures below 60 °C. **(a)** What is the *molality* of nicotine in an aqueous solution that starts to freeze at −0.450 °C? **(b)** If this solution is obtained by dissolving 1.921 g of nicotine in 48.92 g H_2O, what must be the molar mass of nicotine? **(c)** Combustion analysis shows nicotine to consist of 74.03% C, 8.70% H, and 17.27% N, by mass. What is the molecular formula of nicotine?

Analyze

(a) We can establish the molality of the nicotine by using equation (13.5) with the value of K_f for water listed in Table 13.2. **(b)** Once we know the molality, we can use the definition of molality, but with a known molality (from part a) and an unknown molar mass of solute (M). **(c)** To establish the empirical formula of nicotine, we need to use the method of Example 3-5.

Solve

(a) Note that $T_f = -0.450\ °\text{C}$, and that $\Delta T_f = -0.450\ °\text{C} - 0.000\ °\text{C} = -0.450\ °\text{C}$.

$$\text{molality} = \frac{\Delta T_f}{-K_f} = \frac{-0.450\ °\text{C}}{-1.86\ °\text{C}\ m^{-1}} = 0.242\ m$$

(b) Let's represent the molar mass as x g/mol. The amount, in moles, contained in a 1.921g sample is $1.921\text{g} \times (1\ \text{mol}/x\ \text{g}) = (1.921/x)$ mol. Thus,

$$\text{molality} = \frac{1.921\ x^{-1}}{0.04892\ \text{kg water}} = 0.242\ \text{mol (kg water)}^{-1}$$

$$x = 162$$

The molar mass is 162 g/mol.

(c) This calculation is left as an exercise for you to do. The result you should obtain is C_5H_7N. The formula mass based on this empirical formula is 81 u. The molecular mass obtained from the molar mass in part (b) is exactly twice this value—162 u. The molecular formula is twice C_5H_7N, or $C_{10}H_{14}N_2$.

Assess

Using the freezing-point data is another experimental technique that can be used to obtain the chemical properties of a substance. In this example we were able to determine the molecular formula from the freezing-point depression and a known amount of substance dissolved in a solvent. Note that water was used as the solvent here; however, other solvents can be used in freezing-point experiments.

PRACTICE EXAMPLE A: Vitamin B_2, riboflavin, is soluble in water. If 0.833 g of riboflavin is dissolved in 18.1 g H_2O, the resulting solution has a freezing point of −0.227 °C. **(a)** What is the molality of the solution? **(b)** What is the molar mass of riboflavin? **(c)** What is the molecular formula of riboflavin if combustion analysis shows it to consist of 54.25% C, 5.36% H, 25.51% O, and 14.89% N?

PRACTICE EXAMPLE B: An aqueous solution that is 0.205 m urea [$CO(NH_2)_2$] is found to boil at 100.025 °C. Is the prevailing barometric pressure above or below 760.0 mmHg? [*Hint:* At what temperature should the solution begin to boil if atmospheric pressure is 760.0 mmHg?]

than that of water. For example, for cyclohexane $K_f = 20.0\ °\text{C}\ m^{-1}$ and for camphor $K_f = 37.7\ °\text{C}\ m^{-1}$.

Practical Applications

The typical automobile antifreeze is ethylene glycol, $HOCH_2CH_2OH$. It is a good idea to leave the ethylene glycol–water mixture in the cooling system at all times to provide all-weather protection. In summer, the ethylene glycol helps by raising the boiling point of water and preventing the cooling system from boiling over.

Citrus growers faced with an impending freeze know they must take preventive measures only if the temperature drops below 0 °C by several degrees. The juice in the fruit has enough dissolved solutes to lower the freezing point by a degree or two. The growers also know they must protect lemons sooner

▲ Water sprayed on citrus fruit releases its heat of fusion as it freezes into a layer of ice that acts as a thermal insulator. For a time, the temperature remains at 0 °C. The juice of the fruit, having a freezing point below 0 °C, is protected from freezing.

▲ A typical aircraft deicer is propylene glycol, $CH_3CH(OH)CH_2OH$, diluted with water and applied as a hot, high-pressure spray.

than oranges because lemons have a lower concentration of dissolved solutes (sugars) than do oranges.

Salts, such as NaCl, can be used to prepare a *slush bath*, a mixture used to cool or freeze something. One example is the mixture of ice and NaCl(s) used to freeze ice cream in a home ice-cream maker. Because the slush bath is at a temperature well below 0 °C, it is easy to freeze the sugar-and-milk mixture that makes up the ice cream. NaCl is also useful for deicing roads. It is effective in melting ice at temperatures as low as −21 °C (−6 °F). This is the lowest freezing point of a NaCl(aq) solution.

13-8 CONCEPT ASSESSMENT

Why do you suppose that the freezing point of NaCl(aq) is depressed no further than −21 °C, regardless of how much more NaCl(s) is added to water?

▲ Lowering the freezing point of water on roads.

13-9 Solutions of Electrolytes

The discussion of the electrical conductivities of solutions in Section 5-1 retraced some of the work done by the Swedish chemist Svante Arrhenius for his doctoral dissertation (1883). Prevailing opinion at the time was that ions form only with the passage of electric current. Arrhenius, however, reached the conclusion that ions exist in a solid substance and become dissociated from each other when the solid dissolves in water. Such is the case with NaCl, for example. In other cases, as with HCl, ions do not exist in the substance but are formed when it dissolves in water. In any case, electricity is not required to produce ions.

Although Arrhenius developed his theory of electrolytic dissociation to explain the electrical conductivities of solutions, he was able to apply it more widely. One of his first successes came in explaining certain anomalous values of colligative properties described by the Dutch chemist Jacobus van't Hoff (1852–1911).

Anomalous Colligative Properties

Certain solutes produce a greater effect on colligative properties than expected. For example, consider a 0.0100 m aqueous solution. The predicted freezing-point depression of this solution is

$$\Delta T_f = -K_f \times m = -1.86\ ^\circ\text{C}\ m^{-1} \times 0.0100\ m = -0.0186\ ^\circ\text{C}$$

We expect the solution to have a freezing point of $-0.0186\ ^\circ\text{C}$. If the $0.0100\ m$ solution is $0.0100\ m$ urea, the measured freezing point is just about $-0.0186\ ^\circ\text{C}$. If the solution is $0.0100\ m$ NaCl, however, the measured freezing point is about $-0.0361\ ^\circ\text{C}$.

Van't Hoff defined the factor i as the ratio of the measured value of a colligative property to the expected value if the solute is an electrolyte. For $0.0100\ m$ NaCl,

$$i = \frac{\text{measured } \Delta T_f}{\text{expected } \Delta T_f} = \frac{-0.0361\ ^\circ\text{C}}{-1.86\ ^\circ\text{C}\ m^{-1} \times 0.0100\ m} = 1.94$$

◀ Later in this section, we explain why the experimentally determined i for $0.0100\ m$ NaCl is 1.94 instead of 2.

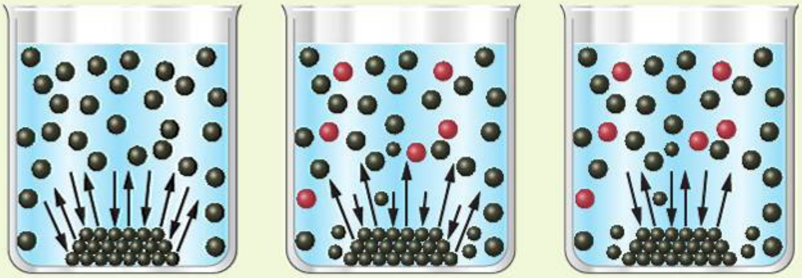
13-2 ARE YOU WONDERING...

If there is a molecular interpretation of the freezing-point depression of a solvent by a solute?

When the solid and liquid phases of a pure substance coexist at a particular temperature, two processes occur. First, liquid molecules that collide with the solid sometimes are captured and added to the solid phase. At the same time, molecules on the surface of the solid sometimes become detached and enter the liquid phase. There is a state of dynamic equilibrium in which, at any given time, the number of molecules leaving the surface of the solid matches the number of molecules that enter the solid from the liquid phase. There is no net change even though individual molecules continue to move back and forth between the phases.

Now, imagine adding a solute to the liquid coexisting with its solid phase. In the solution formed above the solid phase, solute molecules replace some of the solvent molecules, and as a consequence, a given volume of solution contains a smaller number of solvent molecules than does the same volume of pure solvent. The dynamic equilibrium between liquid and solid solvent that existed in the pure solvent is disrupted since fewer solvent molecules in the liquid can get to the surface of the solid in a given time. The rate at which molecules leave the liquid phase is reduced and is no longer equal to the rate at which molecules leave the pure solid phase. However, cooling the solution restores the dynamic equilibrium because it simultaneously reduces the number of molecules that have sufficient energy to break away from the surface of the solid and increases the number of molecules in the liquid phase with sufficiently low kinetic energy to be captured by the solid. The lowered equilibrium temperature corresponds to the freezing-point depression.

Although this kinetic-molecular interpretation of freezing-point depression is an appealing one, the phenomenon is better described by the thermodynamic concept of entropy, which we will introduce in Chapter 19.



Equilibrium at freezing point of solvent

Equilibrium disrupted by solute added to solvent

Equilibrium restored at a lower temperature

▲ Molecular view of freezing-point depression. The addition of solute to the liquid solvent does not change the rate of escape of molecules from the solid phase, but it does decrease the rate at which solvent molecules can enter the solid phase. The dynamic equilibrium between solid and liquid solvent is disrupted, and can be re-established only at a lower temperature.

▲ **Svante Arrhenius (1859–1927)**
At the time Arrhenius was awarded the Nobel Prize in chemistry (1903), his results were described thus: "Chemists would not recognize them as chemistry; nor physicists as physics. They have in fact built a bridge between the two." The field of physical chemistry had its origins in Arrhenius's work.

Arrhenius's theory of electrolytic dissociation allows us to explain different values of the van't Hoff factor i for different solutes. For such solutes as urea, glycerol, and sucrose (all nonelectrolytes), $i = 1$. For a strong electrolyte such as NaCl, which produces *two* moles of ions in solution per mole of solute dissolved, we would expect the effect on freezing-point depression to be twice as great as for a nonelectrolyte. We would expect that $i = 2$. Similarly, for $MgCl_2$, our expectation would be that $i = 3$. For the weak acid CH_3COOH (acetic acid), which is only slightly ionized in aqueous solution, we expect i to be slightly larger than one but not nearly equal to two.

▶ Pure water does not conduct electricity. So why should we be careful with electricity when near water? It is not the water but the electrolytes that are dissolved in water.

This discussion suggests that equations (13.4), (13.5), and (13.6) should all be rewritten in the form

$$\pi = i \times \mathrm{M} \times RT$$
$$\Delta T_f = -i \times K_f \times m$$
$$\Delta T_b = i \times K_b \times m$$

If these equations are used for nonelectrolytes, simply substitute $i = 1$. For strong electrolytes, predict a value of i as suggested in Example 13-11.

Interionic Attractions

Despite its initial successes, there were apparent deficiencies in Arrhenius's theory. The electrical conductivities of concentrated solutions of strong electrolytes are not as great as expected, and values of the van't Hoff factor i depend on the solution concentrations, as shown in Table 13.3. For strong

EXAMPLE 13-11 Predicting Colligative Properties for Electrolyte Solutions

Predict the freezing point of aqueous 0.00145 m $MgCl_2$.

Analyze

We will use a modified freezing-point depression equation in which the van't Hoff factor i is included. We first note that $MgCl_2$ is a salt that completely dissociates when it is dissolved in water. So we determine the value of i for $MgCl_2$. We can do this by writing an equation to represent the dissociation of $MgCl_2(s)$. Then we use the appropriate freezing-point depression expression.

Solve

$$MgCl_2(s) \xrightarrow{H_2O} Mg^{2+}(aq) + 2\,Cl^-(aq)$$

Because *three* moles of ions are obtained per mole of formula units dissolved, we expect the value $i = 3$.

Now use the expression

$$\begin{aligned}\Delta T_f &= -i \times K_f \times m \\ &= -3 \times 1.86\ ^\circ\mathrm{C}\ m^{-1} \times 0.00145\ m \\ &= -0.0081\ ^\circ\mathrm{C}\end{aligned}$$

The predicted freezing point is −0.0081 °C.

Assess

Because the value of i for $MgCl_2$ is not exactly 3, we are not justified in carrying more than one or two significant figures in our answer. If we had ignored the fact that $MgCl_2$ is a strong electrolyte, then our calculated freezing-point depression would have been three times as small as the experimental value. Always remember to include the van't Hoff factor when ionic compounds are given as part of the problem.

PRACTICE EXAMPLE A: What is the expected osmotic pressure of a 0.0530 M $MgCl_2$ solution at 25 °C?

PRACTICE EXAMPLE B: You want to prepare an aqueous solution that has a freezing point of −0.100 °C. How many milliliters of 12.0 M HCl would you use to prepare 250.0 mL of such a solution? [*Hint:* Note that in a dilute aqueous solution, molality and molarity are essentially numerically equal.]

TABLE 13.3 Variation of the van't Hoff Factor, *i*, with Solution Molality

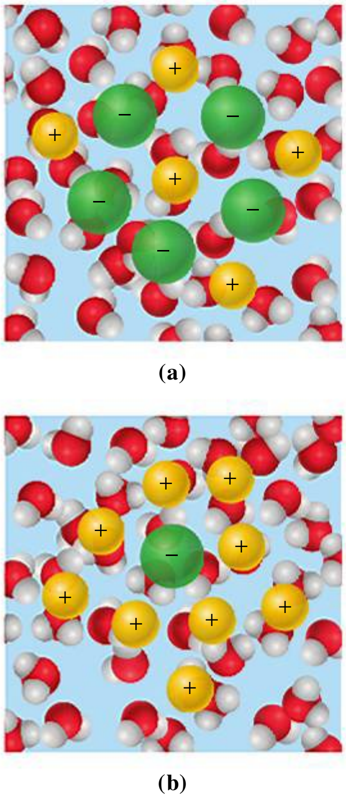
	Molality, *m*					
Solute	1.0	0.10	0.010	0.0010	· · ·	Inf. dil.[a]
NaCl	1.81	1.87	1.94	1.97	· · ·	2
$MgSO_4$	1.09	1.21	1.53	1.82	· · ·	2
$Pb(NO_3)_2$	1.31	2.13	2.63	2.89	· · ·	3

[a] The limiting values: $i = 2, 2,$ and 3 are reached when the solution is infinitely dilute. Note that a solute whose ions are singly charged (for example, NaCl) approaches its limiting value more quickly than does a solute whose ions carry higher charges. Interionic attractions are greater in solutes with more highly charged ions.

electrolytes that exist completely in ionic form in aqueous solutions, we would expect $i = 2$ for NaCl, $i = 3$ for $MgCl_2$, and so on, regardless of the solution concentration.

These difficulties can be resolved with a theory of electrolyte solutions proposed by Peter Debye and Erich Hückel in 1923. This theory continues to view strong electrolytes as existing only in ionic form in aqueous solution, but the ions in solution *do not behave independently of one another*. Instead, each cation is surrounded by a cluster of ions in which anions predominate, and each anion is surrounded by a cluster in which cations predominate. In short, each ion is enveloped by an *ionic atmosphere* with a net charge opposite its own (Fig. 13-20).

In an electric field, the mobility of each ion is reduced because of the attraction or drag exerted by its ionic atmosphere. Similarly, the magnitudes of colligative properties are reduced. This explains why, for example, the value of *i* for 0.010 *m* NaCl is 1.94 rather than 2.00. What we can say is that each type of ion in an aqueous solution has two "concentrations." One is called the *stoichiometric concentration* and is based on the amount of solute dissolved. The other is the "effective" concentration, called the *activity*, which takes into account interionic attractions. Stoichiometric calculations of the type presented in Chapters 4 and 5 can be made with great accuracy using stoichiometric concentrations. However, no calculations involving solution properties are 100% accurate if stoichiometric concentrations are used. Activities are needed instead. The activity of a solution is related to its stoichiometric concentration through a factor called an *activity coefficient*. How much do we need to know about activities? First, it is worth noting that in sufficiently dilute solutions, activity coefficients approximate one: Activities and stoichiometric concentrations are the same. In doing calculations, we will work only with stoichiometric concentrations because a quantitative treatment of activity coefficients is beyond the scope of this text. Mainly, you should be aware of the distinction between activity and stoichiometric concentration because it helps to explain a number of chemical phenomena. We will discuss the importance of activities in more detail in Chapters 15 and 19.



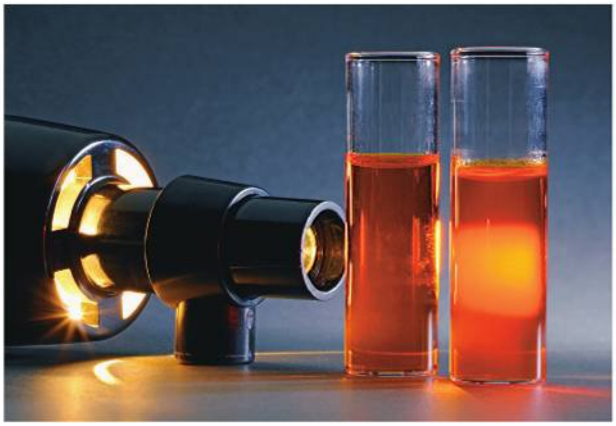
▲ FIGURE 13-20 **Interionic attractions in aqueous solution**
(a) A positive ion in aqueous solution is surrounded by a shell of negative ions.
(b) A negative ion attracts positive ions to its immediate surroundings.

13-10 Colloidal Mixtures

In a mixture of sand and water, the sand (silica, SiO_2) quickly settles to the bottom of the container. Yet mixtures can be prepared containing up to 40% by mass of SiO_2, and the silica may remain dispersed in the aqueous medium for many years. In these mixtures, the silica is *not* present as ions or molecules. Rather, much larger particles of silica are present, though they are still submicroscopic in size. The mixture is said to be a **colloid**. To be classified *colloidal*, a material must have one or more of its dimensions (length, width, or thickness)

◀ Colloids are extremely important to the food industry. Gelatins are colloids, and many foods are colloidal mixtures for which the food industry exerts considerable research effort to prevent their separation.

▲ **Hemodialysis**
An artificial kidney machine cleaning the blood of patients with impaired kidney function.



▶ FIGURE 13-21
The Tyndall effect
The flashlight beam is not visible as it passes through a true solution (left), but it is readily seen as it passes through the colloidal dispersion of Fe_2O_3 (right).

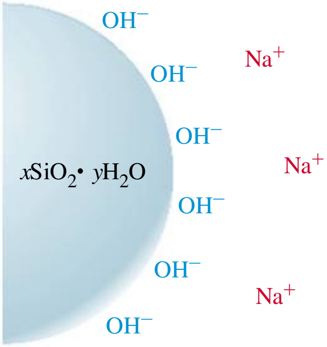
in the approximate range of 1–1000 nm. If all the dimensions are smaller than 1 nm, the particles are of molecular size. If all the dimensions exceed 1000 nm, the particles are of ordinary, or macroscopic, size (even if they are visible only under a microscope). One method of determining whether a mixture is a true solution or a colloid is illustrated in Figure 13-21. When light passes through a true solution, an observer viewing from a direction perpendicular to the light beam sees no light. In a colloidal dispersion, light is scattered in many directions and is readily seen. This effect, first studied by John Tyndall in 1869, is known as the *Tyndall effect*. A common example is the scattering of light by dust particles in a flashlight beam.

The particles in colloidal silica have a spherical shape. Some colloidal particles are rod-shaped, and some, like gamma globulin in human blood plasma, have a disc-like shape. Thin films, like an oil slick on water, are colloidal. And some colloids, such as cellulose fibers, are randomly coiled filaments.

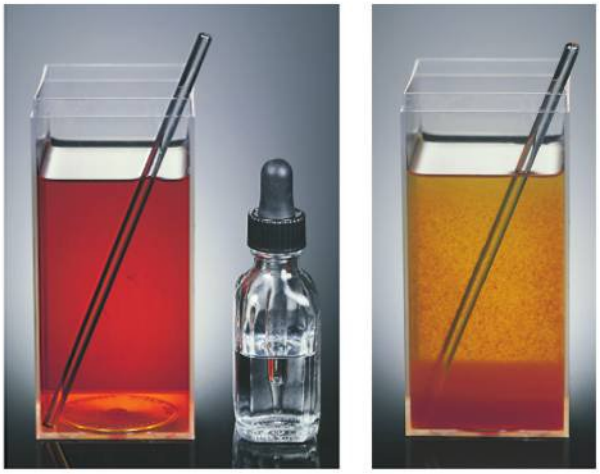
What keeps the SiO_2 particles suspended in colloidal silica? The most important factor is that the surfaces of the particles *adsorb*, or attach to themselves, ions from the solution, and they preferentially adsorb one type of ion over others. In the case of SiO_2, the preferred ions that are adsorbed are OH^- (see Figure 13-22). As a result, the particles acquire a net negative charge. Having like charges, the particles repel one another. These mutual repulsions overcome the force of gravity, and the particles remain suspended indefinitely.

Although electric charge can be important in stabilizing a colloid, a high concentration of ions can also bring about the *coagulation*, or precipitation, of a colloid (Fig. 13-23). The ions responsible for the coagulation are those carrying a charge opposite to that on the colloidal particles. *Dialysis*, a process similar to osmosis, can be used to remove excess ions from a colloidal mixture. As suggested by Figure 13-24, molecules of solvent and molecules or ions of solute pass through a semipermeable membrane, but the much larger colloidal particles do not. In some cases, the process is more effective when carried out in an electric field. In *electrodialysis*, ions are attracted out of a colloidal mixture by an electrode carrying the opposite charge. A human kidney dialyzes blood, a colloidal mixture, to remove excess electrolytes produced by metabolic processes. Certain diseases cause the kidneys to lose this ability, but a dialysis machine, external to the body, can function for the kidneys.

Table 13.4 lists some common colloids, and as so aptly put by Wilder Bancroft, an American pioneer in the field of colloid chemistry, ". . . colloid chemistry is essential to anyone who really wishes to understand . . . oils, greases, soaps, . . . glue, starch, adhesives, . . . paints, varnishes, lacquers, . . . cream, butter, cheese, . . . cooking, washing, dyeing, . . . colloid chemistry is the chemistry of life."



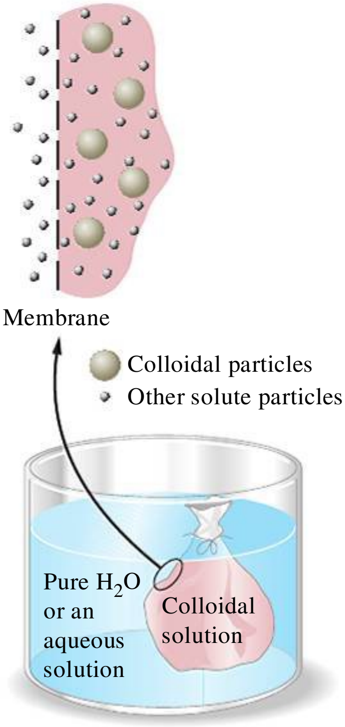
▲ FIGURE 13-22
Surface of SiO_2 particle in colloidal silica
The points made in this simplified drawing are: (1) The SiO_2 particles are hydrated; (2) OH^- ions are preferentially adsorbed on the surface; (3) In the immediate vicinity of the particle, negative ions outnumber positive ions and the particle carries a net negative charge. Not illustrated here are the facts that some of the negative charge comes from silicate anions (for example, SiO_3^{2-}), and as a whole, the solution in which these particles are found is electrically neutral.



▲ FIGURE 13-23

Coagulation of colloidal iron oxide

On the left is red colloidal hydrous Fe_2O_3, obtained by adding $FeCl_3(aq)$ to boiling water. When a few drops of $Al_2(SO_4)_3(aq)$ are added, the suspended particles rapidly coagulate into a precipitate of $Fe_2O_3(s)$, as shown on the right.



▲ FIGURE 13-24

The principles of dialysis

Water molecules, other solute molecules, and dissolved ions are all free to pass through the pores of the membrane (for example, a film of cellophane) in either direction. The direction of net flow of these species depends on their relative concentrations on either side of the membrane. Colloidal particles, however, cannot pass through the pores of the membrane.

TABLE 13.4 Some Common Types of Colloids

Dispersed Phase	Dispersion Medium	Type	Examples
Solid	Liquid	Sol	Clay sols,[a] colloidal silica, colloidal gold
Liquid	Liquid	Emulsion	Oil in water, milk, mayonnaise
Gas	Liquid	Foam	Soap and detergent suds, whipped cream, meringues
Solid	Gas	Aerosol[b]	Smoke, dust-laden air[c]
Liquid	Gas	Aerosol[b]	Fog, mist (as in aerosol products)
Solid	Solid	Solid sol	Ruby glass, certain natural and synthetic gems, blue rock salt, black diamond
Liquid	Solid	Solid emulsion	Opal, pearl
Gas	Solid	Solid foam	Pumice, lava, volcanic ash

[a] In water purification, it is sometimes necessary to precipitate clay particles or other suspended colloidal materials. This is often done by treating the water with an appropriate electrolyte. Clay sols are suspected of adsorbing organic substances, such as pesticides, and distributing them in the environment.

[b] Smogs are complex materials that are at least partly colloidal. The suspended particles are both solid and liquid. Other constituents of smog are molecular, for example, sulfur oxides, nitrogen oxides, and ozone.

[c] The bluish haze of tobacco smoke and the brilliant sunsets in desert regions are both attributable to the scattering of light by colloidal particles suspended in air.

MasteringCHEMISTRY www.masteringchemistry.com

The separation of complex mixtures, such as gasoline, into their individual components can be accomplished using a technique known as chromatography. There are many variations of the technique, but they all take advantage of differences in the way molecules of different compounds interact with a common material. To find out more, go to the Focus On feature for Chapter 13, Chromatography, on the MasteringChemistry site.

Summary

13-1 Types of Solutions: Some Terminology—In a solution, the **solvent**—usually the component present in greatest amount—determines the state of matter in which the solution exists (Table 13.1). **A solute** is a solution component dissolved in the solvent. Dilute solutions contain relatively small amounts of solute and concentrated solutions, large amounts.

13-2 Solution Concentration—Any description of the composition of a solution must indicate the quantities of solute and solvent (or solution) present. Solution concentrations expressed as mass percent, volume percent, and mass/ volume percent all have practical importance, as do the units, parts per million **(ppm)**, parts per billion **(ppb)**, and parts per trillion **(ppt)**. However, the more fundamental concentration units are mole fraction, molarity, and molality. Molarity (moles of solute per liter of solution) is temperature dependent, but mole fraction and **molality** (moles of solute per kilogram of solvent) are not.

13-3 Intermolecular Forces and the Solution Process—Predictions about whether two substances will mix to form a solution involve knowledge of intermolecular forces between like and unlike molecules (Figs. 13-2 and 13-3). This approach makes it possible to identify an **ideal solution**, one whose properties can be predicted from properties of the individual solution components. Most solutions are nonideal.

13-4 Solution Formation and Equilibrium—Generally, a solvent has a limited ability to dissolve a solute. A solution containing the maximum amount of solute possible is a **saturated solution**. A solution with less than this maximum amount is an **unsaturated solution**. Under certain conditions a solution can be prepared that contains more solute than a normal saturated solution; such solutions are called **supersaturated**. **Solubility** refers to the concentration of solute in a saturated solution and depends on temperature. Graphs of solute solubility versus temperature (Fig. 13-8) can be used to devise conditions for recovering a pure solute from a solution of several solutes through **fractional crystallization** (**recrystallization**) (Fig. 13-9).

13-5 Solubilities of Gases—The solubilities of gases depend on pressure as well as temperature, and many familiar phenomena are related to gas solubilities. **Henry's law** (equation 13.2) relates the concentration of a gas in solution to its pressure above the solution.

13-6 Vapor Pressures of Solutions—The vapor pressure of a solution depends on the vapor pressures of its pure components. If the solution is ideal, **Raoult's law** (equation 13.3) can be used to calculate the solution vapor pressure. Liquid–vapor equilibrium curves showing either solution vapor pressures (Fig. 13-12) or solution boiling points (Fig. 13-13) as a function of solution composition help us to visualize **fractional distillation**, a common method of separating the volatile components of a solution. Such curves also illustrate the formation of azeotropes in some nonideal solutions. **Azeotropes** are solutions that boil at a constant temperature and produce vapor of the same composition as the liquid; they have boiling points that in some cases are greater than the boiling points of the pure components and in some cases, less (Fig. 13-15).

13-7 Osmotic Pressure—**Osmosis** is the spontaneous flow of solvent through a semipermeable membrane separating two solutions of different concentration. The net flow is from the less to the more concentrated solution (Fig. 13-17). Osmotic flow can be stopped by applying a pressure, called the **osmotic pressure**, to the more concentrated solution. In **reverse osmosis**, the direction of flow is reversed by applying a pressure that exceeds the osmotic pressure to the more concentrated solution. Both osmosis and reverse osmosis have important practical applications. Osmotic pressure can be calculated with a simple relationship (equation 13.4) resembling the ideal gas equation. **Colligative properties** are certain properties that depend only on the concentration of solute particles in a solution, and not on the identity of the solute. Vapor-pressure lowering (Section 13-6) is one such property, and osmotic pressure is another.

13-8 Freezing-Point Depression and Boiling-Point Elevation of Nonelectrolyte Solutions—Freezing-point depression and boiling-point elevation (Fig. 13-19) are colligative properties having many familiar practical applications. For reasonably dilute solutions, their values are proportional to the molality of the solution (equations 13.5 and 13.6). The proportionality constants are K_f and K_b, respectively (Table 13.2). Historically, freezing-point depression was a common method for determining molar masses.

13-9 Solutions of Electrolytes—Calculating colligative properties of electrolyte solutions is more difficult than for solutions of nonelectrolytes. The solute particles in electrolyte solutions are ions or ions and molecules. Calculations using equations (13.5) and (13.6) must be based on the total number of particles present, and the van't Hoff factor is introduced into these equations to reflect this number. In all but the most dilute solutions, composition must be in terms of activities—effective concentrations that take into account interionic forces.

13-10 Colloidal Mixtures—**Colloids** are an important intermediate state between a true solution and a heterogeneous mixture. Colloidal mixtures are responsible for some unusual phenomena (Fig. 13.21) and are encountered in a broad range of contexts, from fluids in living organisms to pollutants in large air masses (Table 13-4).

Integrative Example

A 50.00 g sample of a solution of naphthalene [$C_{10}H_8(s)$] in benzene [$C_6H_6(l)$] has a freezing point of 4.45 °C. Calculate the mass percent $C_{10}H_8$ and the boiling point of this solution.

Analyze

Equation (13.5) relates freezing-point depression to the molality of a solution, but we will have to devise an algebraic method that yields the mass of each solution component and consequently the mass percent composition. The boiling point of the solution can be determined with a minimum of calculation through equation (13.6).

Solve

Substitute data for benzene from Table 13.2 ($K_f = 5.12\ °C\ m^{-1}$, fp = 5.53 °C) and the measured freezing point of the solution into equation (13.5), to obtain

$$\begin{aligned} \Delta T_f &= -K_f \times m \\ (4.45 - 5.53)\ °C &= -5.12\ \text{kg mol}^{-1}\ °C \times m \\ 1.08 &= 5.12\ \text{kg mol}^{-1} \times m \end{aligned}$$

Express the molality of the solution in terms of the masses of naphthalene, x, and benzene, y, and the molar mass, 128.2 g $C_{10}H_8$/mol.

$$m = \frac{\dfrac{x\ \text{g}\ C_{10}H_8}{128.2\ \text{g}\ C_{10}H_8/\text{mol}}}{y\ \text{g}\ C_6H_6 \times 1\ \text{kg}/1000\ \text{g}\ C_6H_6}$$

Because the total mass is 50.00 g, $x + y = 50.00$ and the expression above reduces to

$$m = \frac{\text{moles}\ C_{10}H_8}{\text{kg}\ C_6H_6} = \frac{(x/128.2)}{(50.00 - x)/1000}\ \text{mol kg}^{-1}$$

Now, substituting this expression of m into the expression derived from equation (13.5), we obtain

$$1.08 = 5.12 \times \frac{(x/128.2)}{(50.00 - x)/1000}$$

which we solve for x, the mass of naphthalene in grams.

$$\begin{aligned} \frac{1.08 \times 128.2}{5.12 \times 1000} &= \frac{x}{50.00 - x} \\ 0.0270 &= \frac{x}{50.00 - x} \\ 1.0270x &= 0.0270 \times 50.00 \\ x &= 1.31 \end{aligned}$$

The mass percent naphthalene in the solution is

$$\%C_{10}H_8 = \frac{1.31\ \text{g}\ C_{10}H_8}{50.00\ \text{g soln}} \times 100\% = 2.62\%$$

A simple way to find the boiling point of the solution is to first solve equation (13.5) for the molality of the solution.

$$\text{molality} = \frac{\Delta T_f}{-K_f} = \frac{-1.08\ °C}{-5.12\ °C\ m^{-1}} = 0.211\ m$$

Because the molality at the boiling point is the same as at the freezing point, substitute 0.211 m into equation (13.6) and solve for ΔT_b.

$$\Delta T_b = K_b \times m = 2.53\ °C\ m^{-1} \times 0.211\ m = 0.534\ °C$$

The boiling point of the solution is 0.534 °C higher than the normal boiling point of benzene (80.10 °C), that is,

$$80.10\ °C + 0.53\ °C = 80.63\ °C$$

Assess

The mass of solution can easily be determined to the nearest 0.01 g and expressed with four significant figures. The freezing point of the solution can also be established to the nearest 0.01 °C with good precision. However, the freezing point depression (−1.08 °C), the difference between two numbers of comparable magnitude, is valid only to about one part per hundred. Although significant-figure rules permit three significant figures in the remainder of the calculation, the actual precision of the calculated quantities is still only about one part per hundred. The final estimate of the boiling point (80.63 °C) seems reasonably good since it required expressing ΔT_b only to two significant figures. We assume that the 0.211 m solution is dilute enough and close enough to ideal in behavior to make equations (13.5) and (13.6) applicable.

PRACTICE EXAMPLE A: Water and phenol are completely miscible at temperatures above 66.8 °C but only partially miscible at temperatures below 66.8 °C. In a mixture prepared at 29.6 °C from 50.0 g water and 50.0 g phenol, 32.8 g of a phase consisting of 92.50% water and 7.50% phenol by mass is obtained. This is a saturated solution of phenol in water. What is the mass percent of water in the second phase—a saturated solution of water in phenol? What is the mole fraction of phenol in the mixture at temperatures above 66.8 °C?

PRACTICE EXAMPLE B: At a constant temperature of 25.00 °C, a current of dry air was passed through pure water and then through a drying tube, D_1, followed by passage through 1.00 *m* sucrose and another drying tube, D_2. After the experiment, D_1 had gained 11.7458 g in mass and D_2 had gained 11.5057 g. Given that the vapor pressure of water is 23.76 mmHg at 25.00 °C, **(a)** what was the vapor pressure lowering in the 1.00 *m* sucrose, and **(b)** what was the expected lowering?

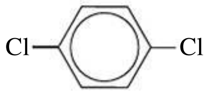
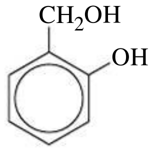
Exercises

Homogeneous and Heterogeneous Mixtures

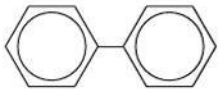
1. Which of the following do you expect to be most water soluble, and why? $C_{10}H_8(s)$, $NH_2OH(s)$, $C_6H_6(l)$, $CaCO_3(s)$.
2. Which of the following is moderately soluble both in water and in benzene [$C_6H_6(l)$], and why? **(a)** 1-butanol, $CH_3(CH_2)_2CH_2OH$; **(b)** naphthalene, $C_{10}H_8$; **(c)** hexane, C_6H_{14}; **(d)** NaCl(s).
3. Substances that dissolve in water generally do not dissolve in benzene. Some substances are moderately soluble in both solvents, however. One of the following is such a substance. Which do you think it is and why?



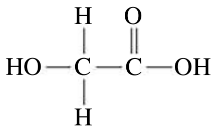
(a) *para*-Dichlorobenzene
(a moth repellent)



(b) Salicyl alcohol
(a local anesthetic)

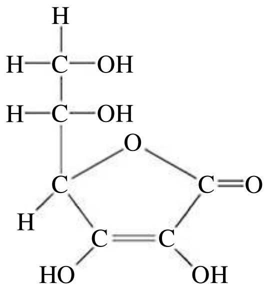


(c) Diphenyl
(a heat transfer agent)

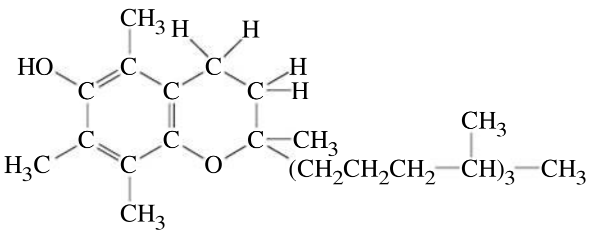


(d) Hydroxyacetic acid
(used in textile dyeing)

4. Some vitamins are water soluble and some are fat soluble. (Fats are substances whose molecules have long hydrocarbon chains.) The structural formulas of two vitamins are shown here—one is water soluble and one is fat soluble. Identify which is which, and explain your reasoning.



Vitamin C



Vitamin E

5. Two of the substances listed here are highly soluble in water, two are only slightly soluble in water, and two are insoluble in water. Indicate the situation you expect for each one.
   (a) iodoform, CHI_3
   (b) benzoic acid,    (c) formic acid,  $H-\overset{\overset{O}{\|}}{C}-OH$
   (d) 1-butanol, $CH_3CH_2CH_2CH_2OH$
   (e) chlorobenzene,    (f) propylene glycol, $CH_3CH(OH)CH_2OH$

6. Benzoic acid, C_6H_5COOH, is much more soluble in NaOH(aq) than it is in pure water. Can you suggest a reason for this? The structural formula for benzoic acid is given in Exercise 5(b).
7. In light of the factors outlined on pages 566–567, which of the following ionic fluorides would you expect to be most water soluble on a moles-per-liter basis: MgF_2, NaF, KF, CaF_2? Explain your reasoning.
8. Explain the observation that all metal nitrates are water soluble but many metal sulfides are not. Among metal sulfides, which would you expect to be most soluble?

Percent Concentration

9. A saturated aqueous solution of NaBr at 20 °C contains 116 g NaBr/100 g H_2O. Express this composition in the more conventional percent by mass, that is, as grams of NaBr per 100 grams of solution.
10. An aqueous solution with density 0.988 g/mL at 20 °C is prepared by dissolving 12.8 mL $CH_3CH_2CH_2OH$ ($d = 0.803$ g/mL) in enough water to produce 75.0 mL of solution. What is the percent $CH_3CH_2CH_2OH$ expressed as **(a)** percent by volume; **(b)** percent by mass; **(c)** percent (mass/volume)?
11. A certain brine has 3.87% NaCl by mass. A 75.0 mL sample weighs 76.9 g. How many liters of this solution should be evaporated to dryness to obtain 725 kg NaCl?
12. You are asked to prepare 125.0 mL of 0.0321 M $AgNO_3$. How many grams would you need of a sample known to be 99.81% $AgNO_3$ by mass?
13. According to Example 13-1, the mass percent ethanol in a particular aqueous solution is less than the volume percent in the same solution. Explain why this is also true for *all* aqueous solutions of ethanol. Would it be true of all ethanol solutions, regardless of the other component? Explain.
14. Blood cholesterol levels are generally expressed as milligrams of cholesterol per deciliter of blood. What is the approximate mass percent cholesterol in a blood sample having a cholesterol level of 176? Why can you not give a more precise answer?
15. A certain vinegar is 6.02% acetic acid (CH_3COOH) by mass. How many grams of CH_3COOH are contained in a 355 mL bottle of vinegar? Assume a density of 1.01 g/mL.
16. 6.00 M sulfuric acid, H_2SO_4(aq), has a density of 1.338 g/mL. What is the percent by mass of sulfuric acid in this solution?
17. The sulfate ion level in a municipal water supply is given as 46.1 ppm. What is $[SO_4^{2-}]$ in this water?
18. A water sample is found to have 9.4 ppb of chloroform, $CHCl_3$. How many grams of $CHCl_3$ would be found in a glassful (250 mL) of this water?

Molarity

19. An aqueous solution is 6.00% methanol (CH_3OH) by mass, with $d = 0.988$ g/mL. What is the molarity of CH_3OH in this solution?
20. A typical commercial grade aqueous phosphoric acid is 75% H_3PO_4 by mass and has a density of 1.57 g/mL. What is the molarity of H_3PO_4 in this solution?
21. How many milliliters of the ethanol–water solution described in Example 13-1 should be diluted with water to produce 825 mL of 0.235 M CH_3CH_2OH?
22. A 30.00%-by-mass solution of nitric acid, HNO_3, in water has a density of 1.18 g/cm^3 at 20 °C. What is the molarity of HNO_3 in this solution?
23. What is the molarity of CO_2 in a liter of ocean water at 25 °C that contains approximately 280 ppm of CO_2? The density of ocean water is 1027 kg/m^3.
24. At 25 °C and 0% salinity the amount of oxygen in the ocean is 5.77 mL/L. What is the molarity of oxygen in the ocean at these conditions?

Molality

25. What is the molality of *para*-dichlorobenzene in a solution prepared by dissolving 2.65 g $C_6H_4Cl_2$ in 50.0 mL benzene ($d = 0.879$ g/mL)?
26. What is the molality of the sulfuric acid solution described in Exercise 16?
27. How many grams of iodine, I_2, must be dissolved in 725 mL of carbon disulfide, CS_2 ($d = 1.261$ g/mL), to produce a 0.236 *m* solution?
28. How many grams of water would you add to 1.00 kg of 1.38 *m* CH_3OH(aq) to reduce the molality to 1.00 *m* CH_3OH?
29. An aqueous solution is 34.0% H_3PO_4 by mass and has a density of 1.209 g/mL. What are the molarity and molality of this solution?
30. A 10.00%-by-mass solution of ethanol, CH_3CH_2OH, in water has a density of 0.9831 g/mL at 15 °C and 0.9804 g/mL at 25 °C. Calculate the molality of the ethanol–water solution at these two temperatures. Does the molality differ at the two temperatures (that is, at 15 and 25 °C)? Would you expect the molarities to differ? Explain.

Mole Fraction, Mole Percent

31. A solution is prepared by mixing 1.28 mol C_7H_{16}, 2.92 mol C_8H_{18}, and 2.64 mol C_9H_{20}. What is the **(a)** mole fraction and **(b)** mole percent of each component of the solution?
32. Calculate the mole fraction of solute in the following aqueous solutions: **(a)** 21.7% CH_3CH_2OH, by mass; **(b)** 0.684 *m* $CO(NH_2)_2$ (urea).

33. Calculate the mole fraction of the solute in the following aqueous solutions: **(a)** 0.112 M $C_6H_{12}O_6$ ($d = 1.006$ g/mL); **(b)** 3.20% ethanol, by volume ($d = 0.993$ g/mL; pure CH_3CH_2OH, $d = 0.789$ g/mL).

34. Refer to Example 13-1. How many grams of CH_3CH_2OH must be added to 100.0 mL of the solution described in part (d) to increase the mole fraction of CH_3CH_2OH to 0.0525?

35. What volume of glycerol, $CH_3CH(OH)CH_2OH$ ($d = 1.26$ g/mL), must be added per kilogram of water to produce a solution with 4.85 mol % glycerol?

36. Two aqueous solutions of sucrose, $C_{12}H_{22}O_{11}$, are mixed. One solution is 0.1487 M $C_{12}H_{22}O_{11}$ and has $d = 1.018$ g/mL; the other is 10.00% $C_{12}H_{22}O_{11}$ by mass and has $d = 1.038$ g/mL. Calculate the mole percent $C_{12}H_{22}O_{11}$ in the mixed solution.

37. The Environmental Protection Agency has a limit of 15 ppm for the amount of lead in drinking water. If a 1.000 mL sample of water at 20 °C contains 15 ppm of lead, how many lead ions are there in this sample of water? What is the mole fraction of lead ion in solution?

38. The amount of CO_2 in the ocean is approximately 280 ppm. What is the mole fraction of CO_2 in a liter of ocean water?

Solubility Equilibrium

39. Refer to Figure 13-8 and determine the molality of NH_4Cl in a saturated aqueous solution at 40 °C.

40. Refer to Figure 13-8 and estimate the temperature at which a saturated aqueous solution of $KClO_4$ is 0.200 *m*.

41. A solution of 20.0 g $KClO_4$ in 500.0 g of water is brought to a temperature of 40 °C.
(a) Refer to Figure 13-8 and determine whether the solution is unsaturated or supersaturated at 40 °C.
(b) Approximately what mass of $KClO_4$, in grams, must be added to saturate the solution (if originally unsaturated), or what mass of $KClO_4$ can be crystallized (if originally supersaturated)?

42. One way to recrystallize a solute from a solution is to change the temperature. Another way is to evaporate solvent from the solution. A 335 g sample of a saturated solution of $KNO_3(s)$ in water is prepared at 25.0 °C. If 55 g H_2O is evaporated from the solution at the same time as the temperature is reduced from 25.0 to 0.0 °C, what mass of $KNO_3(s)$ will recrystallize? (Refer to Figure 13-8.)

Solubility of Gases

43. Under an $O_2(g)$ pressure of 1.00 atm, 28.31 mL of $O_2(g)$ dissolves in 1.00 L H_2O at 25 °C. What will be the molarity of O_2 in the saturated solution at 25 °C when the O_2 pressure is 3.86 atm? (Assume that the solution volume remains at 1.00 L.)

44. Using data from Exercise 43, determine the molarity of O_2 in an aqueous solution at equilibrium with air at normal atmospheric pressure. The volume percent of O_2 in air is 20.95%. [*Hint:* Recall equation (6.17).]

45. Natural gas consists of about 90% methane, CH_4. Assume that the solubility of natural gas at 20 °C and 1 atm gas pressure is about the same as that of CH_4, 0.02 g/kg water. If a sample of natural gas under a pressure of 20 atm is kept in contact with 1.00×10^3 kg of water, what mass of natural gas will dissolve?

46. At 1.00 atm, the solubility of O_2 in water is 2.18×10^{-3} M at 0 °C and 1.26×10^{-3} M at 25 °C. What volume of $O_2(g)$, measured at 25 °C and 1.00 atm, is expelled when 515 mL of water saturated with O_2 is heated from 0 to 25 °C?

47. The aqueous solubility at 20 °C of Ar at 1.00 atm is equivalent to 33.7 mL Ar(g), measured at STP, per liter of water. What is the molarity of Ar in water that is saturated with air at 1.00 atm and 20 °C? Air contains 0.934% Ar by volume. Assume that the volume of water does not change when it becomes saturated with air.

48. The aqueous solubility of CO_2 at 20 °C and 1.00 atm is equivalent to 87.8 mL $CO_2(g)$, measured at STP, per 100 mL of water. What is the molarity of CO_2 in water that is at 20 °C and saturated with air at 1.00 atm? The volume percent of CO_2 in air is 0.0360%. Assume that the volume of the water does not change when it becomes saturated with air.

49. Henry's law can be stated this way: The mass of a gas dissolved by a given quantity of solvent at a fixed temperature is directly proportional to the pressure of the gas. Show how this statement is related to equation (13.2).

50. Another statement of Henry's law is: At a fixed temperature, a given quantity of liquid dissolves the same volume of gas at all pressures. What is the connection between this statement and the one given in Exercise 49? Under what conditions is this second statement not valid?

Raoult's Law and Liquid–Vapor Equilibrium

51. What are the partial and total vapor pressures of a solution obtained by mixing 35.8 g benzene, C_6H_6, and 56.7 g toluene, $C_6H_5CH_3$, at 25 °C? At 25 °C the vapor pressure of $C_6H_6 = 95.1$ mmHg; the vapor pressure of $C_6H_5CH_3 = 28.4$ mmHg.

52. Determine the composition of the vapor above the benzene-toluene solution described in Exercise 51.

53. Calculate the vapor pressure at 25 °C of a solution containing 165 g of the *nonvolatile* solute, glucose, $C_6H_{12}O_6$, in 685 g H_2O. The vapor pressure of water at 25 °C is 23.8 mmHg.

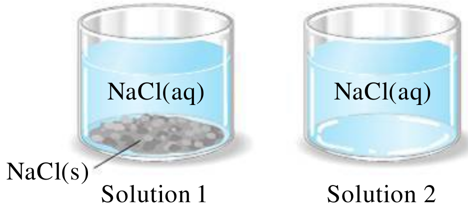
54. Calculate the vapor pressure at 20 °C of a saturated solution of the *nonvolatile* solute, urea, $CO(NH_2)_2$, in methanol, CH_3OH. The solubility is 17 g urea/100 mL methanol. The density of methanol is 0.792 g/mL, and its vapor pressure at 20 °C is 95.7 mmHg.

55. Styrene, used in the manufacture of polystyrene plastics, is made by the extraction of hydrogen atoms from ethylbenzene. The product obtained contains about 38% styrene ($C_6H_5CH{=}CH_2$) and 62% ethylbenzene ($C_6H_5CH_2CH_3$), by mass. The mixture is separated by fractional distillation at 90 °C. Determine the composition of the vapor in equilibrium with this 38%–62% mixture at 90 °C. The vapor pressure of ethylbenzene is 182 mmHg and that of styrene is 134 mmHg.

56. Calculate $x_{C_6H_6}$ in a benzene–toluene liquid solution that is in equilibrium at 25 °C with a vapor phase that contains 62.0 mol % C_6H_6. (Use data from Exercise 51.)

57. A benzene–toluene solution with $x_{benz} = 0.300$ has a normal boiling point of 98.6 °C. The vapor pressure of pure toluene at 98.6 °C is 533 mmHg. What must be the vapor pressure of pure benzene at 98.6 °C? (Assume ideal solution behavior.)

58. The two NaCl(aq) solutions pictured are at the same temperature.



(a) Above which solution is the vapor pressure of water, P_{H_2O}, greater? Explain.
(b) Above one of these solutions, the vapor pressure of water, P_{H_2O}, remains *constant*, even as water evaporates from solution. Which solution is this? Explain.
(c) Which of these solutions has the higher boiling point? Explain.

Osmotic Pressure

59. A 0.72 g sample of polyvinyl chloride (PVC) is dissolved in 250.0 mL of a suitable solvent at 25 °C. The solution has an osmotic pressure of 1.67 mmHg. What is the molar mass of the PVC?

60. Verify that a 20% aqueous solution by mass of sucrose ($C_{12}H_{22}O_{11}$) would rise to a height of about 150 m in an apparatus of the type pictured in Figure 13-17.

61. When the stems of cut flowers are held in concentrated NaCl(aq), the flowers wilt. In a similar solution a fresh cucumber shrivels up (becomes pickled). Explain the basis of these phenomena.

62. Some fish live in saltwater environments and some in freshwater, but in either environment they need water to survive. Saltwater fish drink water, but freshwater fish do not. Explain this difference between the two types of fish.

63. In what volume of water must 1 mol of a nonelectrolyte be dissolved if the solution is to have an osmotic pressure of 1 atm at 273 K? Which of the gas laws does this result resemble?

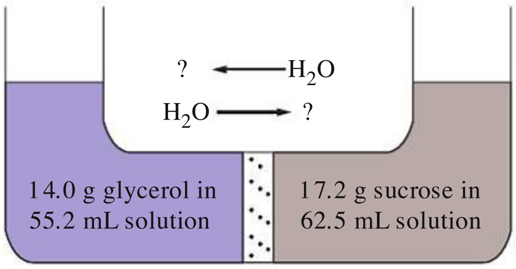
64. The molecular mass of hemoglobin is 6.86×10^4 u. What mass of hemoglobin must be present per 100.0 mL of a solution to exert an osmotic pressure of 7.25 mmHg at 25 °C?

65. At 25 °C a 0.50 g sample of polyisobutylene (a polymer used in synthetic rubber) in 100.0 mL of benzene solution has an osmotic pressure that supports a 5.1 mm column of solution ($d = 0.88$ g/mL). What is the molar mass of the polyisobutylene? (For Hg, $d = 13.6$ g/mL.)

66. Use the concentration of an isotonic saline solution, 0.92% NaCl (mass/ volume), to determine the osmotic pressure of blood at body temperature, 37.0 °C. [*Hint:* Assume that NaCl is completely dissociated in aqueous solutions.]

67. What approximate pressure is required in the reverse osmosis depicted in Figure 13-18 if the saltwater contains 2.5% NaCl, by mass? [*Hint:* Assume that NaCl is completely dissociated in aqueous solutions. Also, assume a temperature of 25 °C.]

68. The two solutions pictured here are separated by a semipermeable membrane that permits only the passage of water molecules. In what direction will a net flow of water occur, that is, from left to right or right to left? Glycerol is $HOCH_2CH(OH)CH_2OH$; sucrose is $C_{12}H_{22}O_{11}$.



? ← H_2O
H_2O → ?
14.0 g glycerol in 55.2 mL solution
17.2 g sucrose in 62.5 mL solution

Freezing-Point Depression and Boiling-Point Elevation

69. 1.10 g of an unknown compound reduces the freezing point of 75.22 g benzene from 5.53 to 4.92 °C. What is the molar mass of the compound?

70. The freezing point of a 0.010 *m* aqueous solution of a nonvolatile solute is −0.072 °C. What would you expect the normal boiling point of this same solution to be?

71. Adding 1.00 g of benzene, C_6H_6, to 80.00 g cyclohexane, C_6H_{12}, lowers the freezing point of the cyclohexane from 6.5 to 3.3 °C.
(a) What is the value of K_f for cyclohexane?
(b) Which is the better solvent for molar mass determinations by freezing-point depression, benzene or cyclohexane? Explain.

72. The boiling point of water at 749.2 mmHg is 99.60 °C. What mass percent sucrose ($C_{12}H_{22}O_{11}$) should be present in an aqueous sucrose solution to raise the boiling point to 100.00 °C at this pressure?

73. A compound is 42.9% C, 2.4% H, 16.7% N, and 38.1% O, by mass. Addition of 6.45 g of this compound to 50.0 mL benzene, C_6H_6 ($d = 0.879$ g/mL), lowers the freezing point from 5.53 to 1.37 °C. What is the molecular formula of this compound?

74. Nicotinamide is a water-soluble vitamin important in metabolism. A deficiency in this vitamin results in the debilitating condition known as pellagra. Nicotinamide is 59.0% C, 5.0% H, 22.9% N, 13.1% O, by mass. Addition of 3.88 g of nicotinamide to 30.0 mL nitrobenzene, $C_6H_5NO_2$ ($d = 1.204$ g/mL), lowers the freezing point from 5.7 to −1.4 °C. What is the molecular formula of this compound?

75. Thiophene (fp = −38.3; bp = 84.4 °C) is a sulfur-containing hydrocarbon sometimes used as a solvent in place of benzene. Combustion of a 2.348 g sample of thiophene produces 4.913 g CO_2, 1.005 g H_2O, and 1.788 g SO_2. When a 0.867 g sample of thiophene is dissolved in 44.56 g of benzene (C_6H_6), the freezing point is lowered by 1.183 °C. What is the molecular formula of thiophene?

76. Coniferin is a glycoside (a derivative of a sugar) found in conifers, such as fir trees. When a 1.205 g sample of coniferin is subjected to combustion analysis (recall Section 3-3), the products are 0.698 g H_2O and 2.479 g CO_2. A 2.216 g sample is dissolved in 48.68 g H_2O, and the normal boiling point of this solution is found to be 100.068 °C. What is the molecular formula of coniferin?

77. Cooks often add some salt to water before boiling it. Some people say this helps the cooking process by raising the boiling point of the water. Others say not enough salt is usually added to make any noticeable difference. Approximately how many grams of NaCl must be added to a liter of water at 1 atm pressure to raise the boiling point by 2 °C? Is this a typical amount of salt that you might add to cooking water?

78. An important test for the purity of an organic compound is to measure its melting point. Usually, if the compound is not pure, it begins to melt at a *lower* temperature than the pure compound.
(a) Why is this the case, rather than the melting point being higher in some cases and lower in others?
(b) Are there any conditions under which the melting point of the impure compound is *higher* than that of the pure compound? Explain.

79. The freezing point of Arctic Ocean waters is about −1.94 °C. What is the molality of ions for a liter of ocean water?

80. If ocean water consisted of 3.5% salt, what would be the freezing point of an ocean?

Strong Electrolytes, Weak Electrolytes, and Nonelectrolytes

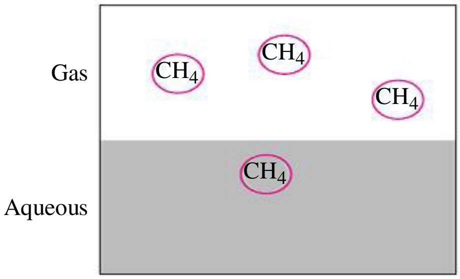
81. Predict the approximate freezing points of 0.10 *m* solutions of the following solutes dissolved in water: **(a)** $CO(NH_2)_2$ (urea); **(b)** NH_4NO_3; **(c)** HCl; **(d)** $CaCl_2$; **(e)** $MgSO_4$; **(f)** C_2H_5OH (ethanol); **(g)** $HC_2H_3O_2$ (acetic acid).

82. Calculate the van't Hoff factors of the following weak electrolyte solutions:
(a) 0.050 *m* $HCHO_2$, which begins to freeze at −0.0986 °C;
(b) 0.100 M HNO_2, which has a hydrogen ion (and nitrite ion) concentration of 6.91×10^{-3} M.

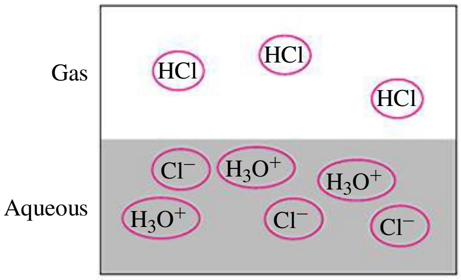
83. $NH_3(aq)$ conducts electric current only weakly. The same is true for acetic acid, $HC_2H_3O_2(aq)$. When these solutions are mixed, however, the resulting solution conducts electric current very well. Propose an explanation.

84. An isotonic solution is described as 0.92% NaCl (mass/volume). Would this also be the required concentration for isotonic solutions of other salts, such as KCl, $MgCl_2$, or $MgSO_4$? Explain.

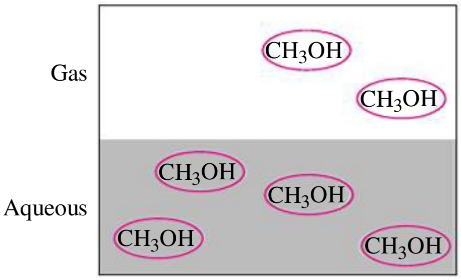
85. In the following diagrams, which representation demonstrates a weak electrolyte?



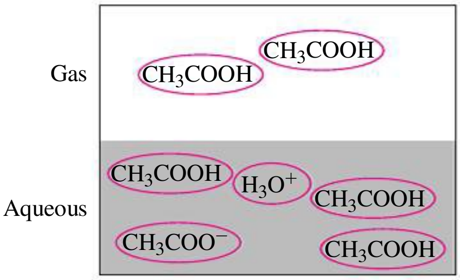
(a)



(b)

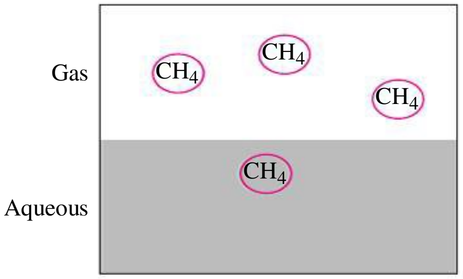


(c)

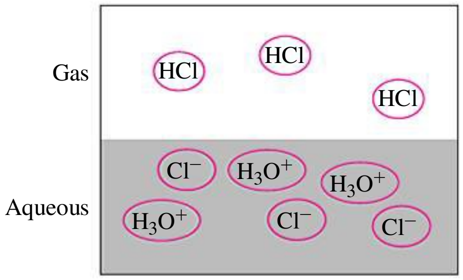


(d)

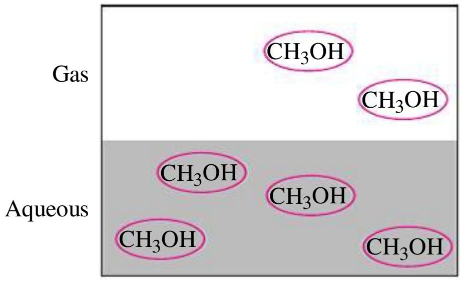
86. In the following diagrams, which representation demonstrates a strong electrolyte?



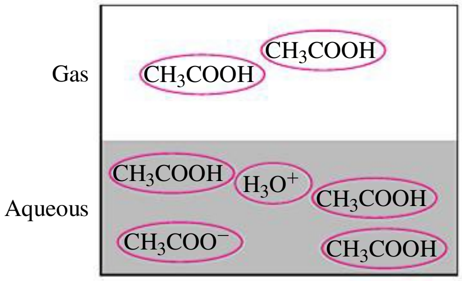
(a)



(b)



(c)



(d)

Integrative and Advanced Exercises

87. A typical root beer contains 0.13% of a 75% H_3PO_4 solution by mass. How many milligrams of phosphorus are contained in a 12 oz can of this root beer? Assume a solution density of 1.00 g/mL; also, 1 oz = 29.6 mL.

88. An aqueous solution has 109.2 g KOH/L solution. The solution density is 1.09 g/mL. Your task is to use 100.0 mL of this solution to prepare 0.250 *m* KOH. What mass of which component, KOH or H_2O, would you add to the 100.0 mL of solution?

89. The term "proof," still used to describe the ethanol content of alcoholic beverages, originated in seventeenth-century England. A sample of whiskey was poured on gunpowder and set afire. If the gunpowder ignited after the whiskey had burned off, this "proved" that the whiskey had not been watered down. The minimum ethanol content for a positive test was about 50%, by volume. The 50% ethanol solution became known as "100 proof." Thus, an 80-proof whiskey would be 40% CH_3CH_2OH by volume. Listed in the table below are some data for several aqueous solutions of ethanol. *With a minimum amount of calculation*, determine which of the solutions are more than 100 proof. Assume that the density of pure ethanol is 0.79 g/mL.

Molarity of Ethanol, *M*	Density of Solution, g/mL
4.00	0.970
5.00	0.963
6.00	0.955
7.00	0.947
8.00	0.936
9.00	0.926
10.00	0.913

90. Four aqueous solutions of acetone, CH_3COCH_3, are prepared at different concentrations: **(a)** 0.100% CH_3COCH_3, by mass; **(b)** 0.100 M CH_3COCH_3; **(c)** 0.100 *m* CH_3COCH_3; and **(d)** $\chi_{\text{acetone}} = 0.100$. Estimate the highest partial pressure of water at 25 °C to be found in the equilibrium vapor above these solutions. Also, estimate the lowest freezing point to be found among these solutions.

91. A solid mixture consists of 85.0% KNO_3 and 15.0% K_2SO_4, by mass. A 60.0 g sample of this solid is added to 130.0 g of water at 60 °C. Refer to Figure 13-8.

(a) Will all the solid dissolve at 60 °C?

(b) If the resulting solution is cooled to 0 °C, what mass of KNO_3 should crystallize?

(c) Will K_2SO_4 also crystallize at 0 °C?

92. Suppose you have available 2.50 L of a solution ($d = 0.9767$ g/mL) that is 13.8% ethanol (CH_3CH_2OH), by mass. From this solution you would like to make the *maximum* quantity of ethanol-water antifreeze solution that will offer protection to −2.0 °C. Would you add more ethanol or more water to the solution? What mass of liquid would you add?

93. Hydrogen chloride is a colorless gas, yet when a bottle of concentrated hydrochloric acid [HCl(conc aq)] is opened, mist-like fumes are often seen to escape from the bottle. How do you account for this?

94. Use the following information to confirm that the triple point temperature of water is about 0.0098 °C.

(a) The slope of the fusion curve of water in the region of the normal melting point of ice (Fig. 12-30) is −0.00750 °C/atm.

(b) The solubility of air in water at STP is 0.02918 mL of air per mL of water.

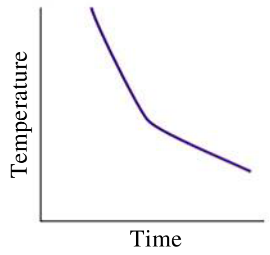
95. Stearic acid ($C_{18}H_{36}O_2$) and palmitic acid ($C_{16}H_{32}O_2$) are common fatty acids. Commercial grades of stearic acid usually contain palmitic acid as well. A 1.115 g sample of a commercial-grade stearic acid is dissolved in 50.00 mL benzene ($d = 0.879$ g/mL). The freezing point of the solution is found to be 5.072 °C. The freezing point of pure benzene is 5.533 °C, and K_f for benzene is 5.12 °C m^{-1}. What is the mass percent of palmitic acid in the stearic acid sample?

96. Nitrobenzene, $C_6H_5NO_2$, and benzene, C_6H_6, are completely miscible in each other. Other properties of the two liquids are *nitrobenzene:* fp = 5.7 °C, K_f = 8.1 °C m^{-1}; *benzene:* fp = 5.5 °C, K_f = 5.12 °C m^{-1}. It is possible to prepare *two different* solutions with these two liquids having a freezing point of 0.0 °C. What are the compositions of these two solutions, expressed as mass percent nitrobenzene?

97. Refer to Figure 13-16(a). Initially, solution A contains 0.515 g urea, $CO(NH_2)_2$, dissolved in 92.5 g H_2O; solution B contains 2.50 g sucrose, $C_{12}H_{22}O_{11}$, dissolved in 85.0 g H_2O. What are the compositions of the two solutions when equilibrium is reached, that is, when the two have the same vapor pressure?

98. In Figure 13-17, why does the net transfer of water stop when the two solutions are of *nearly* equal concentrations rather than of *exactly* equal concentrations?

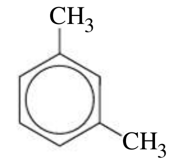
99. Shown below is a typical cooling curve for an aqueous solution. Why is there no straight-line portion comparable to that seen in the cooling curve for pure water in Figure 12-23?

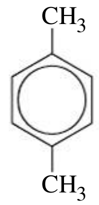


100. Suppose that 1.00 mg of gold is obtained in a colloidal dispersion in which the gold particles are spherical, with a radius of 1.00×10^2 nm. (The density of gold is 19.3 g/cm^3.)
(a) What is the total surface area of the particles?
(b) What is the surface area of a single cube of gold of mass 1.00 mg?

101. At 20 °C, liquid benzene has a density of 0.879 g/cm^3; liquid toluene, 0.867 g/cm^3. Assume ideal solutions.
(a) Calculate the densities of solutions containing 20, 40, 60, and 80 volume percent benzene.
(b) Plot a graph of density versus volume percent composition.
(c) Write an equation that relates the density (d) to the volume percent benzene (V) in benzene-toluene solutions at 20 °C.

102. The two compounds whose structures are depicted here are isomers. When derived from petroleum, they always occur mixed together. *meta*-Xylene is used in aviation fuels and in the manufacture of dyes and insecticides. The principal use of *para*-xylene is in the manufacture of polyester resins and fibers (for example, Dacron). Comment on the effectiveness of fractional distillation as a method of separating these two xylenes. What other method(s) might be used to separate them?





meta-xylene	*para*-xylene
fp, 47.9 °C	fp, 13.3 °C
bp, 139.1 °C	bp, 138.4 °C
d, 0.864 g/mL	*d*, 0.861 g/mL

103. Instructions on a container of antifreeze (ethylene glycol; fp, −12.6 °C, bp, 197.3 °C) give the following volumes of Prestone to be used in protecting a 12 qt cooling system against freeze-up at different temperatures (the remaining liquid is water): 10 °F, 3 qt; 0 °F, 4 qt; −15 °F, 5 qt; −34 °F, 6 qt. Since the freezing point of the coolant is successively lowered by using more antifreeze, why not use even more than 6 qt of antifreeze (and proportionately less water) to ensure the maximum protection against freezing?

104. Demonstrate that
(a) for a *dilute aqueous* solution, the numerical value of the molality is essentially equal to that of the molarity.
(b) in a *dilute* solution, the solute mole fraction is proportional to the molality.
(c) in a *dilute aqueous* solution, the solute mole fraction is proportional to the molarity.

105. At 25 °C and under an $O_2(g)$ pressure of 1 atm, the solubility of $O_2(g)$ in water is 28.31 mL/1.00 L H_2O. At 25 °C and under an $N_2(g)$ pressure of 1 atm, the solubility of $N_2(g)$ in water is 14.34 mL/1.00 L H_2O. The composition of the atmosphere is 78.08% N_2 and 20.95% O_2, by volume. What is the composition of air dissolved in water expressed as volume percents of N_2 and O_2?

106. We noted in Figure 13-13 that the liquid and vapor curves taken together outline a lens-shaped region when the normal boiling points of benzene-toluene solutions are plotted as a function of mole fraction of benzene. That is, unlike Figure 13-12, the liquid curve is not a straight line. Use data from Figure 13-13 and show by calculation that this should be the case.

107. A saturated solution prepared at 70 °C contains 32.0 g $CuSO_4$ per 100.0 g solution. A 335 g sample of this solution is then cooled to 0 °C and $CuSO_4 \cdot 5\,H_2O$ crystallizes out. If the concentration of a saturated solution at 0 °C is 12.5 g $CuSO_4$/100 g soln, what mass of $CuSO_4 \cdot 5\,H_2O$ would be obtained? [*Hint:* Note that the solution composition is stated in terms of $CuSO_4$ and that the solid that crystallizes is the hydrate $CuSO_4 \cdot 5\,H_2O$.]

108. The concentration of Ar in the ocean at 25 °C is 11.5 μM. The Henry's law constant for Ar is 1.5×10^{-3} mol L^{-1} atm^{-1}. Calculate the mass of Ar in a liter of ocean water. Calculate the partial pressure of Ar in the atmosphere.

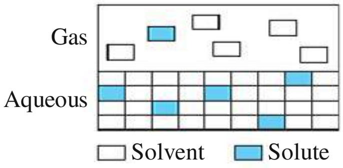
109. The concentration of N_2 in the ocean at 25 °C is 445 μM. The Henry's law constant for N_2 is 0.61×10^{-3} mol L^{-1} atm^{-1}. Calculate the mass of N_2 in a liter of ocean water. Calculate the partial pressure of N_2 in the atmosphere.

110. A solution contains 750 g of ethanol and 85.0 g of sucrose (180 g mol^{-1}). The volume of the solution is 810.0 mL. Determine

(a) the density of the solution
(b) the percent of sucrose in the solution
(c) the mole fraction of sucrose
(d) the molality of the solution
(e) the molarity of the solution

111. What volume of ethylene glycol ($HOCH_2CH_2OH$, density $= 1.12$ g mL^{-1}) must be added to 20.0 L of water ($K_f = 1.86$ °C/m) to produce a solution that freezes at -10 °C?

112. In the figure below, the open squares represent solvent molecules and the filled squares represent solute molecules.



(a) What is the mole fraction of solute in the liquid phase?
(b) Which component has the higher vapor pressure?
(c) What is the percent solute in the vapor?

Feature Problems

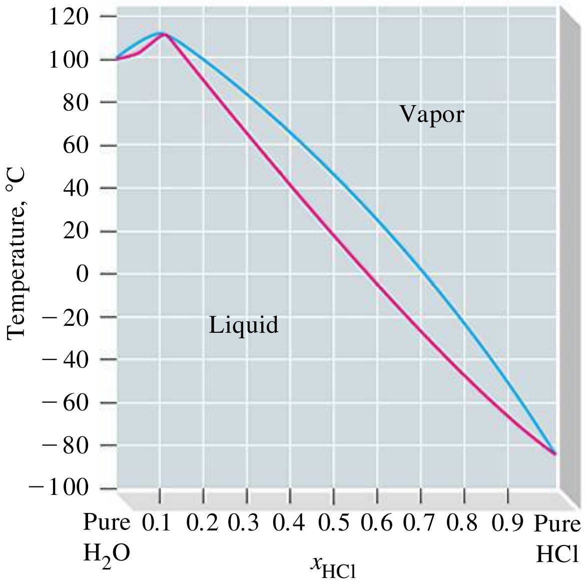
113. Cinnamaldehyde is the chief constituent of cinnamon oil, which is obtained from the twigs and leaves of cinnamon trees grown in tropical regions. Cinnamon oil is used in the manufacture of food flavorings, perfumes, and cosmetics. The normal boiling point of cinnamaldehyde, $C_6H_5CH{=}CHCHO$, is 246.0 °C, but at this temperature it begins to decompose. As a result, cinnamaldehyde cannot be easily purified by ordinary distillation. A method that can be used instead is *steam distillation*. A heterogeneous mixture of cinnamaldehyde and water is heated until the sum of the vapor pressures of the two liquids is equal to barometric pressure. At this point, the temperature remains constant as the liquids vaporize. The mixed vapor condenses to produce two immiscible liquids; one liquid is essentially pure water and the other, pure cinnamaldehyde. The following vapor pressures of cinnamaldehyde are given: 1 mmHg at 76.1 °C; 5 mmHg at 105.8 °C; and 10 mmHg at 120.0 °C. Vapor pressures of water are given in Table 13.2.

(a) What is the approximate temperature at which the steam distillation occurs?

(b) The proportions of the two liquids condensed from the vapor is *independent* of the composition of the boiling mixture, as long as both liquids are present in the boiling mixture. Explain why this is so.

(c) Which of the two liquids, water or cinnamaldehyde, condenses in the greater quantity, by mass? Explain.

114. The phase diagram shown is for mixtures of HCl and H_2O at a pressure of 1 atm. The red curve represents the normal boiling points of solutions of HCl(aq) of various mole fractions. The blue curve represents the compositions of the vapors in equilibrium with boiling solutions.



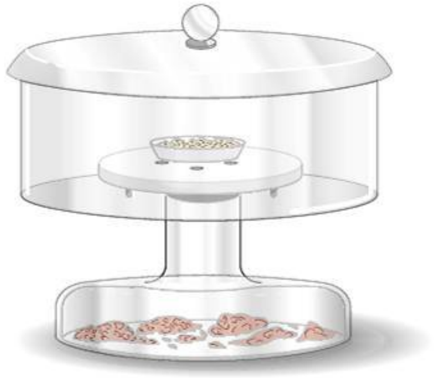
(a) As a solution containing $x_{HCl} = 0.50$ begins to boil, will the vapor have a mole fraction of HCl equal to, less than, or greater than 0.50? Explain.

(b) In the boiling of a pure liquid, there is no change in composition. However, as a solution of HCl(aq) boils in an open container, the composition changes. Explain why this is so.

(c) One particular solution (the azeotrope) is an exception to the observation stated in part (b); that is, its composition remains *unchanged* during boiling. What are the approximate composition and boiling point of this solution?

(d) A 5.00 mL sample of the azeotrope ($d =$ 1.099 g/mL) requires 30.32 mL of 1.006 M NaOH for its titration in an acid-base reaction. Use these data to determine a more precise value of the composition of the azeotrope, expressed as the mole fraction of HCl.

115. The laboratory device pictured on the following page is called a *desiccator*. It can be used to maintain a constant relative humidity within an enclosure. The material(s) used to control the relative humidity are placed in the bottom compartment, and the substance being subjected to a controlled relative humidity is placed on the platform in the container.



(a) If the material in the bottom compartment is a saturated solution of NaCl(aq) in contact with NaCl(s), what will be the approximate relative humidity in the container at a temperature of 20 °C? Obtain the solubility of NaCl from Figure 13-8 and vapor pressure data for water from Table 12.4; use the definition of Raoult's law from page 573 and that of relative humidity from Focus On 6: Earth's Atmosphere; assume that the NaCl is completely dissociated into its ions.
(b) If the material placed on the platform is dry $CaCl_2 \cdot 6\,H_2O(s)$, will the solid deliquesce? Explain. [*Hint:* Recall the discussion on pages 577–578.]
(c) To maintain $CaCl_2 \cdot 6\,H_2O(s)$ in the dry state in a desiccator, should the substance in the saturated solution in the bottom compartment be one with a high or a low water solubility? Explain.

116. Every year, oral rehydration therapy (ORT)—the feeding of an electrolyte solution—saves the lives of countless children worldwide who become severely dehydrated as a result of diarrhea. One requirement of the solution used is that it be *isotonic* with human blood.
(a) One definition of an isotonic solution given in the text is that it have the same osmotic pressure as 0.92% NaCl(aq) (mass/volume). Another definition is that the solution have a freezing point of −0.52 °C. Show that these two definitions are in reasonably close agreement given that we are using solution concentrations rather than activities.
(b) Use the freezing-point definition from part (a) to show that an ORT solution containing 3.5 g NaCl, 1.5 g KCl, 2.9 g $Na_3C_6H_5O_7$ (sodium citrate), and 20.0 g $C_6H_{12}O_6$ (glucose) per liter meets the requirement of being isotonic. [*Hint:* Which of the solutes are nonelectrolytes, and which are strong electrolytes?]

Self-Assessment Exercises

117. In your own words, define or explain the following terms or symbols: **(a)** x_B; **(b)** P°_A; **(c)** K_f; **(d)** i; **(e)** activity.

118. Briefly describe each of the following ideas or phenomena: **(a)** Henry's law; **(b)** freezing-point depression; **(c)** recrystallization; **(d)** hydrated ion; **(e)** deliquescence.

119. Explain the important distinctions between each pair of terms: **(a)** molality and molarity; **(b)** ideal and nonideal solution; **(c)** unsaturated and supersaturated solution; **(d)** fractional crystallization and fractional distillation; **(e)** osmosis and reverse osmosis.

120. An aqueous solution is 0.010 M CH_3OH. The concentration of this solution is also very nearly **(a)** 0.010% CH_3OH (mass/volume); **(b)** 0.010 m CH_3OH; **(c)** $x_{CH_3OH} = 0.010$; **(d)** 0.990 M H_2O.

121. The most likely of the following mixtures to be an ideal solution is **(a)** $NaCl{-}H_2O$; **(b)** $CH_3CH_2OH{-}C_6H_6$; **(c)** $C_7H_{16}{-}H_2O$; **(d)** $C_7H_{16}{-}C_8H_{18}$.

122. The solubility of a nonreactive gas in water increases with **(a)** an increase in gas pressure; **(b)** an increase in temperature; **(c)** increases in both temperature and pressure; **(d)** an increase in the volume of gas in equilibrium with the available water.

123. Of the following aqueous solutions, the one with the lowest freezing point is **(a)** 0.010 m $MgSO_4$; **(b)** 0.011 m NaCl; **(c)** 0.018 m CH_3CH_2OH; **(d)** 0.0080 m $MgCl_2$.

124. An ideal liquid solution has two volatile components. In the vapor in equilibrium with the solution, the mole fractions of the components are **(a)** both 0.50; **(b)** equal, but not necessarily 0.50; **(c)** not very likely to be equal; **(d)** 1.00 for the solvent and 0.00 for the solute.

125. A solution prepared by dissolving 1.12 mol NH_4Cl in 150.0 g H_2O is brought to a temperature of 30 °C. Use Figure 13-8 to determine whether the solution is unsaturated or whether excess solute will crystallize.

126. NaCl(aq) isotonic with blood is 0.92% NaCl (mass/volume). For this solution, what is **(a)** $[Na^+]$; **(b)** the total molarity of ions; **(c)** the osmotic pressure at 37 °C; **(d)** the approximate freezing point? (Assume that the solution has a density of 1.005 g/mL.)

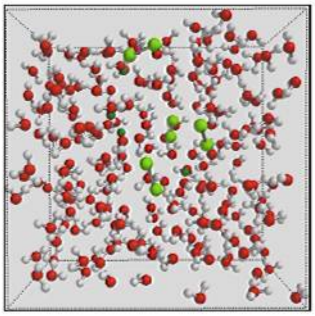
127. A solution ($d = 1.159$ g/mL) is 62.0% glycerol, $HOCH_2CH(OH)CH_2OH$, and 38.0% H_2O, by mass. Determine **(a)** the molarity of glycerol with H_2O as the solvent; **(b)** the molarity of H_2O with glycerol as the solvent; **(c)** the molality of H_2O in glycerol; **(d)** the mole fraction of glycerol; **(e)** the mole percent of H_2O.

128. Which aqueous solution from the column on the right has the property listed on the left? Explain your choices.

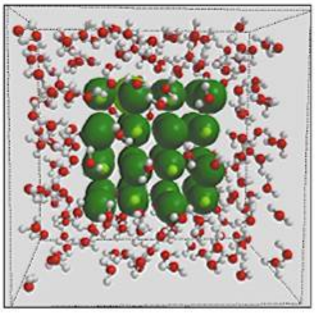
Property	Solution
1. lowest electrical conductivity	**a.** 0.10 m KCl(aq)
2. lowest boiling point	**b.** 0.15 m $C_{12}H_{22}O_{11}(aq)$
3. highest vapor pressure of water at 25 °C	**c.** 0.10 m $CH_3COOH(aq)$
4. lowest freezing point	**d.** 0.05 m NaCl

129. Which of the following represents $MgCl_2$ in solution?

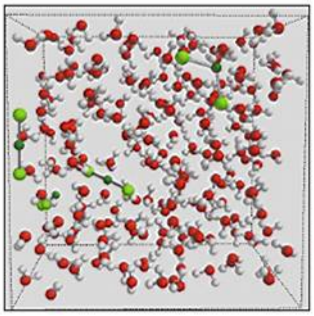
(a)



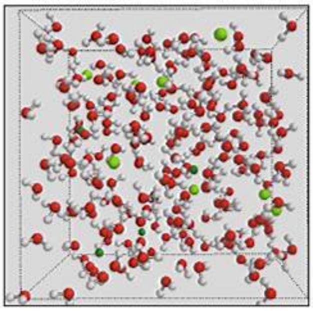
(b)



(c)



(d)



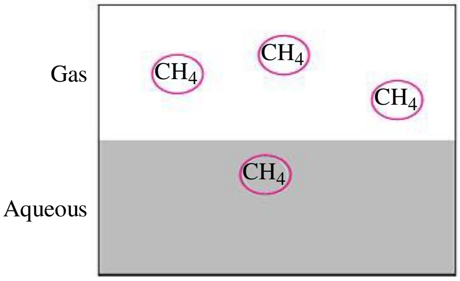
Legend: O ● H ● Cl ● Mg ●

130. Which of the following ions has the greater charge density? **(a)** Na^+; **(b)** F^-; **(c)** K^+; **(d)** Cl^-.

131. When NH_4Cl dissolves in a test tube of water, the test tube becomes colder. Is the magnitude of $\Delta H_{lattice}$ for NH_4Cl larger or smaller than the sum of $\Delta H_{hydration}$ of the ions?

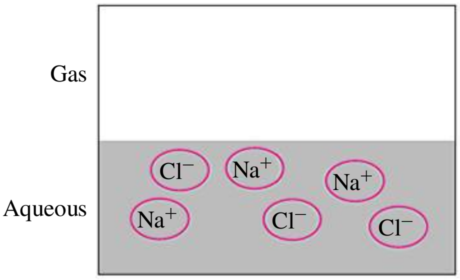
132. In a saturated solution at 25 °C and 1 bar, for the following solutes, which condition will increase solubility? **(a)** Ar(g), decrease temperature; **(b)** NaCl(s), increase pressure; **(c)** N_2, decrease pressure; **(d)** CO_2, increase volume.

133. Which of the following represents a nonvolatile solute?



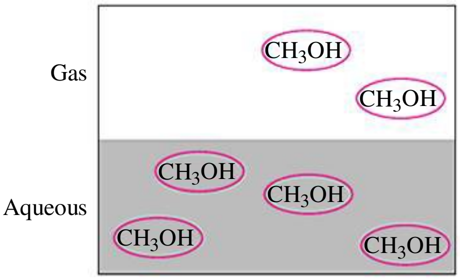
Gas
CH4
CH4
CH4
Aqueous
CH4

(a)



Gas
Aqueous
Cl−
Na+
Na+
Na+
Cl−
Cl−

(b)



Gas
CH3OH
CH3OH
Aqueous
CH3OH
CH3OH
CH3OH

Although stable at room temperature, ammonium dichromate decomposes very rapidly once ignited:

$$(NH_4)_2Cr_2O_7(s) \xrightarrow{\Delta} N_2(g) + 4H_2O(g) + Cr_2O_3(s)$$

The rates of chemical reactions and the effect of temperature on those rates are among several key concepts explored in this chapter.

Rocket fuel is designed to give a rapid release of gaseous products and energy to provide a rocket maximum thrust. Milk is stored in a refrigerator to slow down the chemical reactions that cause it to spoil. Current strategies to reduce the rate of deterioration of the ozone layer try to deprive the ozone-consuming reaction cycle of key intermediates that come from chlorofluorocarbons (CFCs). Catalysts are used to reduce the harmful emissions from internal combustion engines that contribute to smog. These examples illustrate the importance of the rates of chemical reactions. Moreover, how fast a reaction occurs depends on the reaction mechanism—the step-by-step molecular pathway leading from reactants to products. Thus, *chemical kinetics* concerns how rates of chemical reactions are measured, how they can be predicted, and how reaction-rate data are used to deduce probable reaction mechanisms.

The chapter begins with a discussion of the meaning of a rate of reaction and some ideas about measuring rates of reaction. This is followed by the introduction of mathematical equations, called rate laws, that relate the rates of reactions to the concentrations of the reactants. Finally, with this information as background, rate laws are related to plausible reaction mechanisms, which are a central focus of this chapter.

14-1 The Rate of a Chemical Reaction

Rate, or speed, refers to something that happens in a unit of time. A car traveling at 60 mph, for example, covers a distance of 60 miles in one hour. For chemical reactions, the rate of reaction describes how fast the concentration of a reactant or product changes with time.

To illustrate, let's consider the reaction that begins immediately after the ions Fe^{3+} and Sn^{2+} are simultaneously introduced into water.

$$2\,Fe^{3+}(aq) + Sn^{2+}(aq) \longrightarrow 2\,Fe^{2+}(aq) + Sn^{4+}(aq) \qquad \textbf{(14.1)}$$

Suppose that 38.5 s after the reaction starts, $[Fe^{2+}]$ is found to be 0.0010 M. During the period of time, $\Delta t = 38.5\,\text{s}$, the *change* in concentration of Fe^{2+}, which we can designate as $\Delta[Fe^{2+}]$, is $\Delta[Fe^{2+}] = 0.0010\,\text{M} - 0 = 0.0010\,\text{M}$. The *average* rate at which Fe^{2+} is formed in this interval is the change in concentration of Fe^{2+} divided by the change in time.

◀ Recall that the symbol [ ] means "concentration." Also, Δ means "the change in," that is, the final value minus the initial value.

$$\text{rate of formation of } Fe^{2+} = \frac{\Delta[Fe^{2+}]}{\Delta t} = \frac{0.0010\,\text{M}}{38.5\,\text{s}} = 2.6 \times 10^{-5}\,\text{M s}^{-1}$$

How has the concentration of Sn^{4+} changed during the 38.5 s we were monitoring the Fe^{2+}? Can you see that in 38.5 s, $\Delta[Sn^{4+}]$ will be $0.00050\,\text{M} - 0 = 0.00050\,\text{M}$? Because only *one* Sn^{4+} ion is produced for every *two* Fe^{2+} ions, the buildup of $[Sn^{4+}]$ will be only one-half that of $[Fe^{2+}]$. Consequently the rate of formation of Sn^{4+} is

$$\text{rate of formation of } Sn^{4+} = \frac{0.00050\,\text{M}}{38.5\,\text{s}} = 1.3 \times 10^{-5}\,\text{M s}^{-1}$$

We can also follow the course of the reaction by monitoring the concentrations of the starting reactants. Thus, the amount of Fe^{3+} consumed is the same as the amount of Fe^{2+} produced. The *change* in concentration of Fe^{3+} is $\Delta[Fe^{3+}] = -0.0010\,\text{M}$. Thus,

$$\frac{\Delta[Fe^{3+}]}{\Delta t} = \frac{-0.0010\,\text{M}}{38.5\,\text{s}} = -2.6 \times 10^{-5}\,\text{M s}^{-1}$$

The quantity above is the average rate of change of change of $[Fe^{3+}]$ in this interval. It is a negative quantity because $[Fe^{3+}]$ decreases with time. The average rate of disappearance of Fe^{3+} is defined as follows.

$$\text{rate of disappearance of } Fe^{3+} = -\frac{\Delta[Fe^{3+}]}{\Delta t} = 2.6 \times 10^{-5}\,\text{M s}^{-1}$$

Why is a negative sign incorporated into the definition of rate in this case? It is because the term "rate of disappearance" implies that $[Fe^{3+}]$ decreases with time. When told the rate of disappearance of Fe^{3+} is $2.6 \times 10^{-5}\,\text{M s}^{-1}$, we know the rate of change of *concentration* must be $-2.6 \times 10^{-5}\,\text{M s}^{-1}$.

In the same way that we related the rate of formation of Sn^{4+} to that of Fe^{2+}, we can relate the rate of disappearance of Sn^{2+} to that of Fe^{3+}. That is, the rate of disappearance of Sn^{2+} is half that of Fe^{3+}, giving

$$\text{rate of disappearance of } Sn^{2+} = -1.3 \times 10^{-5}\,\text{M s}^{-1}$$

When we refer to the rate of reaction (14.1), which of the four quantities described here should we use? To avoid confusion in this matter, the International Union of Pure and Applied Chemistry (IUPAC) recommends that we use a *general* rate of reaction, which, for the hypothetical reaction represented by the balanced equation,

$$aA + bB \longrightarrow gG + hH$$

is

$$\text{rate of reaction} = -\frac{1}{a}\frac{\Delta[A]}{\Delta t} = -\frac{1}{b}\frac{\Delta[B]}{\Delta t} = \frac{1}{g}\frac{\Delta[G]}{\Delta t} = \frac{1}{h}\frac{\Delta[H]}{\Delta t} \tag{14.2}$$

In this expression, we take the negative value of $\Delta[X]/\Delta t$, when X refers to a reactant to ensure that the **rate of reaction** is a positive quantity. To obtain a single, positive quantity it is necessary to divide all rates by the appropriate stoichiometric coefficients. If we apply this expression to reaction (14.1), we obtain

$$\text{rate of reaction} = -\frac{1}{2}\frac{\Delta[Fe^{3+}]}{\Delta t} = -\frac{\Delta[Sn^{2+}]}{\Delta t}$$

$$= \frac{1}{2}\frac{\Delta[Fe^{2+}]}{\Delta t} = \frac{\Delta[Sn^{4+}]}{\Delta t} = 1.3 \times 10^{-5}\,\text{M s}^{-1}$$

EXAMPLE 14-1 Expressing the Rate of a Reaction

Suppose that at some point in the reaction

$$A + 3B \longrightarrow 2C + 2D$$

$[B] = 0.9986$ M, and that 13.20 min later $[B] = 0.9746$ M. What is the average rate of reaction during this time period, expressed in M s^{-1}?

Analyze

This is a straightforward application of the definition of reaction rate, expression (14.2). To formulate the rate, we use $\Delta[B] = 0.9746\text{ M} - 0.9986\text{ M} = -0.0240$ M and $\Delta t = 13.20$ min.

Solve

The solution is

$$\text{average rate of reaction} = -\frac{1}{3}\frac{\Delta[B]}{\Delta t} = -\frac{1}{3} \times \frac{-0.0240\text{ M}}{13.20\text{ min}} = 6.06 \times 10^{-4}\,\text{M min}$$

To express the rate of reaction in moles per liter per second, we must convert from min^{-1} to s^{-1}. We can do this with the conversion factor 1 min/60 s.

$$\text{rate of reaction} = 6.06 \times 10^{-4}\,\text{M min}^{-1} \times \frac{1\text{ min}}{60\text{ s}} = 1.01 \times 10^{-5}\,\text{M s}^{-1}$$

Alternatively, we could have converted 13.20 min to 792 s and used $\Delta t = 792$ s in evaluating the rate of reaction.

Assess

By monitoring changes in concentration over a time period, we can obtain the average rate of reaction. Remember that the rate of reaction can be defined in terms of any reactant or product.

PRACTICE EXAMPLE A: At some point in the reaction $2A + B \longrightarrow C + D$, $[A] = 0.3629$ M. At a time 8.25 min later $[A] = 0.3187$ M. What is the average rate of reaction during this time interval, expressed in M s^{-1}?

PRACTICE EXAMPLE B: In the reaction $2A \longrightarrow 3B$, $[A]$ drops from 0.5684 M to 0.5522 M in 2.50 min. What is the average rate of formation of B during this time interval, expressed in M s^{-1}?

14-1 CONCEPT ASSESSMENT

In the reaction of gaseous nitrogen and hydrogen to form gaseous ammonia, what are the relative rates of disappearance of the two reactants? How is the rate of formation of the product related to the rates of disappearance of the reactants?

14-2 Measuring Reaction Rates

To determine a rate of reaction, we need to measure changes in concentration over time. A change in time can be measured with a stopwatch or other timing device, but how do we measure concentration changes during a chemical reaction? Also, why is the *term average* used in referring to a rate of reaction? These are two of the questions that are answered in this section.

KEEP IN MIND

that according to expression (14.2), the rate of this reaction can be expressed either as rate of disappearance of H_2O_2 or 2 × rate of formation of $O_2(g)$.

Following a Chemical Reaction

A 3% aqueous solution of hydrogen peroxide is a common antiseptic. Its antiseptic action results from the release of $O_2(g)$ as the H_2O_2 decomposes. $O_2(g)$ escapes from the $H_2O_2(aq)$, and ultimately the reaction goes to completion.*

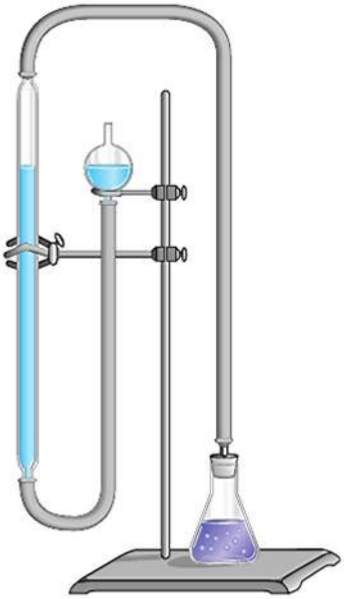
$$H_2O_2(aq) \longrightarrow H_2O(l) + \frac{1}{2}O_2(g) \qquad \textbf{(14.3)}$$

We can follow the progress of the reaction by focusing either on the formation of $O_2(g)$ or on the disappearance of H_2O_2. For example, we can

- Measure the volumes of $O_2(g)$ produced at different times and relate these volumes to decreases in concentration of H_2O_2 (Fig. 14-1).
- Remove small samples of the reaction mixture from time to time, and analyze these samples for their H_2O_2 content. One way to do this is by titration with $KMnO_4$ in acidic solution. The net ionic equation for this oxidation–reduction reaction is

$$2\,MnO_4^-(aq) + 5\,H_2O_2(aq) + 6\,H^+(aq) \longrightarrow 2\,Mn^{2+}(aq) + 8\,H_2O(l) + 5\,O_2(g) \qquad \textbf{(14.4)}$$

Table 14.1 lists typical data for the decomposition of H_2O_2, and Figure 14-2 displays comparable data graphically.



▲ FIGURE 14-1
Experimental setup for determining the rate of decomposition of H_2O_2
Oxygen gas given off by the reaction mixture is trapped, and its volume is measured in the gas buret. The amount of H_2O_2 consumed and the remaining concentration of H_2O_2 can be calculated from the measured volume of $O_2(g)$.

Rate of Reaction Expressed as Concentration Change over Time

Some data extracted from Figure 14-2 are listed in Table 14.2 (in blue). Column III lists the molarities of H_2O_2 at the times shown in column I. Column II lists the *arbitrary* time interval between data points—400 s. Column IV reports the concentration changes that occur for each 400 s interval. The rates of reaction, expressed as the rate of disappearance of H_2O_2, are shown in column V. The data show that the reaction rate is not constant—the lower the remaining concentration of H_2O_2, the more slowly the reaction proceeds.

Rate of Reaction Expressed as the Slope of a Tangent Line

When the rate of reaction is expressed as $-\Delta[H_2O_2]/\Delta t$, the result is an *average* value for the time interval Δt. For example, in the interval from 1200 to 1600 s, the rate averages $6.3 \times 10^{-4}\ M\ s^{-1}$ (fourth entry in column V of Table 14.2). This can be thought of as the reaction rate at about the middle of the interval—1400 s. We could just as well have chosen $\Delta t = 200$ s in Table 14.2. In this case, to obtain the rate of reaction at $t = 1400$ s, we would use concentration data at $t = 1300$ s and $t = 1500$ s. The rate of reaction would be slightly less than $6.3 \times 10^{-4}\ M\ s^{-1}$. The smaller the time interval used, the closer the result is to the actual rate at $t = 1400$ s. As Δt approaches 0 s, the rate of reaction approaches the *negative*

TABLE 14.1
Decomposition of H_2O_2

Time, s	$[H_2O_2]$, M
0	2.32
200	2.01
400	1.72
600	1.49
1200	0.98
1800	0.62
3000	0.25

---

*Although reaction (14.3) goes to completion, it does so very slowly. Generally, a catalyst is used to speed up the reaction. We describe the catalysis in this reaction in Section 14-11. When $H_2O_2(aq)$ is applied to an open wound, the enzyme catalase in blood catalyzes its decomposition.

▶ FIGURE 14-2
Graphical representation of kinetic data for the reaction:

$$H_2O_2(aq) \longrightarrow H_2O(l) + \frac{1}{2}O_2(g)$$

This is the usual form in which concentration–time data are plotted. Reaction rates are determined from the slopes of the tangent lines. The blue line has a slope of $-1.70\,M/2800\,s = -6.1 \times 10^{-4}\,M\,s^{-1}$. The slope of the black line and its relation to the initial rate of reaction are described in Example 14-2.

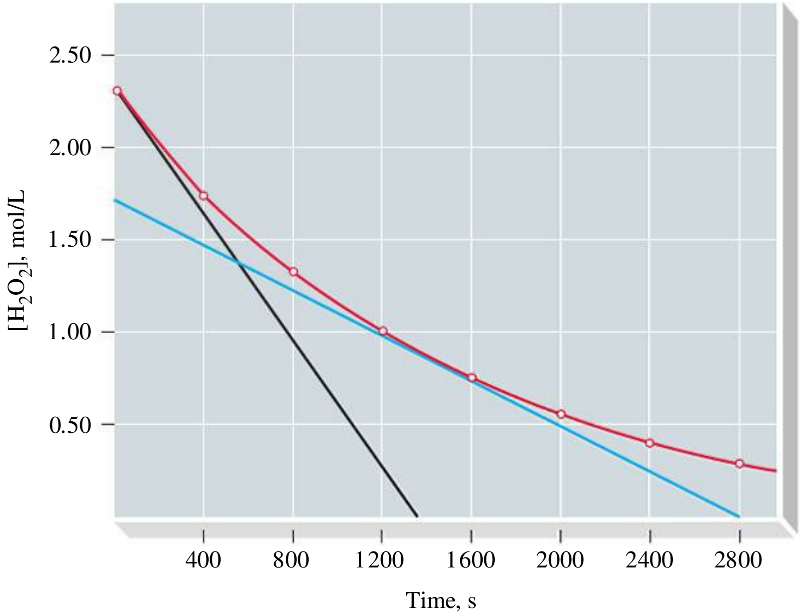


TABLE 14.2 Decomposition of H_2O_2—Derived Rate Data

I	II	III	IV	V
Time, s	Δt, s	$[H_2O_2]$, M	$\Delta[H_2O_2]$, M	Reaction Rate $-\Delta[H_2O_2]/\Delta t$, $M\,s^{-1}$
0		2.32		
	400		−0.60	15.0×10^{-4}
400		1.72		
	400		−0.42	10.5×10^{-4}

2800		0.28		

of the slope of the tangent line to the curve of Figure 14-2. The rate of reaction determined from the slope of a tangent line to a concentration–time curve is the **instantaneous rate of reaction** at the point where the tangent line touches the curve. The best estimate of the rate of reaction of H_2O_2 at 1400 s, then, is obtained as follows from the slope of the blue tangent line in Figure 14-2: $-(-6.1 \times 10^{-4}\,M\,s^{-1}) = 6.1 \times 10^{-4}\,M\,s^{-1}$.

To better understand the difference between average and instantaneous reaction rates, think of taking a 108 mi highway trip in 2.00 h. The *average* speed is 54.0 mph. The *instantaneous* speed is the speedometer reading at any instant.

▶ Your instantaneous speed can result in a speeding ticket even if the average speed never exceeds the speed limit.

14-1 ARE YOU WONDERING...

How to differentiate between the average rate of reaction and the instantaneous rate?

If you are familiar with differential calculus, you probably know the answer. If the rate of reaction (14.3) is written as

$$\lim_{\Delta t \longrightarrow 0} \frac{-\Delta[\mathrm{H_2O_2}]}{\Delta t}$$

the delta quantities can be replaced by the differentials $-d[\mathrm{H_2O_2}]$ and dt, leading to the expression

$$\frac{-d[\mathrm{H_2O_2}]}{dt}$$

Thus, the delta notation (not taken to the limit of $\Delta t \longrightarrow 0$) signifies an *average* rate and the differential notation, an *instantaneous* rate.

Initial Rate of Reaction

Sometimes we simply want to find the rate of reaction when the reactants are first brought together—the **initial rate of reaction**. This rate can be obtained from the tangent line to the concentration-time curve at $t = 0$. An alternative way is to measure the concentration of the chosen reactant as soon as possible after mixing, in this way obtaining $\Delta[\text{reactant}]$ for a very short time interval (Δt) at essentially $t = 0$. These two approaches give the same result if the time interval used is limited to that in which the tangent line and the concentration-time curve practically coincide. In Figure 14-2 this condition occurs for about the first 200 s.

EXAMPLE 14-2 Determining and Using an Initial Rate of Reaction

From the data in Table 14.1 and Figure 14-2 for the decomposition of $\mathrm{H_2O_2}$, determine **(a)** the initial rate of reaction, and **(b)** $[\mathrm{H_2O_2}]_t$ at $t = 100$ s, assuming that the initial rate is constant for at least 100 s.

Analyze

To determine the initial rate of reaction from the slope of the tangent line in part **(a)**, we use the intersection of the black tangent line with the axis. In part **(b)** we will assume that the rate determined in **(a)** remains essentially constant for at least 100 s.

Solve

(a) $t = 0, [\mathrm{H_2O_2}] = 2.32\ \mathrm{M}; t = 1360\ \mathrm{s}, [\mathrm{H_2O_2}] = 0.$

$$\text{initial rate of reaction} = -(\text{slope of tangent line}) = \frac{-(0 - 2.32)\ \mathrm{M}}{(1360 - 0)\ \mathrm{s}}$$

$$= 1.71 \times 10^{-3}\ \mathrm{M\ s^{-1}}$$

An alternative method is to use data from Table 14.1: $[\mathrm{H_2O_2}] = 2.32\ \mathrm{M}$ at $t = 0$ and $[\mathrm{H_2O_2}] = 2.01\ \mathrm{M}$ at $t = 200$ s.

$$\text{initial rate} = \frac{-\Delta[\mathrm{H_2O_2}]}{\Delta t} = \frac{-(2.01 - 2.32)\ \mathrm{M}}{200\ \mathrm{s}}$$

$$= 1.6 \times 10^{-3}\ \mathrm{M\ s^{-1}}$$

(continued)

(b) Since

$$\text{rate of reaction} = \frac{-\Delta[H_2O_2]}{\Delta t}$$

then

$$1.71 \times 10^{-3}\,\text{M s}^{-1} = \frac{-\Delta[H_2O_2]}{100\,\text{s}}$$

$$-(1.71 \times 10^{-3}\,\text{M s}^{-1})(100\,\text{s}) = \Delta[H_2O_2] = [H_2O_2]_t - [H_2O_2]_0$$

$$-1.71 \times 10^{-1}\,\text{M} = [H_2O_2]_t - 2.32\,\text{M}$$

$$[H_2O_2]_t = 2.32\,\text{M} - 0.17\,\text{M} = 2.15\,\text{M}$$

Assess

In part **(a)** the agreement between the two methods is fairly good, although it might be better if the time interval were shorter than 200 s. Of the two results, the one based on the tangent line is presumably more precise because it is expressed with more significant figures. However, the reliability of the tangent line depends on how carefully the tangent line is constructed. Another reason for favoring a graphical method is that it tends to minimize the effect of errors that may be found in individual data points. In part **(b)** if we had used initial rate $= 1.6 \times 10^{-3}\,\text{M s}^{-1}$, we would have calculated $[H_2O_2]_t = 2.16$ M.

PRACTICE EXAMPLE A: For reaction (14.3), determine **(a)** the *instantaneous* rate of reaction at 2400 s and **(b)** $[H_2O_2]$ at 2450 s. [*Hint:* Assume that the instantaneous rate of reaction at 2400 s holds constant for the next 50 s.]

PRACTICE EXAMPLE B: Use data *only* from Table 14.2 to determine $[H_2O_2]$ at $t = 100$ s. Compare this value with the one calculated in Example 14-2(b). Explain the reason for the difference.

14-2 CONCEPT ASSESSMENT

As shown later in the chapter, for certain reactions the initial and instantaneous rates of reaction are equal throughout the course of the reaction. What must be the shape of the concentration–time graph for such a reaction?

14-3 Effect of Concentration on Reaction Rates: The Rate Law

▶ Most rate laws are obtained experimentally and are empirical.

One of the goals in a chemical kinetics study is to derive an equation that can be used to predict the relationship between the rate of reaction and the concentrations of reactants. Such an experimentally determined equation is called a **rate law**, or **rate equation**.

Consider the hypothetical reaction

$$aA + bB \cdots \longrightarrow gG + hH \cdots \qquad \textbf{(14.5)}$$

where $a, b, \ldots$ stand for coefficients in the balanced equation. We can often express the rate of such a reaction as*

$$\text{rate of reaction} = k[A]^m[B]^n \cdots \qquad \textbf{(14.6)}$$

▶ The exponents in the rate law are not necessarily equal to the stoichiometric coefficients in the chemical equation. In addition, the value of k varies with temperature even though it is called a rate *constant*.

The terms $[A], [B], \ldots$ represent reactant molarities. The required exponents, $m, n, \ldots$ are generally small, positive whole numbers, although in some cases

---

*We assume that reaction (14.5) goes to completion. If it is reversible, the rate equation is more complex than (14.6). Even for reversible reactions, though, equation (14.6) applies to the *initial* rate of reaction because in the early stages of the reaction there are not enough products for a significant reverse reaction to occur.

they may be zero, fractional, or negative. They must be determined by experiment and are generally *not* related to stoichiometric coefficients $a, b, \ldots$. That is, often $m \neq a$, $n \neq b$, and so on.

The term *order* is related to the exponents in the rate law and is used in two ways: (1) If $m = 1$, we say that the reaction is *first order in A*. If $n = 2$, the reaction is *second order in B*, and so on. (2) The *overall* **order of reaction** is the sum of all the exponents: $m + n + \cdots$. The proportionality constant k relates the rate of reaction to reactant concentrations and is called the **rate constant** of the reaction. Its value depends on the specific reaction, the presence of a catalyst (if any), and the temperature. *The larger the value of k, the faster a reaction goes.* The order of the reaction establishes the general form of the rate law and the appropriate units of k (that is, depending on the values of the exponents).

◀ A common misconception is that rate and k are the same. As equation (14.6) clearly shows, rate $\neq k$ in general. The rate k is one of the factors affecting the rate of reaction but not the only one.

With the rate law for a reaction, we can

- calculate rates of reaction for known concentrations of reactants
- derive an equation that expresses a reactant concentration as a function of time

But how do we establish the rate law? We need to use *experimental* data of the type described in Section 14-2. The method we describe next works especially well.

Method of Initial Rates

As its name implies, this method requires us to work with *initial* rates of reaction. As an example, let's look at a specific reaction: that between mercury(II) chloride and oxalate ion.

$$2\,\mathrm{HgCl_2(aq)} + \mathrm{C_2O_4{}^{2-}(aq)} \longrightarrow 2\,\mathrm{Cl^-(aq)} + 2\,\mathrm{CO_2(g)} + \mathrm{Hg_2Cl_2(s)} \qquad \textbf{(14.7)}$$

The tentative rate law that we can write for this reaction is

$$\text{rate of reaction} = k[\mathrm{HgCl_2}]^m[\mathrm{C_2O_4{}^{2-}}]^n \qquad \textbf{(14.8)}$$

We can follow the reaction by measuring the quantity of $\mathrm{Hg_2Cl_2(s)}$ formed as a function of time. Some representative data are given in Table 14.3, which we can assume are based on either the rate of formation of $\mathrm{Hg_2Cl_2}$ or the rate of disappearance of $\mathrm{C_2O_4{}^{2-}}$. In Example 14-3, we will use some of these data to illustrate the method of initial rates.

TABLE 14.3 Kinetic Data for the Reaction: $2\,\mathrm{HgCl_2} + \mathrm{C_2O_4{}^{2-}} \longrightarrow 2\,\mathrm{Cl^-} + 2\,\mathrm{CO_2} + \mathrm{Hg_2Cl_2}$

Experiment	$[\mathrm{HgCl_2}]$, M	$[\mathrm{C_2O_4{}^{2-}}]$, M	Initial Rate, M min^{-1}
1	$[\mathrm{HgCl_2}]_1 = 0.105$	$[\mathrm{C_2O_4{}^{2-}}]_1 = 0.15$	$R_1 = 1.8 \times 10^{-5}$
2	$[\mathrm{HgCl_2}]_2 = 0.105$	$[\mathrm{C_2O_4{}^{2-}}]_2 = 0.30$	$R_2 = 7.1 \times 10^{-5}$
3	$[\mathrm{HgCl_2}]_3 = 0.052$	$[\mathrm{C_2O_4{}^{2-}}]_3 = 0.30$	$R_3 = 3.5 \times 10^{-5}$

EXAMPLE 14-3 Establishing the Order of a Reaction by the Method of Initial Rates

Use data from Table 14.3 to establish the order of reaction (14.7) with respect to $\mathrm{HgCl_2}$ and $\mathrm{C_2O_4{}^{2-}}$ and also the overall order of the reaction.

Analyze

We need to determine the values of m and n in equation (14.8). In comparing Experiment 2 with Experiment 3, note that $[\mathrm{HgCl_2}]$ is essentially doubled $(0.105\,\mathrm{M} \approx 2 \times 0.052\,\mathrm{M})$ while $[\mathrm{C_2O_4{}^{2-}}]$ is held constant (at 0.30 M). Note also that $R_2 = 2 \times R_3\,(7.1 \times 10^{-5} \approx 2 \times 3.5 \times 10^{-5})$. Rather than use the actual concentrations and rates in the following rate equation, let's work initially with their symbolic equivalents.

(continued)

Solve

We begin by writing

$$R_2 = k \times [\mathrm{HgCl_2}]_2^m \times [\mathrm{C_2O_4}^{2-}]_2^n = k \times (2 \times [\mathrm{HgCl_2}]_3)^m \times [\mathrm{C_2O_4}^{2-}]_3^n$$

$$R_3 = k \times [\mathrm{HgCl_2}]_3^m \times [\mathrm{C_2O_4}^{2-}]_3^n$$

$$\frac{R_2}{R_3} = \frac{2 \times \cancel{R_3}}{\cancel{R_3}} = 2 = \frac{\cancel{k} \times 2^m \times \cancel{[\mathrm{HgCl_2}]_3^m} \times \cancel{[\mathrm{C_2O_4}^{2-}]_3^n}}{\cancel{k} \times \cancel{[\mathrm{HgCl_2}]_3^m} \times \cancel{[\mathrm{C_2O_4}^{2-}]_3^n}} = 2^m$$

In order that $2^m = 2$, $m = 1$.

To determine the value of n, we can form the ratio R_2/R_1. Now, $[\mathrm{C_2O_4}^{2-}]$ is doubled and $[\mathrm{HgCl_2}]$ is held constant. This time, let's use actual concentrations instead of symbolic equivalents. Also, we now have the value $m = 1$.

$$R_2 = k \times [\mathrm{HgCl_2}]_2^1 \times [\mathrm{C_2O_4}^{2-}]_2^n = k \times (0.105)^1 \times (2 \times 0.15)^n$$

$$R_1 = k \times [\mathrm{HgCl_2}]_1^1 \times [\mathrm{C_2O_4}^{2-}]_1^n = k \times (0.105)^1 \times (0.15)^n$$

$$\frac{R_2}{R_1} = \frac{7.1 \times 10^{-5}}{1.8 \times 10^{-5}} \approx 4 = \frac{\cancel{k} \times \cancel{(0.105)^1} \times 2^n \times \cancel{(0.15)^n}}{\cancel{k} \times \cancel{(0.105)^1} \times \cancel{(0.15)^n}} = 2^n$$

In order that $2^n = 4$, $n = 2$.

Assess

In summary, the reaction is *first* order in $\mathrm{HgCl_2}$ $(m = 1)$, *second* order in $\mathrm{C_2O_4}^{2-}$ $(n = 2)$, and *third* order overall $(m + n = 1 + 2 = 3)$. In this example we found n by solving the equation $2^n = 4$. In some cases we may need to solve equations containing a noninteger number, such as in $2^n = 1.4143$. To solve this kind of equation, we take the logarithm of both sides, for example, $\log(2^n) = \log(1.4143)$, and rearrange to get $n = \log(1.4143)/\log(2)$. The answer is $n = 0.5$. Consult Appendix A-2 if you are unfamiliar with logarithms.

PRACTICE EXAMPLE A: The decomposition of $\mathrm{N_2O_5}$ is given by the following equation:

$$2\,\mathrm{N_2O_5} \longrightarrow 4\,\mathrm{NO_2} + \mathrm{O_2}$$

At an initial $[\mathrm{N_2O_5}] = 3.15$ M, the initial rate of reaction $= 5.45 \times 10^{-5}\ \mathrm{M\,s^{-1}}$, and when $[\mathrm{N_2O_5}] = 0.78$ M, the initial rate of reaction $= 1.35 \times 10^{-5}\ \mathrm{M\,s^{-1}}$. Determine the order of this decomposition reaction.

PRACTICE EXAMPLE B: Consider a hypothetical Experiment 4 in Table 14.3, in which the initial conditions are $[\mathrm{HgCl_2}]_4 = 0.025$ M and $[\mathrm{C_2O_4}^{2-}]_4 = 0.045$ M. Predict the initial rate of reaction.

We made an important observation in Example 14-3: If a reaction is *first order* in one of the reactants, doubling the initial concentration of that reactant causes the initial rate of reaction to double. Following is the general effect of *doubling* the initial concentration of a particular reactant (with other reactant concentrations held constant).

▶ Note that rates that are too fast for traditional methods of analysis are followed by spectroscopic methods.

- *Zero order* in the reactant—there is *no effect* on the initial rate of reaction.
- *First order* in the reactant—the initial rate of reaction *doubles*.
- *Second order* in the reactant—the initial rate of reaction *quadruples*.
- *Third order* in the reactant—the initial rate of reaction *increases eightfold*.

As previously mentioned, the order of a reaction, as indicated through the rate law, establishes the units of the rate constant, k. That is, if on the left side of the rate law the rate of reaction has the units $\mathrm{M(time)^{-1}}$, on the right side, the units of k must provide for the cancellations that also lead to $\mathrm{M(time)^{-1}}$. Thus, for the rate law established in Example 14-3,

$$\begin{array}{lccccccc} \textit{rate law:} & \text{rate of reaction} & = & k & \times & [\mathrm{HgCl_2}] & \times & [\mathrm{C_2O_4}^{2-}]^2 \\ \textit{units:} & \mathrm{M\,min^{-1}} & & \mathrm{M^{-2}\,min^{-1}} & & \mathrm{M} & & \mathrm{M^2} \end{array}$$

Once we have the exponents in a rate equation, we can determine the value of the rate constant, k. To do this, all we need is the rate of reaction corresponding to known initial concentrations of reactants, as illustrated in Example 14-4.

EXAMPLE 14-4 Using the Rate Law

Use the results of Example 14-3 and data from Table 14.3 to establish the value of k in the rate law (14.8).

Analyze

We can use data from any one of the three experiments of Table 14.3, together with the values $m = 1$ and $n = 2$.

Solve

First, we solve equation (14.8) for k.

$$k = \frac{R_1}{[\mathrm{HgCl_2}][\mathrm{C_2O_4}^{2-}]^2} = \frac{1.8 \times 10^{-5}\ \mathrm{M\ min^{-1}}}{0.105\ \mathrm{M} \times (0.15)^2\ \mathrm{M}^2}$$
$$= 7.6 \times 10^{-3}\ \mathrm{M^{-2}\ min^{-1}}$$

Assess

If the rate data in Table 14.3 were based on the disappearance of $HgCl_2$ instead of $C_2O_4^{2-}$, R_1 in this setup would be twice as great and k for the general rate of reaction would be based on $-\frac{1}{2} \times \Delta[\mathrm{HgCl_2}]/\Delta t$. Note the units on the rate constant are $\mathrm{M^{-2}\ min^{-1}}$, which are appropriate units for a third-order rate constant. Checking the units in an answer is one way to ensure that we have not made any mistakes.

PRACTICE EXAMPLE A: A reaction has the rate law: rate $= k[\mathrm{A}]^2[\mathrm{B}]$. When $[\mathrm{A}] = 1.12\ \mathrm{M}$ and $[\mathrm{B}] = 0.87\ \mathrm{M}$, the rate of reaction $= 4.78 \times 10^{-2}\ \mathrm{M\ s^{-1}}$. What is the value of the rate constant, k?

PRACTICE EXAMPLE B: What is the rate of reaction (14.7) at the point where $[\mathrm{HgCl_2}] = 0.050\ \mathrm{M}$ and $[\mathrm{C_2O_4}^{2-}] = 0.025\ \mathrm{M}$?

14-3 CONCEPT ASSESSMENT

The rate of decomposition of gaseous acetaldehyde, CH_3CHO, to gaseous methane and carbon monoxide is found to increase by a factor of 2.83 when the initial concentration of acetaldehyde is doubled. What is the order of this reaction?

14-4 Zero-Order Reactions

An overall **zero-order reaction** has a rate law in which the sum of the exponents, $m + n \cdots$, is equal to 0. As an example, let's take a reaction in which a single reactant A decomposes to products.

$$\mathrm{A} \longrightarrow \text{products}$$

If the reaction is zero order, the rate law is

$$\text{rate of reaction} = k[\mathrm{A}]^0 = k = \text{constant} \qquad \textbf{(14.9)}$$

Other features of this zero-order reaction are

- The concentration–time graph is a straight line with a *negative* slope (Fig. 14-3).
- The rate of reaction, which is equal to k and remains constant throughout the reaction, is the *negative* of the slope of this line.
- The units of k are the same as the units of the rate of a reaction: mol $\mathrm{L^{-1}\ (time)^{-1}}$, for example, $\mathrm{mol\ L^{-1}\ s^{-1}}$ or $\mathrm{M\ s^{-1}}$.

Equation (14.9) is the rate law for a zero-order reaction. Another useful equation, called an **integrated rate law**, expresses the concentration of a reactant as

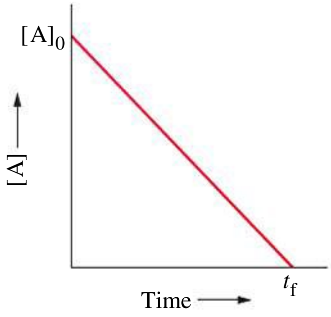
▶ The dependence of k on temperature is discussed in Section 14-9.

14-2 ARE YOU WONDERING...

About the difference between the rate of a reaction and the rate *constant* of a reaction?

Many students have difficulty with this distinction. Remember, a *rate of reaction* tells how the amount of a reactant or product changes with time and is usually expressed as moles per liter per time. A rate of reaction can be established through an expression of the type $-\Delta[\mathrm{A}]/\Delta t$, from a tangent to a concentration–time curve, and by calculation from a rate law. In most cases, the rate of a reaction strongly depends on reactant concentrations and therefore changes continuously during a reaction.

The *rate constant* of a reaction (k) relates the rate of a reaction to reactant concentrations. Generally, it is not itself a rate of reaction, but it can be used it to calculate rates of reaction. Once the value of k at a given temperature has been established, *this value stays fixed* for the given reaction, regardless of the reactant concentrations. Whereas the units of rates of reaction do not depend on the order of a reaction, those of k do, as we shall see in this and the following two sections.



▲ FIGURE 14-3
A zero-order reaction: A ⟶ products
The initial concentration of the reactant A is $[\mathrm{A}]_0$, that is, $[\mathrm{A}] = [\mathrm{A}]_0$ at $t = 0$. $[\mathrm{A}]$ decreases in concentration until the reaction stops. This occurs at the time, t_f, where $[\mathrm{A}] = 0$. The slope of the line is

$$\frac{(0 - [\mathrm{A}]_0)}{(t_\mathrm{f} - 0)} = -\frac{[\mathrm{A}]_0}{t_\mathrm{f}}.$$

The rate constant is the *negative* of the slope:

$$k = -\mathrm{slope} = \frac{[\mathrm{A}]_0}{t_\mathrm{f}}.$$

a function of time. This equation can be established rather easily from the graph in Figure 14-3. Let's start with the general equation for a straight line

$$y = mx + b$$

and substitute $y = [\mathrm{A}]_t$ (the concentration of A at some time t); $x = t$ (time); $b = [\mathrm{A}]_0$ (the initial concentration of A at time $t = 0$); and $m = -k$ (m, the slope of the straight line, is obtained as indicated in the caption to Figure 14-3).

$$[\mathrm{A}]_t = -kt + [\mathrm{A}]_0 \qquad \textbf{(14.10)}$$

▶ Perhaps the most important examples of zero-order reactions are found in the action of enzymes. Enzyme-catalyzed reactions are discussed in Section 14-11.

14-3 ARE YOU WONDERING...

If the term "integrated" rate law has anything to do with integral calculus?

Not surprisingly, it does. The rate of reaction in a rate law, such as (14.9), is an *instantaneous* rate, which we learned in Are You Wondering 14-1 can be represented through differentials. When $-d[\mathrm{A}]/dt$ is substituted for the rate of reaction in the rate law for a zero-order reaction, we get this equation, $-d[\mathrm{A}]/dt = k$. We can separate the differentials to obtain $d[\mathrm{A}] = -k dt$. At this point we can apply the calculus procedure of integration to obtain, successively, the following expressions. The final one is the integrated rate law for a zero-order reaction (14.10).

$$\int_{[\mathrm{A}]_0}^{[\mathrm{A}]_t} d[\mathrm{A}] = -k\int_0^t dt, \qquad [\mathrm{A}]_t - [\mathrm{A}]_0 = -kt, \qquad [\mathrm{A}]_t = -kt + [\mathrm{A}]_0 \quad \textbf{(14.10)}$$

14-5 First-Order Reactions

An overall **first-order reaction** has a rate law in which the sum of the exponents, $m + n + \cdots$, is equal to 1. A particularly common type of first-order reaction, and the only type we will consider, is one in which a single reactant decomposes into products. Reaction (14.3), the decomposition of H_2O_2 that we described in Section 14-2, is a first-order reaction.

$$H_2O_2(aq) \longrightarrow H_2O(l) + \frac{1}{2}O_2(g)$$

The rate of reaction depends on the concentration of H_2O_2 raised to the *first* power, that is,

$$\text{rate of reaction} = k[H_2O_2] \qquad \textbf{(14.11)}$$

It is easy to establish that reaction (14.3) is first order by the method of initial rates, but there are also other ways of recognizing a first-order reaction.

An Integrated Rate Law for a First-Order Reaction

Let us begin our discussion of first-order reactions as we did zero-order reactions, by examining a hypothetical reaction

$$A \longrightarrow \text{products}$$

for which the rate law is

$$\text{rate of reaction} = -\frac{\Delta[A]}{\Delta t} = k[A] \qquad \textbf{(14.12)}$$

◀ Most processes in nature follow first-order chemical kinetics. If you had a bank that compounded interest continuously, then your funds would grow exponentially.

We can obtain the *integrated* rate law for this first-order reaction by applying the calculus technique of *integration* to equation (14.12). The result of this derivation (shown in Are You Wondering 14-4) is

$$\ln\frac{[A]_t}{[A]_0} = -kt \quad \text{or} \quad \ln[A]_t = -kt + \ln[A]_0 \qquad \textbf{(14.13)}$$

$[A]_t$ is the concentration of A at time t, $[A]_0$ is its concentration at $t = 0$, and k is the rate constant. Because the logarithms of numbers are dimensionless (have no units), the product $-k \times t$ must also be dimensionless. This means that the unit of k in a first-order reaction is $(\text{time})^{-1}$, such as s^{-1} or $\min^{-1}$. Equation (14.13) is that of a straight line.

Equation of straight line

$$\underbrace{\ln[A]_t}_{y} = \underbrace{(-k)t}_{m \cdot x} + \underbrace{\ln[A]_0}_{b}$$

KEEP IN MIND

that scatter of experimental data on a straight-line graph often make a value of k calculated from equation (14.13) less reliable than a value obtained from the slope of the straight line.

14-4 ARE YOU WONDERING...

How to obtain the integrated rate law for a first-order reaction?

In differential form, the rate law for the reaction $A \longrightarrow$ products is $d[A]/dt = -k[A]$.

Separation of the differentials leads to the expression $d[A]/[A] = -kdt$.

Integration of this expression between the limits $[A]_0$ at time $t = 0$ and $[A]_t$ at time t is indicated through the expression

$$\int_{[A]_0}^{[A]_t} \frac{d[A]}{[A]} = -k\int_0^t dt, \qquad \text{yielding } \ln\frac{[A]_t}{[A]_0} = -kt$$

The result of the integration is the integrated rate law.

$$\ln\frac{[A]_t}{[A]_0} = -kt \qquad \textbf{(14.13)}$$

EXAMPLE 14-5 Using the Integrated Rate Law for a First-Order Reaction

$H_2O_2(aq)$, initially at a concentration of 2.32 M, is allowed to decompose. What will $[H_2O_2]$ be at $t = 1200 s$? Use $k = 7.30 \times 10^{-4} s^{-1}$ for this first-order decomposition.

Analyze

We have values for three of the four quantities in equation (14.13):

$$\begin{array}{ll} k = 7.30 \times 10^{-4} s^{-1} & t = 1200 \text{ s} \\ [H_2O_2]_0 = 2.32 \text{ M} & [H_2O_2]_t = ? \end{array}$$

We need to solve for the fourth quantity.

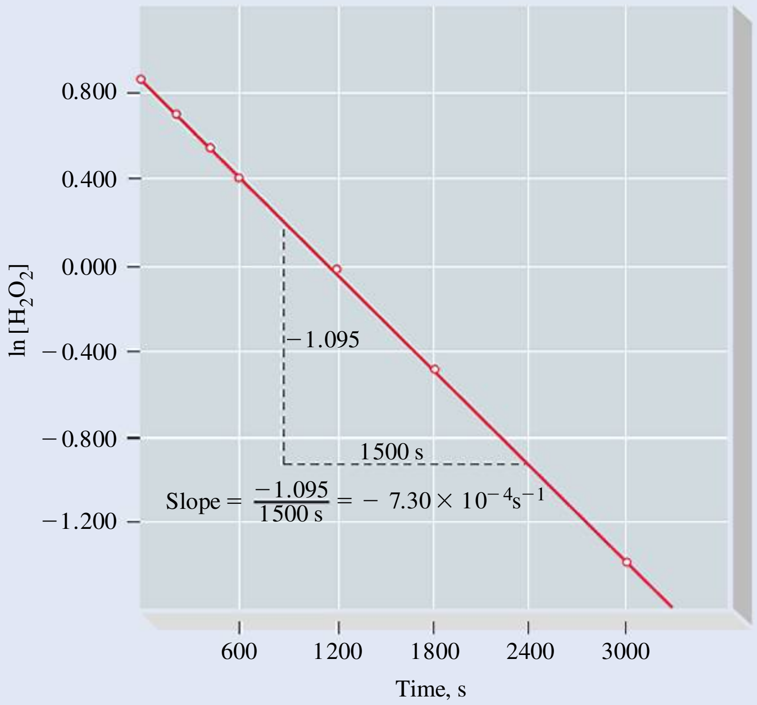
Solve

We substitute into the expression

$$\begin{aligned} \ln[H_2O_2]_t &= -kt + \ln[H_2O_2]_0 \\ &= -(7.30 \times 10^{-4} s^{-1} \times 1200 \text{ s}) + \ln 2.32 \\ &= -0.876 + 0.842 = -0.034 \\ [H_2O_2]_t &= e^{-0.034} = 0.967 \text{ M} \end{aligned}$$

Assess

This calculated value agrees well with the experimentally determined value of 0.98 M, shown below.



◀ FIGURE 14-4
Test for a first-order reaction: Decomposition of $H_2O_2(aq)$
Plot of ln H_2O_2 versus *t*. The data are based on Table 14.1 and are listed below. The slope of the line is used in the text.

t, s	$[H_2O_2]$, M	$\ln[H_2O_2]$
0	2.32	0.842
200	2.01	0.698
400	1.72	0.542
600	1.49	0.399
1200	0.98	−0.020
1800	0.62	−0.48
3000	0.25	−1.39

PRACTICE EXAMPLE A: The reaction $A \longrightarrow 2B + C$ is first order. If the initial $[A] = 2.80$ M and $k = 3.02 \times 10^{-3} s^{-1}$, what is the value of $[A]$ after 325 s?

PRACTICE EXAMPLE B: Use data tabulated in Figure 14-4, together with equation (14.13), to show that the decomposition of H_2O_2 is a first-order reaction. [*Hint:* Use a pair of data points for $[H_2O_2]_0$ and $[H_2O_2]_t$ and their corresponding times to solve for *k*. Repeat this calculation using other sets of data. How should the results compare?]

An easy test for a first-order reaction is to plot the natural logarithm of a reactant concentration versus time and see if the graph is linear. The data from Table 14.1 are plotted in Figure 14-4, and the rate constant k is derived from the slope of the line: $k = -\text{slope} = -(-7.30 \times 10^{-4}\,\text{s}^{-1}) = 7.30 \times 10^{-4}\,\text{s}^{-1}$. An alternative, nongraphical approach, illustrated in Practice Example 14-5B, is to substitute data points into equation (14.13) and solve for k.

Although until now we have used only molar concentrations in kinetics equations, we can sometimes work directly with the masses of reactants. Another possibility is to work with a fraction of reactant consumed, as is done in the concept of half-life.

The **half-life** of a reaction is the time required for one-half of a reactant to be consumed. It is the time during which the amount of reactant or its concentration decreases to one-half of its initial value. That is, at $t = t_{1/2}, [\text{A}]_t = \frac{1}{2}[\text{A}]_0$. At this time, equation (14.13) takes the form

$$\ln\frac{[\text{A}]_t}{[\text{A}]_0} = \ln\frac{\frac{1}{2}\cancel{[\text{A}]_0}}{\cancel{[\text{A}]_0}} = \ln\frac{1}{2} = -\ln 2 = -k \times t_{1/2}$$

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k} \tag{14.14}$$

Equation (14.14) is valid only for first-order reactions. We will derive half-life expressions for other types of reactions as we encounter them.

For the decomposition of $\text{H}_2\text{O}_2(\text{aq})$, the reaction described in Section 14-2, we conclude that the half-life is

$$t_{1/2} = \frac{0.693}{7.30 \times 10^{-4}\,\text{s}^{-1}} = 9.49 \times 10^{2}\,\text{s} = 949\,\text{s}$$

Equation (14.14) indicates that *the half-life is constant for a first-order reaction*. Thus, regardless of the value of $[\text{A}]_0$ at the time we begin to follow a reaction, at $t = t_{1/2}, [\text{A}] = \frac{1}{2}[\text{A}]_0$. After *two* half-lives, that is, at $t = 2 \times t_{1/2}$. $[\text{A}] = \frac{1}{2} \times \frac{1}{2}[\text{A}]_0 = \frac{1}{4}[\text{A}]_0$. At $t = 3 \times t_{1/2}, [\text{A}] = \frac{1}{8}[\text{A}]_0$, and so on.

◀ Half-life is constant for first-order reactions but not constant for zero-order or second-order reactions. For a zero-order reaction half-life decreases with decreasing reactant concentration. For a second-order reaction, half-life increases with decreasing reactant concentration.

The constancy of the half-life and its independence of the initial concentration can be used as a test for a first-order reaction. Try it with the simple concentration-time graph of Figure 14-2. That is, starting with $[\text{H}_2\text{O}_2] = 2.32\,\text{M}$ at $t = 0$, at what time is $[\text{H}_2\text{O}_2]$ equal to 1.16 M? 0.58 M? 0.29 M? Starting with $[\text{H}_2\text{O}_2] = 1.50\,\text{M}$ at $t = 600\,\text{s}$, at what time is $[\text{H}_2\text{O}_2] = 0.75\,\text{M}$?

In the discussion above we made the assumption that the stoichiometric coefficient $a = 1$. What would the rate equations look like if $a \neq 1$? In this case we would write

$$a\text{A} \longrightarrow \text{products}$$

for which the rate law is

$$\text{rate of reaction} = -\frac{1}{a}\frac{\Delta[\text{A}]}{\Delta t} = k[\text{A}]$$

which can be rearranged to give

$$-\frac{\Delta[\text{A}]}{\Delta t} = ak[\text{A}]$$

The expression above is very similar to equation (14.12) except that ak has taken the place of k in that equation. As a result, the integrated rate law and the half-life for the reaction $aA \longrightarrow$ products can be obtained from equations (14.13) and (14.14) by replacing k with ak. We obtain

$$\ln[\text{A}]_t = -akt + \ln[\text{A}]_0 \quad \text{and} \quad t_{1/2} = \frac{0.693}{ak}$$

As illustrated in Example 14-6, a first-order reaction can also be described in terms of the percent of a reactant consumed or remaining.

EXAMPLE 14-6 Expressing Fraction (or Percent) of Reactant Consumed in a First-Order Reaction

Use a value of $k = 7.30 \times 10^{-4}\,\text{s}^{-1}$ for the first-order decomposition of $H_2O_2(aq)$ to determine the percent H_2O_2 that has decomposed in the first 500.0 s after the reaction begins.

Analyze

The ratio $[H_2O_2]_t/[H_2O_2]_0$ represents the fractional part of the initial amount of H_2O_2 that remains *unreacted* at time t. Our problem is to evaluate this ratio at $t = 500.0$ s. This is done by making use of equation (14.13), which relates the concentration at $t = 0$ to the concentration at some other time.

Solve

Substituting into equation (14.13),

$$\ln\frac{[H_2O_2]_t}{[H_2O_2]_0} = -kt = -7.30 \times 10^{-4}\,\text{s}^{-1} \times 500.0\,\text{s} = -0.365$$

$$\frac{[H_2O_2]_t}{[H_2O_2]_0} = e^{-0.365} = 0.694 \qquad \text{and} \qquad [H_2O_2]_t = 0.694[H_2O_2]_0$$

The fractional part of the H_2O_2 remaining is 0.694, or 69.4%. The percent of H_2O_2 that has decomposed is 100.0% − 69.4% = 30.6%.

Assess

The integrated form of the rate law is used for determining concentrations as a function of time. The integrated form of the rate law for first-order reactions is useful for many types of reactions and events. We will see this equation later when we talk about radioactivity.

PRACTICE EXAMPLE A: Consider the first-order reaction $A \longrightarrow$ products, with $k = 2.95 \times 10^{-3}\,\text{s}^{-1}$. What percent of A remains after 150 s?

PRACTICE EXAMPLE B: At what time after the start of the reaction is a sample of $H_2O_2(aq)$ two-thirds decomposed?

Reactions Involving Gases

For gaseous reactions, rates are often measured in terms of gas pressures. For the hypothetical reaction, $A(g) \longrightarrow$ products, the initial partial pressure, $(P_A)_0$, and the partial pressure at some time t, $(P_A)_t$, are related through the expression

$$\ln\frac{(P_A)_t}{(P_A)_0} = -kt \tag{14.15}$$

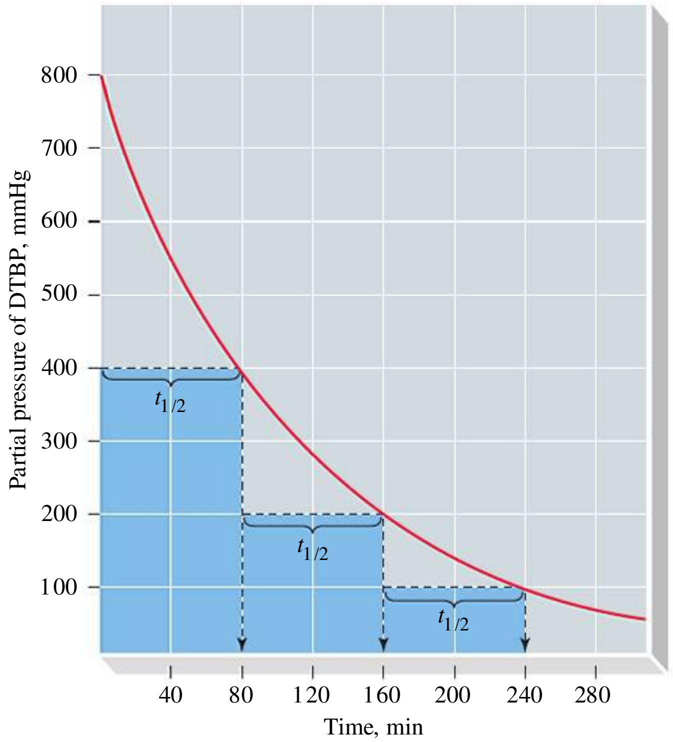
To see how this equation is derived, start with the ideal gas equation written for reactant A: $P_AV = n_ART$. Note that the ratio n_A/V is the same as $[A]$. So, $[A]_0 = (P_A)_0/RT$ and $[A]_t = (P_A)_t/RT$. Substitute these terms into equation (14.13), and note that the RT terms cancel in the numerator and denominator and leave the simple ratio $(P_A)_t/(P_A)_0$.

Di-*t*-butyl peroxide (DTBP) is used as a catalyst in the manufacture of polymers. In the gaseous state, DTBP decomposes into acetone and ethane by a first-order reaction.

$$\underset{\text{DTBP}}{C_8H_{18}O_2(g)} \longrightarrow \underset{\text{acetone}}{2\,CH_3COCH_3(g)} + \underset{\text{ethane}}{CH_3CH_3(g)} \tag{14.16}$$

Partial pressures of DTBP are plotted as a function of time in Figure 14-5, and the half-life of the reaction is indicated.

As shown in Are You Wondering 14-5, the partial pressure of the reactant DTBP can be obtained from two experimentally determined quantities: the initial pressure P_0, and the total pressure P_{total}.



▲ FIGURE 14-5
Decomposition of di-*t*-butyl peroxide (DTBP) at 147 °C
The decomposition reaction is described through equation (14.16). In this graph of the partial pressure of DTBP as a function of time, three successive half-life periods of 80 min each are indicated. This constancy of the half-life is proof that the reaction is first order.

14-5 ARE YOU WONDERING...

How the partial pressure can be obtained experimentally in a reaction involving gases?

In the study of a reaction like the decomposition of DTBP, the *total* pressure is typically measured as a function of time. At any time t, the total pressure is

$$(P_{\text{total}})_t = (P_{\text{DTBP}})_t + (P_{\text{acetone}})_t + (P_{\text{ethane}})_t$$

If the initial presure of DTBP is P_0, then using the stoichiometry of the balanced chemical equation, the partial pressure of DTBP is $P_{\text{DTBP}} = (P_0 - P_{\text{ethane}})$ since for every mole of DTBP that decomposes, a mole of ethane is produced. The partial pressure of acetone is $P_{\text{acetone}} = 2\,P_{\text{ethane}}$, again using the stoichiometry of the reaction. The total pressure is then given by

$$P_{\text{total}} = (P_0 - P_{\text{ethane}}) + 2\,P_{\text{ethane}} + P_{\text{ethane}} = P_0 + 2\,P_{\text{ethane}}$$

and

$$P_{\text{ethane}} = \frac{P_{\text{total}} - P_0}{2}$$

So that

$$P_{\text{DTBP}} = (P_0 - P_{\text{ethane}}) = \frac{2\,P_0 - (P_{\text{total}} - P_0)}{2} = \frac{3\,P_0 - P_{\text{total}}}{2}$$

◀ Note that the total pressure in reaction (14.16) increases from P_0 at the start of the reaction to $3\,P_0$ when P_{DTBP} has fallen to zero.

EXAMPLE 14-7 Applying First-Order Kinetics to a Reaction Involving Gases

Reaction (14.16) is started with pure DTBP at 147 °C and 800.0 mmHg pressure in a flask of constant volume. **(a)** What is the value of the rate constant k? **(b)** At what time will the partial pressure of DTBP be 50.0 mmHg?

Analyze

In part **(a)** we observe from Figure 14-5 that $t_{1/2} = 8.0 \times 10^1$ min. Recall that for a first-order reaction the relationship between $t_{1/2}$ and the rate constant is $t_{1/2} = 0.693/k$. In part **(b)** the final DTBP partial pressure of 50.0 mmHg is $\frac{1}{16}$ of the starting pressure of 800.0 mmHg; that is, $P_{\text{DTBP}} = (\frac{1}{2})^4 \times 800.0 = 50.0$ mmHg. The reaction must go through *four* half-lives.

Solve

(a) Substituting in the appropriate values we have

$$k = 0.693/t_{1/2} = 0.693/8.0 \times 10^1\ \text{min} = 8.7 \times 10^{-3}\ \text{min}^{-1}$$

(b) Therefore, $t = 4 \times t_{1/2} = 4 \times 8.0 \times 10^1\ \text{min} = 3.2 \times 10^2\ \text{min}$.

Assess

This type of analysis is useful only if we have the half-life data. If we do not, we will need to use equation (14.13).

PRACTICE EXAMPLE A: Start with DTBP at a pressure of 800.0 mmHg at 147 °C. What will be the pressure of DTBP at $t = 125$ min, if $t_{1/2} = 8.0 \times 10^1$ min? [*Hint:* Because 125 min is not an exact multiple of the half-life, you must use equation (14.15). Can you see that the answer is between 200 and 400 mmHg?]

PRACTICE EXAMPLE B: Use data from Table 14.4 to determine **(a)** the partial pressure of ethylene oxide, and **(b)** the total gas pressure after 30.0 h in a reaction vessel at 415 °C if the initial partial pressure of $(CH_2)_2O(g)$ is 782 mmHg.

TABLE 14.4 Some Typical First-Order Processes

Process	Half-Life, $t_{1/2}$	Rate Constant k, s^{-1}
Radioactive decay of $^{238}_{92}U$	4.51×10^9 yr	4.87×10^{-18}
Radioactive decay of $^{14}_{6}C$	5.73×10^3 yr	3.83×10^{-12}
Radioactive decay of $^{32}_{15}P$	14.3 d	5.61×10^{-7}
Radioactive decay of $^{131}_{53}I$	8.04 d	9.98×10^{-7}
$\underset{\text{sucrose}}{C_{12}H_{22}O_{11}(aq)} + H_2O(l) \xrightarrow{15\,°C} \underset{\text{glucose}}{C_6H_{12}O_6(aq)} + \underset{\text{fructose}}{C_6H_{12}O_6(aq)}$	8.4 h	2.3×10^{-5}
$\underset{\text{ethylene oxide}}{(CH_2)_2O(g)} \xrightarrow{415\,°C} CH_4(g) + CO(g)$	56.3 min	2.05×10^{-4}
$N_2O_5(g) \xrightarrow[45\,°C]{\text{In } CCl_4} N_2O_4(g) + \frac{1}{2}O_2(g)$	18.6 min	6.21×10^{-4}
$CH_3COOH(aq) \longrightarrow H^+(aq) + CH_3COO^-(aq)$	8.9×10^{-7}s	7.8×10^5

Examples of First-Order Reactions

One of the most familiar examples of a first-order process is radioactive decay. For example, the radioactive isotope iodine-131, used in treating thyroid disorders, has a half-life of 8.04 days. Whatever number of iodine-131 atoms are in a sample at a given moment, there will be half that number in 8.04 days; one-quarter of that number in 8.04 + 8.04 = 16.08 days; and so on. The rate constant for the decay is $k = 0.693/t_{1/2}$, and in equation (14.13) we can use numbers of atoms, that is, N_t for $[A]_t$ and N_0 for $[A]_0$. Table 14.4 lists several examples of first-order processes. Note the great range of values of $t_{1/2}$ and k. The processes range from very slow to ultrafast.

▶ We will explore radioactive decay in some detail in Chapter 25.

14-4 CONCEPT ASSESSMENT

Without doing calculations, sketch **(a)** concentration versus time plots for two first-order reactions, one having a large *k* and the other a small *k*, and **(b)** ln *k* versus time plots for the same two situations. Describe the similarities and differences between the two plots in each case.

14-6 Second-Order Reactions

An overall **second-order reaction** has a rate law with the sum of the exponents, $m + n \cdots$, equal to 2. As with zero- and first-order reactions, our discussion will be limited to reactions involving the decomposition of a single reactant

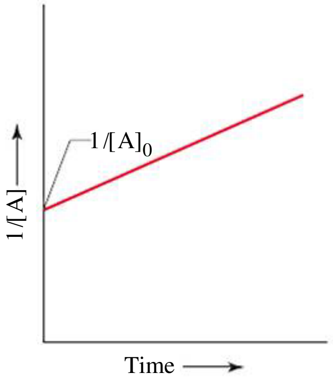
$$\text{A} \longrightarrow \text{products}$$

that follow the rate law

$$\text{rate of reaction} = k[\text{A}]^2 \qquad \textbf{(14.17)}$$

Again, our primary interest will be in the integrated rate law that is derived from the rate law. This proves to be the equation of a straight-line graph.

$$\frac{1}{[\text{A}]_t} = kt + \frac{1}{[\text{A}]_0} \qquad \textbf{(14.18)}$$



▲ FIGURE 14-6
A straight-line plot for the second order reaction A ⟶ products
The reciprocal of the concentration, 1/[A], is plotted against time. As the reaction proceeds, [A] decreases and 1/[A] increases in a linear fashion. The slope of the line is the rate constant *k*.

Figure 14-6 is a plot of $1/[\text{A}]_t$ against time. The slope of the line is *k*, and the intercept is $1/[\text{A}]_0$. From the graph, we can see that the units of *k* must be the *reciprocal* of concentration divided by time: $\text{M}^{-1}/(\text{time})$ or $\text{M}^{-1}(\text{time})^{-1}$—for example, $\text{M}^{-1}\,\text{s}^{-1}$ or $\text{M}^{-1}\,\text{min}^{-1}$. We can reach this same conclusion by determining the units of *k* that produce the required units for the rate of a reaction, that is, moles per liter per time. From equation (14.17):

$$\begin{array}{lll} \textit{rate law}: & \text{rate of reaction} = & k \times [\text{A}]^2 \\ \textit{units}: & \text{M time}^{-1} & \text{M}^{-1}\,\text{time}^{-1}\,\text{M}^2 \end{array}$$

For the half-life of the second-order reaction A ⟶ products, we can substitute $t = t_{1/2}$ and $[\text{A}] = \frac{1}{2}[\text{A}]_0$ into equation (14.18).

$$\frac{1}{[\text{A}]_0/2} = kt_{1/2} + \frac{1}{[\text{A}]_0}; \qquad \frac{2}{[\text{A}]_0} = kt_{1/2} + \frac{1}{[\text{A}]_0} \qquad \textbf{(14.19a)}$$

and

$$t_{1/2} = \frac{1}{k[\text{A}]_0} \qquad \textbf{(14.19b)}$$

From equation (14.19a and 14.19b), we see that the half-life depends on both the rate constant *and* the initial concentration $[\text{A}]_0$. The *half-life is not constant.* Its value depends on the concentration of reactant at the start of each half-life interval. Because the starting concentration is always one-half that of the previous half-life, each successive half-life is twice as long as the one before it.

Pseudo-First-Order Reactions

At times, it is possible to simplify the kinetic study of complex reactions by getting them to behave like reactions of a lower order. Then their rate laws become easier to work with. Consider the hydrolysis of ethyl acetate, which is second order overall.

$$\underset{\text{Ethyl acetate}}{CH_3COOCH_2CH_3} + H_2O \longrightarrow \underset{\text{Acetic acid}}{CH_3COOH} + \underset{\text{Ethanol}}{CH_3CH_2OH}$$

Suppose we follow the hydrolysis of 1 L of aqueous 0.01 M ethyl acetate to completion. $[CH_3COOCH_2CH_3]$ decreases from 0.01 M to essentially zero. This means that 0.01 mol $CH_3COOCH_2CH_3$ is consumed, and along with it, 0.01 mol H_2O. Now consider what happens to the molarity of the H_2O. Initially, the solution contains about 1000 g H_2O, or about 55.5 mol H_2O. When the reaction is completed, there is still 55.5 mol H_2O (that is, $55.5 - 0.01 \approx 55.5$). The molarity of the water remains essentially constant throughout the reaction—55.5 M. The rate of reaction does not appear to depend on $[H_2O]$. So, the reaction appears to be *zero* order in H_2O, *first* order in $CH_3COOCH_2CH_3$, and *first* order overall. A second-order reaction that is made to behave like a first-order reaction by holding one reactant concentration constant is called a *pseudo*-first-order reaction. We can treat the reaction with the methods of first-order reaction kinetics. Other reactions of higher order can be made to behave like reactions of lower order under certain conditions. Thus, a third-order reaction might be converted to pseudo-second order or even to pseudo-first order.

▶ The rate constant obtained from a study that used an excess of one reactant, sometimes called Ostwald's isolation method after the kineticist who invented it, is a pseudo-rate constant and is concentration-dependent.

14-6 ARE YOU WONDERING...

How we obtain the integrated rate law for the second-order reaction A ⟶ products?

In differential form, the rate law for the reaction A ⟶ products, is $d[A]/dt = -k[A]^2$.

Separation of the differentials leads to the expression $d[A]/[A]^2 = -kdt$.

Integration of this expression between the limits $[A]_0$ at time $t = 0$ and $[A]_t$ at time t is indicated through the expression

$$\int_{[A]_0}^{[A]_t} \frac{d[A]}{[A]^2} = -\int_0^t kdt$$

The result of the integration is the integrated rate law.

$$-\frac{1}{[A]_t} + \frac{1}{[A]_0} = -kt \quad \text{or} \quad \frac{1}{[A]_t} = kt + \frac{1}{[A]_0} \tag{14.18}$$

14-7 Reaction Kinetics: A Summary

Let's pause briefly to review what we have learned about rates of reaction, rate constants, and reaction orders. Although a problem often can be solved in several different ways, these approaches are generally most direct.

1. To calculate a rate of reaction when the rate law is known, use this expression: rate of reaction $= k[A]^m[B]^n \cdots$
2. To determine a rate of reaction when the rate law is not given, use
   - the slope of an appropriate tangent line to the graph of $[A]$ versus t
   - the expression $-\Delta[A]/\Delta t$, with a short time interval Δt

TABLE 14.5 Reaction Kinetics: A Summary for the Hypothetical Reaction A ⟶ Products

Order	Rate Law[a]	Integrated Rate Equation	Straight Line	$k =$	Units of k	Half-Life
0	rate $= k$	$[\mathrm{A}]_t = -akt + [\mathrm{A}]_0$	$[\mathrm{A}]$ v. time	−slope	$\mathrm{mol\ L^{-1}\ s^{-1}}$	$\dfrac{[\mathrm{A}]_0}{2\,ak}$
1	rate $= k[\mathrm{A}]$	$\ln[\mathrm{A}]_t = -akt + \ln[\mathrm{A}]_0$	$\ln[\mathrm{A}]$ v. time	−slope	$\mathrm{s^{-1}}$	$\dfrac{0.693}{ak}$
2	rate $= k[\mathrm{A}]^2$	$\dfrac{1}{[\mathrm{A}]_t} = akt + \dfrac{1}{[\mathrm{A}]_0}$	$\dfrac{1}{[\mathrm{A}]}$ v. time	slope	$\mathrm{L\ mol^{-1}\ s^{-1}}$	$\dfrac{1}{ak[\mathrm{A}]_0}$

[a] rate $= -\left(\dfrac{1}{a}\right)\dfrac{\Delta[\mathrm{A}]}{\Delta t}$

3. To determine the order of a reaction, use one of the following methods.
- Use the method of initial rates if the experimental data are given in the form of reaction rates at different initial concentrations.
- Find the graph of rate data that yields a straight line (Table 14.5).
- Test for the constancy of the half-life (good only for first-order).
- Substitute rate data into integrated rate laws to find the one that gives a constant value of k.

4. To find the rate constant k for a reaction, use one of the following methods.
- Obtain k from the slope of a straight-line graph.
- Substitute concentration–time data into the appropriate integrated rate law.
- Obtain k from the half-life of the reaction (good only for a first-order reaction).

5. To relate reactant concentrations and times, use the appropriate integrated rate law after first determining k.

EXAMPLE 14-8 Graphing Data to Determine the Order of a Reaction

The data listed in Table 14.6 were obtained for the decomposition reaction A ⟶ products. **(a)** Establish the order of the reaction. **(b)** What is the rate constant, k? **(c)** What is the half-life, $t_{1/2}$, if $[\mathrm{A}]_0 = 1.00$ M?

TABLE 14.6 Kinetic Data for Example 14-8

Time, min	[A], M	ln[A]	1/[A]
0	1.00	0.00	1.00
5	0.63	−0.46	1.6
10	0.46	−0.78	2.2
15	0.36	−1.02	2.8
25	0.25	−1.39	4.0

Analyze

To determine the order of the reaction, we need to plot the data according to the integrated rate law for the different reaction orders. The plot yielding a straight line shows the overall reaction order. Recall that the slope of the straight line is related to the rate constant. The half-life of the reaction is also dependent on the overall reaction order.

Solve

(a) Plot the following three graphs.

1. $[\mathrm{A}]$ versus time. (If a straight line, reaction is zero order.)

(continued)

2. ln[A] versus time. (If a straight line, reaction is first order.)
3. 1/[A] versus time. (If a straight line, reaction is second order.)

These graphs are plotted in Figure 14-7. The reaction is second order.

(b) The slope of graph 3 in Figure 14-7 is

$$k = \frac{(4.00 - 1.00)\,\mathrm{L/mol}}{25\ \mathrm{min}} = 0.12\ \mathrm{M^{-1}\,min^{-1}}$$

(c) According to equation (14.19),

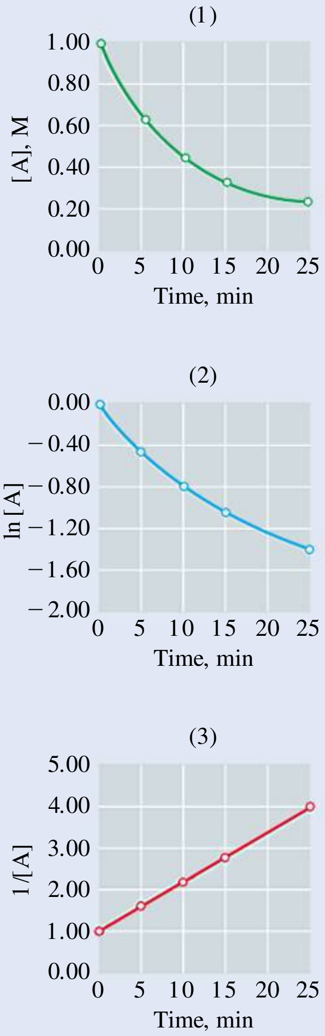
$$t_{1/2} = \frac{1}{k[\mathrm{A}]_0} = \frac{1}{0.12\ \mathrm{M^{-1}\,min^{-1}} \times 1.00\ \mathrm{M}} = 8.3\ \mathrm{min}$$

Assess

We can check the result in this example by examining the half-life results on the plot of [A] versus time. The plot shows that [A] decreases to 0.5 M between $t = 5$ min and $t = 10$ min, and so $t_{1/2} = 8.3$ min is a reasonable answer.

PRACTICE EXAMPLE A: In the decomposition reaction $\mathrm{B} \longrightarrow$ products, the following data are obtained: $t = 0$ s, $[\mathrm{B}] = 0.88$ M; $t = 25$ s, 0.74 M; $t = 50$ s, 0.62 M; $t = 75$ s, 0.52 M; $t = 100$ s, 0.44 M; $t = 150$ s, 0.31 M; $t = 200$ s, 0.22 M; $t = 250$ s, 0.16 M. What are the order of this reaction and its rate constant k?

PRACTICE EXAMPLE B: The following data are obtained for the reaction $\mathrm{A} \longrightarrow$ products: $t = 0$ min, $[\mathrm{A}] = 0.250$ M; $t = 4.22$ min, $[\mathrm{A}] = 0.210$ M; $t = 6.60$ min, $[\mathrm{A}] = 0.188$ M; $t = 10.61$ min, $[\mathrm{A}] = 0.150$ M; $t = 14.48$ min, $[\mathrm{A}] = 0.114$ M; $t = 18.00$ min, $[\mathrm{A}] = 0.083$ M. What are the order of this reaction and its rate constant, k?



▶ FIGURE 14-7
Testing for the order of a reaction—Example 14-8 illustrated
The straight-line plot is obtained for 1/[A] versus t, graph (3). The reaction is second order.

14-5 CONCEPT ASSESSMENT

How could you ascertain, by examining only a plot of [A] versus time, whether a reaction is **(a)** zero order; **(b)** first order; **(c)** second order?

14-8 Theoretical Models for Chemical Kinetics

Practical aspects of reaction kinetics—rate laws, rate constants—can be described without considering the behavior of individual molecules. However, insight into the processes involved requires examination at the molecular level. For example, experiments show that the decomposition of H_2O_2 is first order, but *why* is this so? The remainder of the chapter considers the theoretical aspects of chemical kinetics that help answer such questions.

▶ Not all collisions are effective in causing a reaction. The average time between collisions in a gas at STP is about 10^{-10} s and the time that the collision is actually taking place is about 10^{13} s.

Collision Theory

In our discussion of kinetic-molecular theory in Chapter 6 our emphasis was on molecular speeds. A further aspect of the theory with relevance to chemical kinetics is collision density, the number of collisions per unit volume per unit time.

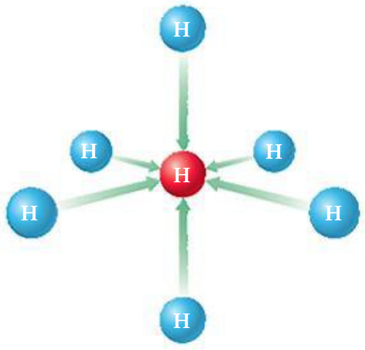
In a typical gas-phase reaction, the calculated collision density is of the order of 10^{32} collisions per liter per second. If each collision yielded product molecules, the rate of reaction would be about $10^6\ \mathrm{M\,s^{-1}}$, an extremely rapid rate. The typical gas-phase reaction would go essentially to completion in a fraction of a second. Gas-phase reactions generally proceed at a much slower rate, perhaps on the order of $10^{-4}\ \mathrm{M\,s^{-1}}$. This must mean that, generally, *only a fraction of the collisions among gaseous molecules lead to chemical reaction.* This is a reasonable conclusion; we should not expect every collision to result in a reaction.

For a reaction to occur following a collision between molecules, there must be a redistribution of energy that puts enough energy into certain key bonds to break them. We would not expect two slow-moving molecules to bring enough kinetic energy into their collision to permit bond breakage. We would expect two fast-moving molecules to do so, however, or perhaps one extremely fast molecule colliding with a slow-moving one. The **activation energy** of a reaction is the minimum kinetic energy that molecules must bring to their collisions for a chemical reaction to occur.

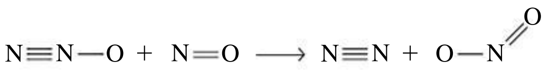
The kinetic-molecular theory can be used to establish the fraction of all the molecules in a mixture that possess certain kinetic energies. The results of this calculation are depicted in Figure 14-8. On this graph, a hypothetical energy is noted and the fraction of all molecules having energies in excess of this value is identified. Let's assume that these are the molecules whose molecular collisions are most likely to lead to chemical reaction. The rate of a reaction, then, depends on the product of the collision frequency *and* the fraction of these "activated" molecules—in other words, on how often molecules with sufficient kinetic energy to react are likely to collide with each other. Because the fraction of high-energy molecules is generally so small, the rate of reaction is usually much smaller than the collision frequency. Moreover, the *higher* the activation energy of a reaction, the *smaller* is the fraction of energetic collisions and the slower the reaction.

Another factor that can strongly affect the rate of a reaction is the *orientation* of molecules at the time of their collision. In a reaction in which two hydrogen atoms combine to form a hydrogen molecule (see margin) no bonds are broken and a H—H bond forms

$$\mathrm{H\cdot} + \mathrm{\cdot H} \longrightarrow \mathrm{H_2}$$

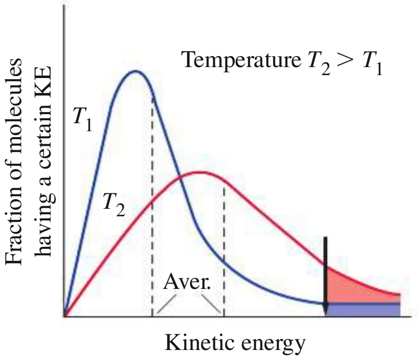


The H atoms are spherically symmetrical, and all approaches of one H atom to another prior to collision are equivalent. Orientation is *not* a factor, and the reaction occurs about as rapidly as the atoms collide. Orientation of the colliding molecules, however, is a crucial matter in the reaction of N_2O and NO, represented here in an equation highlighting chemical bonds.

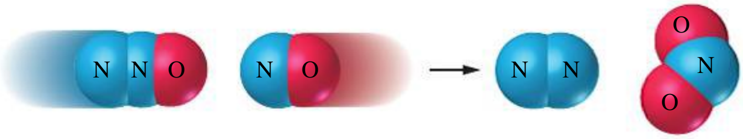


$$\mathrm{N{\equiv}N{-}O} + \mathrm{N{=}O} \longrightarrow \mathrm{N{\equiv}N} + \mathrm{O{-}N{=}O} \qquad \textbf{(14.20)}$$

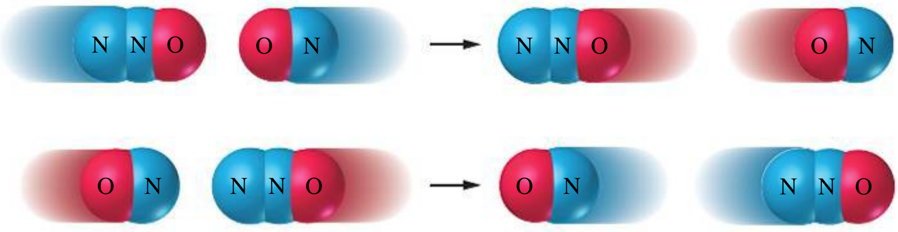
The fundamental changes that occur during a successful collision are that the N—O bond in N_2O breaks and a new O—N bond is established to the NO



◀ FIGURE 14-8
Distribution of molecular kinetic energies
At both temperatures, the fraction of all molecules having kinetic energies in excess of the value marked by the heavy black arrow is small. (Note the shaded areas on the right.) At the higher temperature T_2 (red), however, this fraction is considerably larger than at the lower temperature T_1 (blue).



(a) Favorable collision



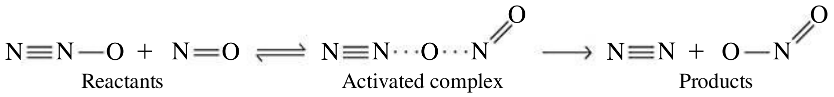
(b) Unfavorable collisions

▶ FIGURE 14-9
Molecular collisions and chemical reactions
(a) A favorable collision between N_2O and NO molecules, resulting in the products N_2 and NO_2. **(b)** Two unfavorable collisions between N_2O and NO molecules; no reaction follows the collisions.

molecule. As a result of the collision, the molecules N_2 and NO_2 are formed. As suggested by Figure 14-9, a favorable collision requires the N atom of the NO molecule to strike the O atom of N_2O during a collision. Other orientations, such as the N atom of NO striking the terminal N atom of N_2O, do not produce a reaction. The number of unfavorable collisions in the reaction mixture exceeds the number of favorable ones.

Transition State Theory

In a theory proposed by Henry Eyring (1901–1981) and others, special emphasis is placed on a hypothetical species believed to exist in a transitory state that lies between the reactants and the products. We call this state the **transition state**, and the hypothetical species, the **activated complex**. The activated complex, formed through collisions, either dissociates back into the original reactants or forms product molecules. We can represent an activated complex for reaction (14.20) in this way.



$$\underset{\text{Reactants}}{N{\equiv}N{-}O + N{=}O} \rightleftharpoons \underset{\text{Activated complex}}{N{\equiv}N\cdots O\cdots N{=}O} \longrightarrow \underset{\text{Products}}{N{\equiv}N + O{-}N{=}O}$$

In the reactants, there is no bond between the O atom of N_2O and the N atom of NO. In the activated complex, the O atom has been partially removed from the N_2O molecule and partially joined to the NO molecule, as indicated by the *partial bonds* (···). The formation of the activated complex is a reversible process. Once formed, some molecules of the activated complex may dissociate back into the reactants, but others may dissociate into the product molecules, where the partial bond of the O atom in N_2O has been completely severed and the partial bond between the O atom and NO has become a complete bond.

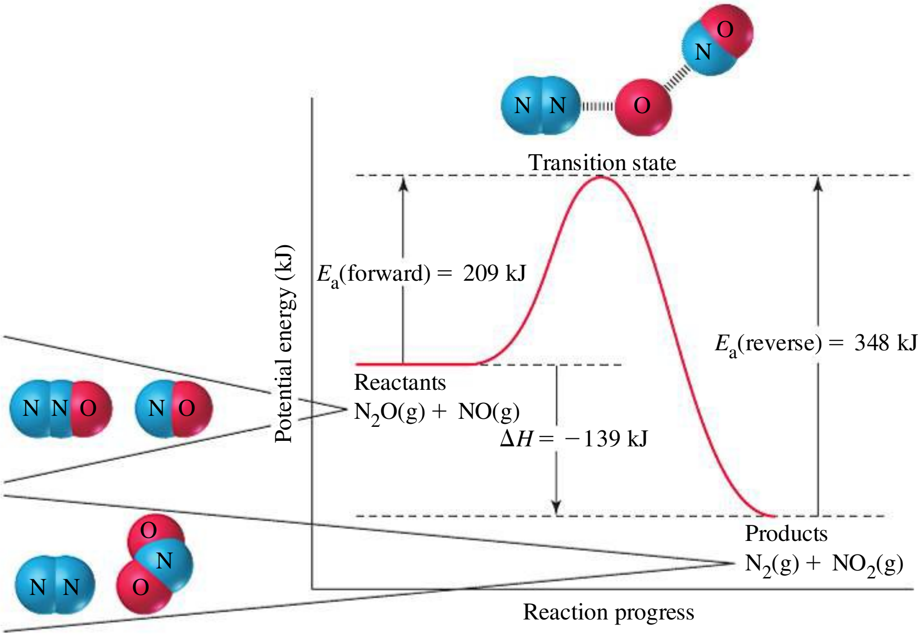
▶ Modern Raman laser spectroscopic methods can be used to study reactions that occur in the femtosecond (10^{-15}) time scale. This allows all motions, except electronic transitions, to be frozen. Such techniques are used to study activated complexes.

Figure 14-10, called a reaction profile, is a graphical way of looking at activation energy. In a **reaction profile**, energies are plotted on the vertical axis against a quantity called "progress of reaction," or simply reaction progress, on the horizontal axis. Think of the progress of reaction as representing the extent of the reaction. That is, the reaction starts with reactants on the left, progresses through a transition state, and ends with products on the right.

The difference in energies between the reactants and products is ΔH for the reaction. Reaction (14.20) is an exothermic reaction with $\Delta H = -139$ kJ. The difference in energy between the activated complex and the reactants, 209 kJ, is the *activation energy* of the reaction. Thus, a large energy barrier separates the reactants from the products, and only very energetic molecules can pass over this barrier. Figure 14-11 suggests an analogy to activation energy and the reaction profile.

KEEP IN MIND

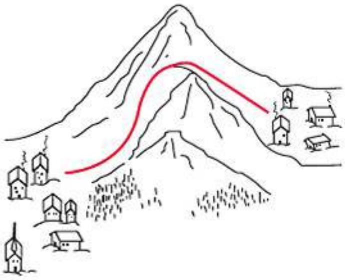
that the difference in potential energy between reactants and product is ΔU of a reaction. For this reaction $\Delta U = \Delta H$ because the number of product gas molecules is equal to the number of reactant gas molecules. As we learned in Chapter 7, even when this is not the case, the differences between ΔU and ΔH are usually quite small.



▲ FIGURE 14-10
A reaction profile for the reaction

$$N_2O(g) + NO(g) \longrightarrow N_2(g) + NO_2(g)$$

The simplified reaction profile traces energy changes during the course of reaction (14.20). The reactant and product molecules are depicted by the molecular models, as is the activated complex.



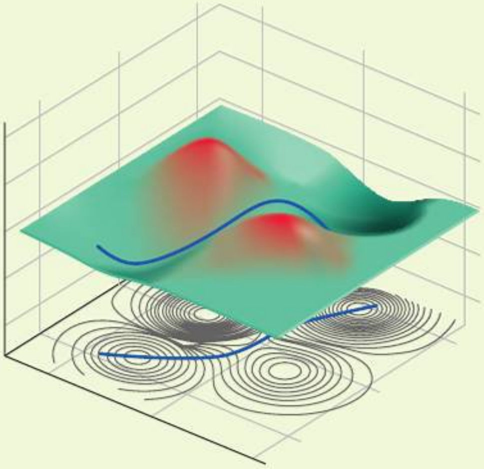
▲ FIGURE 14-11
An analogy for a reaction profile and activation energy
A hike (red path) is taken from the valley on the left (reactants) over the ridge to the valley on the right (products). The ridge above the starting point corresponds to the transition state. It is probably the height of this ridge (activation energy) more than anything else that determines how many people are willing to take the hike, regardless of the fact that it is all downhill on the other side.

Figure 14-10 describes both the forward reaction and its reverse—the reaction of N_2 and NO_2 to form N_2O and NO. The activation energy for the reverse reaction is 348 kJ; this reverse reaction is highly endothermic. Figure 14-10 also illustrates two useful ideas. (1) The enthalpy change of a reaction is equal to the difference in activation energies of the forward and reverse reactions. (2) For an

14-7 ARE YOU WONDERING...

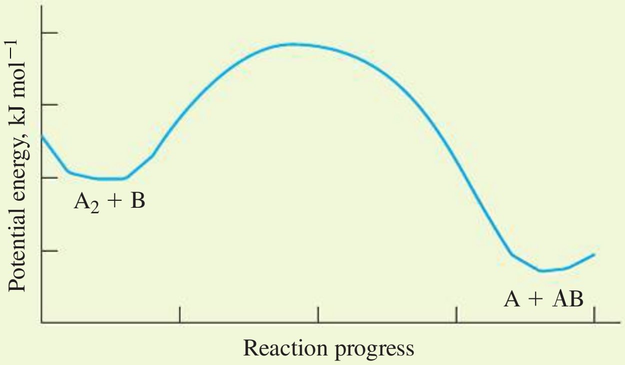
Is there a molecular interpretation of reaction progress?

Simply stated, the reaction progress refers to the minimum energy path (MEP) that leads from reactants to products. To understand MEP we must know how the potential energy (PE) of the system depends on the relative positions of all the particles in the reaction. Let us consider a very simple exothermic gas phase reaction: $A_2(g) + B(g) \longrightarrow AB(g) + A(g)$. The PE as a function of two degrees of freedom for this reaction can be visualized as shown on the right. Such a representation of the PE is commonly referred to as a potential energy surface (PES). In this case the reaction progress is highlighted by the blue line on the PES, and this represents the MEP.



(continued)

The blue line on the PES is the reaction progress and represents the PE of the reactants as they proceed to the transition state and end at the products. The reaction profile for this reaction is given below.



The reaction profile represents a simplified, one-dimensional plot of the MEP on the three-dimensional PES. Note that the highest point on the reaction profile (i.e., along the reaction path) symbolizes the transition state and is not necessarily the highest point on the PES for this reaction.

endothermic reaction, the activation energy must be equal to or greater than the enthalpy of reaction (and usually it is greater).

Attempts at purely theoretical predictions of rate constants have not been very successful. The principal value of reaction-rate theories is to help us explain experimentally observed reaction-rate data. For example, in the next section we will see how the concept of activation energy enters into a discussion of the effect of temperature on reaction rates.

14-6 CONCEPT ASSESSMENT

Indicate whether the following conditions can exist for a chemical reaction: **(a)** $\Delta H < 0 < E_a$; **(b)** $0 < \Delta H < E_a$; **(c)** $0 < E_a < \Delta H$; **(d)** $0 = \Delta H < E_a$; **(e)** $E_a < \Delta H < 0$. Where the conditions can exist, describe the reaction profile.

14-9 The Effect of Temperature on Reaction Rates

From practical experience, we expect chemical reactions to go faster at higher temperatures. To speed up the biochemical reactions involved in cooking, we raise the temperature, and to slow down other reactions, we lower the temperature—as in refrigerating milk to prevent it from souring.

In 1889, Svante Arrhenius demonstrated that the rate constants of many chemical reactions vary with temperature in accordance with the expression

$$k = Ae^{-E_a/RT} \tag{14.21}$$

By taking the natural logarithm of both sides of this equation, we obtain the following expression.

$$\ln k = -\frac{E_a}{RT} + \ln A$$

▶ This equation indicates that a rate constant *increases* as the temperature *increases* and as the activation energy *decreases*.

A graph of ln k versus $1/T$ is a straight line, thus giving us a graphical method for determining the activation energy of a reaction, as shown in

Figure 14-12. We can also derive a useful variation of the equation by writing it twice—each time for a different value of k and the corresponding temperature—and then eliminating the constant ln A. The result, also called the Arrhenius equation, is

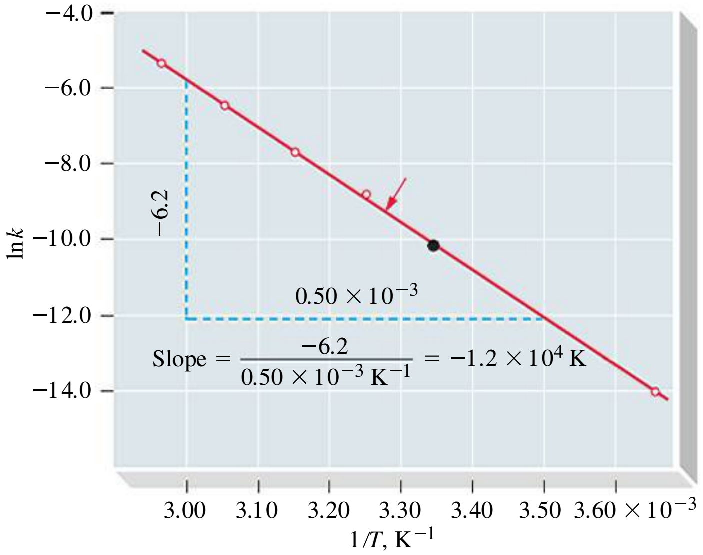
◀ This is the same technique used for the Clausius–Clapeyron equation on page 516 and illustrated in Appendix A-4.

$$\ln\frac{k_2}{k_1} = \frac{E_a}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad \textbf{(14.22)}$$

In equation (14.22)* T_2 and T_1 are two Kelvin temperatures; k_2 and k_1 are the rate constants at these temperatures; and E_a is the activation energy in joules per mole. R is the gas constant expressed as $8.3145\ \text{J mol}^{-1}\ \text{K}^{-1}$.

Equation (14.22) can be rewritten in several ways.

$$\ln\frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) = -\frac{E_a}{R}\left(\frac{T_1 - T_2}{T_2 T_1}\right) = \frac{E_a}{R}\left(\frac{T_2 - T_1}{T_2 T_1}\right)$$



▲ FIGURE 14-12
Temperature dependence of the rate constant *k* for the reaction

$$\mathbf{N_2O_5\,(in\ CCl_4) \longrightarrow N_2O_4\,(in\ CCl_4) + \frac{1}{2}\,O_2(g)}$$

Data are plotted as follows, for the representative point in black.

$$\begin{aligned} t &= 25\,^\circ\text{C} = 298\ \text{K} \\ 1/T &= 1/298 = 0.00336 = 3.36 \times 10^{-3}\,\text{K}^{-1} \\ k &= 3.46 \times 10^{-5}\,\text{s}^{-1};\ \ln k = \ln 3.46 \times 10^{-5} = -10.272 \end{aligned}$$

To evaluate E_a,

$$\begin{aligned} \text{slope of line} &= -E_a/R = -1.2 \times 10^4\,\text{K} \\ E_a &= 8.3145\ \text{J mol}^{-1}\,\text{K}^{-1} \times 1.2 \times 10^4\,\text{K} \\ &= 1.0 \times 10^5\ \text{J/mol} = 1.0 \times 10^2\ \text{kJ/mol} \end{aligned}$$

(A more precise plot yields a value of E_a = 106 kJ/mol. The arrow points to data referred to in Example 14-9.)

---

*To see that this expression is dimensionally correct, note that on the right side the units in the numerator are J mol^{-1} (for E_a) and K^{-1} (for the quantity in parentheses) and that in the denominator the units are $\text{J mol}^{-1}\,\text{K}^{-1}$ (for R). Cancellation yields a dimensionless quantity on the right, to match the dimensionless logarithmic term on the left.

The first form brings out the minus sign and reverses the T_1 and T_2, and the next two combine the fractions within the parentheses. Also, the equation can be written in exponential form.

$$\frac{k_2}{k_1} = e^{-\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)}$$

Which equation is used is a matter of calculational convenience.

Arrhenius established equation (14.22) by fitting experimental data into his equation. This was before the collision theory of chemical reactions had been developed, but his equation is consistent with the collision theory. In the preceding section, we discussed the importance of (1) the frequency of molecular

EXAMPLE 14-9 Applying the Arrhenius Equation

Use data from Figure 14-12 to determine the temperature at which $t_{1/2}$ for the first-order decomposition of N_2O_5 in CCl_4 is 2.00 h.

Analyze

First, find the rate constant k corresponding to a 2.00 h half-life. This can be done by using the half-life for a *first-order reaction*,

$$k = \frac{\ln 2}{t_{1/2}} = \frac{0.693}{2.00\text{ h}} = \frac{0.693}{7200\text{ s}} = 9.63 \times 10^{-5}\text{ s}^{-1}$$

Now, the temperature at which $k = 9.63 \times 10^{-5}\text{ s}^{-1}$ can be determined in two ways: graphically and analytically.

Solve

Graphical Method. The temperature at which $\ln k = \ln 9.63 \times 10^{-5} = -9.248$ is marked by the red arrow in Figure 14-12. The value of $1/T$ corresponding to $\ln k = -9.248$ is $1/T = 3.28 \times 10^{-3}\text{ K}^{-1}$, which means that

$$T = \left(\frac{1}{3.28 \times 10^{-3}\text{ K}^{-1}}\right) = 305\text{ K} = 32\text{ °C}$$

Analytical Method. Take T_2 to be the temperature at which $k = k_2 = 9.63 \times 10^{-5}\text{ s}^{-1}$. T_1 is some other temperature at which a value of k is known. Suppose we take $T_1 = 298\text{ K}$ and $k_1 = 3.46 \times 10^{-5}\text{ s}^{-1}$, a point referred to in the caption of Figure 14-12. The activation energy is 106 kJ/mol = 1.06×10^5 J/mol (the more precise value given in Figure 14-12). Now we can solve equation (14.22) for T_2. (For simplicity, we have omitted units below, but the temperature is obtained in kelvins.)

$$\ln\frac{k_2}{k_1} = \frac{E_a}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

$$\ln\frac{9.63 \times 10^{-5}}{3.46 \times 10^{-5}} = \frac{1.06 \times 10^5}{8.3145}\left(\frac{1}{298} - \frac{1}{T_2}\right)$$

$$1.024 = 1.27 \times 10^4\left(0.00336 - \frac{1}{T_2}\right) = 42.7 - \frac{1.27 \times 10^4}{T_2}$$

$$\frac{1.27 \times 10^4}{T_2} = 42.7 - 1.024 = 41.7$$

$$T_2 = \frac{(1.27 \times 10^4)}{41.7} = 305\text{ K}$$

Assess

Both methods agree extremely well in this case. Depending on the circumstance one method may be preferred over the other.

PRACTICE EXAMPLE A: What is the half-life of the first-order decomposition of N_2O_5 at 75.0 °C? Use data from Example 14-9.

PRACTICE EXAMPLE B: At what temperature will it take 1.50 h for two-thirds of a sample of N_2O_5 in CCl_4 to decompose in Example 14-9?

collisions, (2) the fraction of collisions energetic enough to produce a reaction, and (3) the need for favorable orientations during collisions. Let's represent the collision frequency by the symbol Z_0. From kinetic-molecular theory, the fraction of sufficiently energetic collisions proves to be $e^{-E_a/RT}$. The probability of favorable orientations of colliding molecules is p and commonly referred to as the steric factor. Typical steric factors are given in the table below. Notice that the steric factor decreases as the complexity of the reactant molecules increases. This reflects the fact that fewer collisions will occur with the proper orientation to produce chemical reactions.

In collision theory, the rate constant of a reaction can be expressed as the product of Z_0, $e^{-E_a/RT}$, and p. If the product $Z_0 \times p$ is replaced by A, collision theory yields a result identical to Arrhenius's experimentally determined equation.

$$k = Z_0 \cdot p \cdot e^{-E_a/RT} = Ae^{-E_a/RT}$$

▲ Both the rate of chirping of tree crickets and the flashing of fireflies roughly double for a 10 °C temperature rise. This corresponds to an activation energy of about 50 kJ/mol and suggests that the physiological processes governing these phenomena involve chemical reactions.

Steric Factors (p) for Selected Reactions

Reaction	Steric Factor, p
$H + H \longrightarrow H_2(g)$	1
$O(g) + N_2(g) \longrightarrow N_2O(g)$	0.8
$2\,CH_3(g) \longrightarrow C_2H_6(g)$	0.073
$SO(g) + O_2(g) \longrightarrow SO_2(g) + O(g)$	2.4×10^{-3}
$CH_3(g) + C_2H_6(g) \longrightarrow CH_4(g) + C_2H_5(g)$	7.3×10^{-4}
$H_2(g) + C_2H_4(g) \longrightarrow C_2H_6(g)$	2.5×10^{-6}

14-7 CONCEPT ASSESSMENT

Without doing calculations, use a 1n k versus $1/T$ graph to explain whether the rate of change of the rate constant with temperature is affected more strongly by a low or high energy of activation.

14-10 Reaction Mechanisms

$NO_2(g)$ is known to play a key role in the formation of photochemical smog (see page 635), but it is unlikely that very much of this gas is formed in the atmosphere by the direct reaction

$$2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g) \qquad \textbf{(14.23)}$$

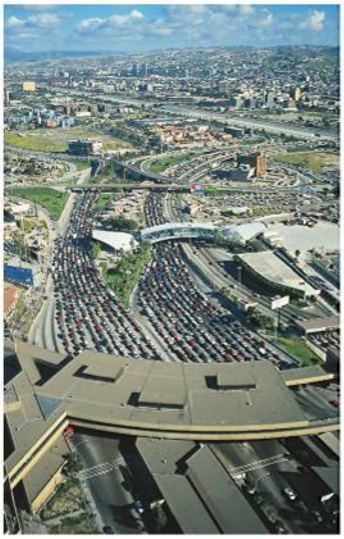
◀ Although much progress has been made in the theoretical understanding of reaction mechanisms, by far most of the data and rate constants are obtained experimentally.

For this reaction to occur in a single step in the manner suggested by equation (14.23), *three* molecules would have to collide simultaneously, or very nearly so. A three-molecule collision is an unlikely event. The reaction appears to follow a different mechanism or pathway. One of the main purposes in determining rate laws of chemical reactions is to relate them to probable reaction mechanisms.

A **reaction mechanism** is a step-by-step detailed description of a chemical reaction. Each step in a mechanism is called an **elementary process**, which describes any molecular event that significantly alters a molecule's energy or geometry or produces a new molecule. Two requirements of a plausible reaction mechanism are that it must

- be consistent with the stoichiometry of the overall reaction
- account for the *experimentally determined* rate law

In this section, we will first explore the nature of elementary processes and then apply these processes to two simple types of reaction mechanisms.



▲ FIGURE 14-13
The San Ysidro/Tijuana border station: An analogy for a rate-determining step
Note the tie-up of traffic on the Mexican side of the border (top) and the relatively few cars on the United States side (bottom). This station is a bottleneck and hence the rate-determining part of the trip by car from Tijuana, Mexico, to San Diego, California, two cities located only about a dozen miles apart.

Elementary Processes

The characteristics of elementary processes are as follows:

1. Elementary processes are either **unimolecular**—a process in which a single molecule dissociates—or **bimolecular**—a process involving the collision of two molecules. A *termolecular* process, which would involve the simultaneous collision of three molecules, is relatively rare as an elementary process.
2. The exponents of the concentration terms in the rate law for an elementary process are the *same* as the stoichiometric coefficients in the balanced equation for the process. (Note that this is unlike the case of the overall rate law, for which the exponents are *not* necessarily related to the stoichiometric coefficients in the overall equation.)
3. Elementary processes are reversible, and some may reach a condition of equilibrium in which the rates of the forward and reverse processes are equal.
4. Certain species are produced in one elementary process and consumed in another. In a proposed reaction mechanism, such intermediates must not appear in either the overall chemical equation or the overall rate law.
5. One elementary process may occur much more slowly than all the others, and in some cases may determine the rate of the overall reaction. Such a process is called the **rate-determining step** (Fig. 14-13).

Keep these characteristics in mind as we will apply them in our analysis of different mechanisms below.

A Mechanism with a Slow Step Followed by a Fast Step

The reaction between gaseous iodine monochloride and gaseous hydrogen produces iodine and hydrogen chloride as gaseous products.

$$H_2(g) + 2\,ICl(g) \longrightarrow I_2(g) + 2\,HCl(g)$$

The experimentally determined rate law for this reaction is

$$\text{rate of reaction} = k[H_2][ICl]$$

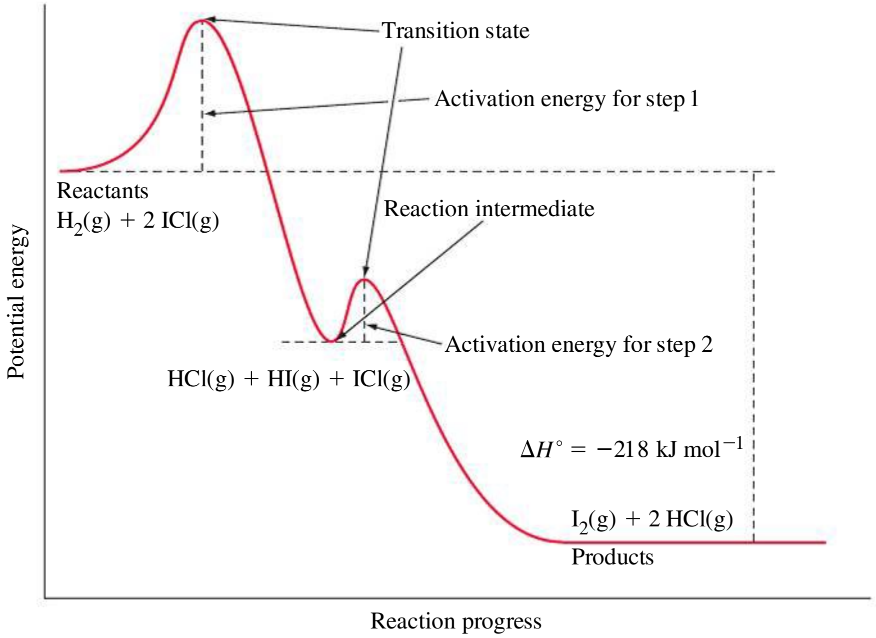
Let's begin with a mechanism that seems plausible, such as the following two-step mechanism.

$$\begin{array}{ll} \textit{(1) Slow:} & H_2 + ICl \longrightarrow HI + HCl \\ \textit{(2) Fast:} & HI + ICl \longrightarrow I_2 + HCl \\ \hline \textit{Overall:} & H_2 + 2\,ICl \longrightarrow I_2 + 2\,HCl \end{array}$$

This scheme seems plausible for two reasons: (1) The sum of the two steps yields the experimentally observed *overall* reaction. (2) As we have noted, unimolecular and bimolecular elementary processes are most plausible, and each step in the above mechanism is bimolecular. Because each step is an elementary process, we can write

$$\text{rate (1)} = k_1[H_2][ICl] \qquad \text{and} \qquad \text{rate (2)} = k_2[HI][ICl]$$

Now, note that our mechanism proposes that step (1) occurs slowly but step (2) occurs rapidly. This suggests that HI is consumed in the second step just as fast as it is formed in the first. The first step is the rate-determining step, and



◀ FIGURE 14-14
A reaction profile for a two-step mechanism

the rate of the overall reaction is governed just by the rate at which HI is formed in this first step, that is, by rate (1). This explains why the observed rate law for the net reaction is rate of reaction = $k[H_2][ICl]$. The proposed mechanism gives a rate law that is in agreement with experiment, as it should if we have made a reasonable proposal.

The species HI is called a **reaction intermediate**, and it does not appear in the experimental rate law. In this case, the intermediate species is a well-known stable molecule. Often, when postulating mechanisms, we have to invoke less well-known and less stable species; and in these instances, we have to rely on the chemical reasonableness of the basic assumptions. The presence of a reaction intermediate leads to a slightly more complicated reaction profile. The reaction profile for the two steps in the proposed mechanism is shown in Figure 14-14. We see that there are two transition states and one reaction intermediate. The activation energy for the first step is greater than that for the second step, which we would expect if the first step in the reaction mechanism is the slowest. It is important to understand the difference between a transition state (activated complex) and a reaction intermediate. The transition state represents the highest energy structure involved in a reaction (or step in a mechanism). While transition states exist only momentarily and can never be isolated, reaction intermediates can sometimes be isolated. Transition states have *partially formed bonds*, whereas reaction intermediates have *fully formed bonds*.

◀ A transition state is not a “real” species. It is only hypothetical.

A Mechanism with a Fast Reversible First Step Followed by a Slow Step

The rate law for the reaction of NO(g) and $O_2(g)$

$$2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g) \qquad \textbf{(14.23)}$$

is found to be

$$\text{rate of reaction} = k[NO]^2[O_2] \qquad \textbf{(14.24)}$$

Even though it is consistent with this rate law, we have already noted that the one-step *termolecular* mechanism suggested by equation (14.23) is highly improbable. Let’s explore instead the following mechanism.

$$\text{Fast:} \qquad 2\,NO(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} N_2O_2(g) \qquad (14.25)$$

$$\text{Slow:} \qquad N_2O_2(g) + O_2(g) \xrightarrow{k_2} 2\,NO_2(g) \qquad (14.26)$$

$$\text{Overall:} \qquad 2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g) \qquad (14.23)$$

In this mechanism, there is a rapid equilibrium as the first step, but some of the N_2O_2 is slowly drawn off and consumed in the second, slow step. The rate law for the slow, or *rate-determining*, step (14.26) is

$$\text{rate of reaction} = k_2[N_2O_2][O_2] \qquad (14.27)$$

Because N_2O_2 is an *intermediate*, however, we must eliminate it from the rate law. We are told that the first step of the mechanism consists of a fast reversible reaction, so we can assume that this step progresses rapidly to equilibrium. If this is the case, the forward and reverse rates of reaction in the first step become equal and we write

$$\text{rate of forward reaction} = \text{rate of reverse reaction}$$
$$k_1[NO]^2 = k_{-1}[N_2O_2]$$

Now, let us arrange this equation into an expression having a ratio of rate constants on one side and a ratio of concentration terms on the other. Also, we can replace the ratio of rate constants by a single constant, which we will represent as K_1.

$$K_1 = \frac{k_1}{k_{-1}} = \frac{[N_2O_2]}{[NO]^2}$$

The above expression is known as an equilibrium constant expression; the numerical constant, K_1, is an equilibrium constant. Next, we rearrange the expression to solve for the term $[N_2O_2]$.

$$[N_2O_2] = K_1[NO]^2$$

Then, substituting this into equation (14.27) we obtain the experimentally observed rate law.

$$\text{rate of reaction} = k_2[N_2O_2][O_2] = k_2K_1[NO]^2[O_2]$$

The experimentally observed rate constant, k, is related to the other constants in the proposed mechanism, as follows:

$$k = k_2K_1 = k_2 \times \frac{k_1}{k_{-1}}$$

The type of mechanism described here with a *rapid pre-equilibrium* is a very common mechanism and is to be expected when the overall stoichiometry suggests an unlikely termolecular collision.

We have just shown that the proposed mechanism is consistent with (a) the reaction stoichiometry and (b) the experimentally determined rate law. Whether this mechanism is the actual reaction path, we cannot say, however. All that we can say is that it is *plausible*; it has not been ruled out by kinetics.

▶ The IUPAC convention for labeling rate constants is as follows: The rate constants for the steps in a mechanism are numbered sequentially, k_1, k_2, k_3, and so on. If step n is a reversible step, then the rate constant for the reverse reaction is denoted k_{-n}. This is just a labeling convention and no mathematical relationship is implied.

▶ Equilibrium constant expressions are of fundamental importance throughout chemistry. Here, we see their significance in chemical kinetics. In Chapter 15, we describe the experimental basis of equilibrium constant expressions and their application to the stoichiometry of reversible reactions. In Chapter 19, we explore their thermodynamic basis.

The Steady-State Approximation

The reaction mechanisms considered so far have had one particular rate-determining step, and the rate law of the reaction could be deduced from the rate of this step after the relationships for the concentrations of any intermediates were established. In complex multistep reaction mechanisms, however, more than one step may control the rate of a reaction.

EXAMPLE 14-10 Testing a Reaction Mechanism

An alternative mechanism of the reaction $2\,\mathrm{NO(g)} + \mathrm{O_2(g)} \longrightarrow 2\,\mathrm{NO_2(g)}$ follows. Show that this mechanism is consistent with the rate law (14.24).

$$\begin{array}{ll} \textit{Fast:} & \mathrm{NO(g)} + \mathrm{O_2(g)} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{NO_3(g)} \\ \textit{Slow:} & \mathrm{NO_3(g)} + \mathrm{NO(g)} \xrightarrow{k_2} 2\,\mathrm{NO_2(g)} \\ \hline \textit{Overall:} & 2\,\mathrm{NO(g)} + \mathrm{O_2(g)} \longrightarrow 2\,\mathrm{NO_2(g)} \end{array}$$

Analyze

In this type of problem we begin by identifying the slow step (which is typically given) and using it to write the rate of reaction. Because the fast step shown above is given as an equilibrium, we can assume that the equilibrium is rapidly established. The common species between the two reactions, NO_3, also called an intermediate, is not found in the rate law, and so it can be eliminated by using the reaction equilibrium constant expression for the fast step.

Solve

The rate equation for the rate-determining step is

$$\text{rate of reaction} = k_2[\mathrm{NO_3}][\mathrm{NO}]$$

Eliminate $[NO_3]$, by assuming that the pre-equilibrium is rapidly established.

$$\text{rate of forward reaction} = \text{rate of reverse reaction}$$
$$k_1[\mathrm{NO}][\mathrm{O_2}] = k_{-1}[\mathrm{NO_3}]$$

Rearrange the previous equation to develop an expression for an equilibrium constant (K) in terms of the rate constants k_1 and k_{-1}.

$$K = \frac{k_1}{k_{-1}} = \frac{[\mathrm{NO_3}]}{[\mathrm{NO}][\mathrm{O_2}]}$$

Rearrange this expression for K to solve for $[NO_3]$.

$$[\mathrm{NO_3}] = K[\mathrm{NO}][\mathrm{O_2}]$$

Finally, substitute the value of $[NO_3]$ into the rate equation to obtain the observed rate law (equation 14.24).

$$\text{rate} = k_2[\mathrm{NO_3}][\mathrm{NO}]$$
$$\text{rate of reaction} = k_2K[\mathrm{NO}]^2[\mathrm{O_2}] = k_2\frac{k_1}{k_{-1}}[\mathrm{NO}]^2[\mathrm{O_2}] = k[\mathrm{NO}]^2[\mathrm{O_2}]$$

Assess

The final rate law obtained, rate $= k[\mathrm{NO}]^2[\mathrm{O_2}]$, is consistent with the experimental rate law. This alternative mechanism is plausible based on this analysis. However, it does not mean that this is the reaction mechanism.

PRACTICE EXAMPLE A: In a proposed two-step mechanism for the reaction $\mathrm{CO(g)} + \mathrm{NO_2(g)} \longrightarrow \mathrm{CO_2(g)} + \mathrm{NO(g)}$, the second, fast step is $\mathrm{NO_3(g)} + \mathrm{CO(g)} \longrightarrow \mathrm{NO_2(g)} + \mathrm{CO_2(g)}$. What must be the *slow* step? What would you expect the rate law of the reaction to be? Explain.

PRACTICE EXAMPLE B: Show that the proposed mechanism for the reaction $2\,\mathrm{NO_2(g)} + \mathrm{F_2(g)} \longrightarrow 2\,\mathrm{NO_2F(g)}$ is plausible. The rate law is rate $= k[\mathrm{NO_2}][\mathrm{F_2}]$.

$$\begin{array}{ll} \textit{Fast:} & \mathrm{NO_2(g)} + \mathrm{F_2(g)} \rightleftharpoons \mathrm{NO_2F_2(g)} \\ \textit{Slow:} & \mathrm{NO_2F_2(g)} \longrightarrow \mathrm{NO_2F(g)} + \mathrm{F(g)} \\ \textit{Fast:} & \mathrm{F(g)} + \mathrm{NO_2(g)} \longrightarrow \mathrm{NO_2F(g)} \end{array}$$

To illustrate, let's reconsider the first mechanism presented for the reaction of nitric oxide with oxygen, but this time we will make no assumptions about the relative rates of the steps in the mechanism. The proposed mechanism is

$$\mathrm{NO} + \mathrm{NO} \xrightarrow{k_1} \mathrm{N_2O_2}$$
$$\mathrm{N_2O_2} \xrightarrow{k_{-1}} \mathrm{NO} + \mathrm{NO}$$
$$\mathrm{N_2O_2} + \mathrm{O_2} \xrightarrow{k_2} 2\,\mathrm{NO_2}$$

For clarity, the first, reversible reaction is written as two separate steps.

We choose one of the steps of the mechanism that provides a convenient relationship to the observed rate of reaction. In this case, we will use the last step, since it involves the disappearance of O_2. Therefore, the rate of the reaction from this mechanism is

KEEP IN MIND

that if the rate of change of the concentration of a substance is zero, then the concentration of that substance is constant.

$$\text{rate of reaction} = k_2[N_2O_2][O_2] \qquad \textbf{(14.27)}$$

As before, the intermediate N_2O_2 must be eliminated from this rate law. We can do this by assuming that the $[N_2O_2]$ reaches a *steady-state condition* in which N_2O_2 is produced and consumed at equal rates. That is, $[N_2O_2]$ remains constant throughout most of the reaction. We can use the steady-state assumption to express $[N_2O_2]$ in terms of $[NO]$.

$$\Delta[N_2O_2]/\Delta t = \text{rate of formation of } N_2O_2 - \text{rate of disappearance of } N_2O_2 = 0$$

$$\text{rate of formation of } N_2O_2 = \text{rate of disappearance of } N_2O_2$$

The rate of disappearance of N_2O_2 is made up of two parts—the reverse step of equation (14.25) and the forward step of (14.26)—so we write

$$\text{rate of disappearance of } N_2O_2 = k_{-1}[N_2O_2] + k_2[N_2O_2][O_2]$$

The two rates for the steps depleting the concentration of N_2O_2 have been added. Now, as dictated by the steady-state assumption, the rate of disappearance of N_2O_2 is equated with the rate of appearance of N_2O_2, which is $k_1[NO]^2$.

$$k_1[NO]^2 = k_{-1}[N_2O_2] + k_2[N_2O_2][O_2] = [N_2O_2](k_{-1} + k_2[O_2])$$

Rearranging to solve for $[N_2O_2]$, we have

$$[N_2O_2] = \frac{k_1[NO]^2}{k_{-1} + k_2[O_2]}$$

We now substitute this into equation (14.27) to obtain

$$\text{rate} = k_2[O_2][N_2O_2] = k_2[O_2]\left(\frac{k_1[NO]^2}{k_{-1} + k_2[O_2]}\right)$$

▶ Note that this rate does not follow the usual *n*th order reaction rate law as seen in Table 14.5.

or

$$\text{rate} = \frac{k_1k_2[O_2][NO]^2}{k_{-1} + k_2[O_2]}$$

This is the rate law for the proposed mechanism based on our steady-state analysis. This rate law is more complicated than the observed rate law. What happened? In carrying out the steady-state calculation, we did not make any assumptions about the relative rates of the three steps in the mechanism. If we now make the assumption that the rate of disappearance of N_2O_2 in the second step of the proposed mechanism is greater than the rate of disappearance of N_2O_2 in the third step of the proposed mechanism, then

$$k_{-1}[N_2O_2] > k_2[N_2O_2][O_2]$$

which means

$$k_{-1} > k_2[O_2]$$

and

$$k_{-1} + k_2[O_2] \approx k_{-1}$$

so that

$$[N_2O_2] = \frac{k_1[NO]^2}{k_{-1}}$$

If we substitute this value of $[N_2O_2]$ into the rate equation (14.27) and replace k_1k_2/k_{-1} by k, we obtain for the overall reaction

$$\text{rate of reaction} = \frac{k_1k_2}{k_{-1}}[NO]^2[O_2] = k[NO]^2[O_2] \qquad \textbf{(14.24)}$$

The result of a steady-state analysis of any mechanism in which no rate-determining step can be identified will often be a complicated rate law. The use of this type of rate law is illustrated in the section on enzyme catalysis later in this chapter.

Smog—An Environmental Problem with Roots in Chemical Kinetics

About 100 years ago, a new word entered the English language—**smog**. It referred to a condition, common in London, in which a combination of *smoke* and *fog* obscured visibility and produced health hazards (including death). These conditions are often associated with heavy industry, and this type of smog is now called *industrial* smog.

◀ Air quality in London has been greatly improved by control measures, such as elimination of coal as a household fuel, introduced after a severe smog episode in 1952.

A more familiar form of air pollution commonly thought of as smog results from the action of sunlight on the products of combustion. Chemical reactions brought about by light are called *photochemical* reactions, and the smog formed primarily as a result of photochemical reactions is photochemical smog. This type of smog is associated with high-temperature combustion processes, such as those that occur in internal combustion engines. Because the combustion of motor fuels takes place in air rather than in pure oxygen, oxides of nitrogen, principally NO(g), are inevitably found in the exhaust from motor vehicles. Other products found in the exhaust are hydrocarbons (unburned gasoline) and partially oxidized hydrocarbons. These, then, are the starting materials—the precursors—of photochemical smog.

Many substances have been identified in smoggy air, including NO, NO_2, O_3 (ozone, an allotrope of oxygen introduced on page 416 and discussed further in Section 22-4), and a variety of organic compounds derived from gasoline hydrocarbons. Ozone is very reactive and is largely responsible for the breathing difficulties that some people experience during smog episodes. Another noxious substance found in smog is an organic compound known as peroxyacetyl nitrate (PAN). PAN is a powerful lacrimator—that is, it causes tear formation in the eyes. Photochemical smog components cause heavy crop damages (to oranges, for example) and the deterioration of rubber goods. And, of course, the best-known symbol of photochemical smog is the hazy brown air that results in reduced visibility (Fig. 14-15).

▲ FIGURE 14-15
Smog in Mexico City
At times, the topographical features, climatic conditions, traffic congestion, and heavy industrial pollution combine to create severe smog conditions in Mexico City.

Chemists who have been studying photochemical smog formation over the past several decades have determined that certain precursors are converted to the observable smog components through the action of sunlight. Because the chemical reactions involved are very complex and still not totally understood, we will give only a very brief, simplified reaction mechanism showing how photochemical smog is formed.

Smog formation begins with NO(g), produced by reaction (14.28).

$$N_2(g) + O_2(g) \xrightarrow{\Delta} 2\,NO(g) \qquad \textbf{(14.28)}$$

NO(g) is subsequently converted to $NO_2(g)$, which then absorbs ultraviolet radiation from sunlight and decomposes.

$$NO_2 + \text{sunlight} \longrightarrow NO + O \qquad \textbf{(14.29)}$$

This is followed by a reaction forming ozone, O_3.

$$O + O_2 \longrightarrow O_3 \qquad \textbf{(14.30)}$$

Thus, a large buildup of ozone in photochemical smog requires a plentiful source of NO_2. At one time, this source was believed to be reaction (14.31).

$$2\,NO + O_2 \longrightarrow 2\,NO_2 \qquad \textbf{(14.31)}$$

It is now well established, however, that reaction (14.31) occurs much too slowly to yield the required levels of NO_2 in photochemical smog. Instead, NO is rapidly converted to NO_2 when it reacts with O_3,

$$O_3 + NO \longrightarrow O_2 + NO_2 \qquad \textbf{(14.32)}$$

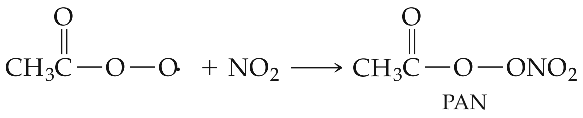
Even though reaction (14.32) accounts for the formation of NO_2, it leads to the destruction of ozone. Thus, photochemical smog formation cannot occur just through the reaction sequence: (14.28), (14.29), (14.30), and (14.31). The ozone would be consumed as quickly as it was formed, and there would be no ozone buildup at all.

It is now known that organic compounds, particularly unburned hydrocarbons in automotive exhaust, provide a pathway for the conversion of NO to NO_2. The reaction sequence that follows involves some highly reactive molecular fragments. Recall (page 418) that these fragments are known as *free radicals* and are represented by formulas written with a bold dot. RH represents a hydrocarbon molecule, and $R\cdot$ is a free-radical fragment of a hydrocarbon molecule. Oxygen atoms, fragments of the O_2 molecule, are also represented as free radicals, as are hydroxyl groups, fragments of the H_2O molecule.

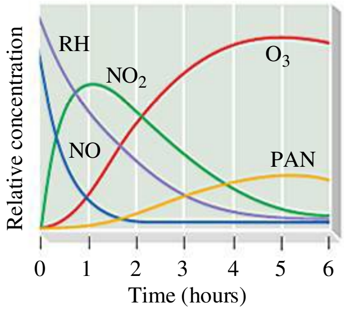
$$\begin{aligned} RH + O\cdot &\longrightarrow R\cdot + \cdot OH \\ RH + \cdot OH &\longrightarrow R\cdot + H_2O \\ R\cdot + O_2 &\longrightarrow RO_2\cdot \\ RO_2\cdot + NO &\longrightarrow RO\cdot + NO_2 \end{aligned}$$

The final step in this reaction mechanism accounts for the rapid conversion of NO to NO_2 that seems essential to smog formation.

The role of NO_2 in the formation of the smog component PAN is suggested by the equation



$$CH_3\overset{\overset{O}{\|}}{C}{-}O{-}O\cdot + NO_2 \longrightarrow \underset{PAN}{CH_3\overset{\overset{O}{\|}}{C}{-}O{-}ONO_2}$$



▲ FIGURE 14-16
Smog component profile
Data from a smog chamber show how the concentrations of smog components change with time. For example, the concentrations of hydrocarbon (RH) and nitrogen monoxide (NO) fall continuously, whereas that of nitrogen dioxide (NO_2) rises to a maximum and then drops off. The concentrations of ozone (O_3) and peroxyacetyl nitrate (PAN) build up more slowly. Any reaction scheme proposed to explain smog formation must be consistent with observations such as these. Under actual smog conditions, the pattern of concentration changes shown here repeats itself on a daily basis.

The details of smog formation have been worked out in part through the use of smog chambers. By varying experimental conditions in these chambers, scientists have been able to create polluted atmospheres very similar to smog. For example, they have found that if hydrocarbons are omitted from the starting materials in the smog chamber, no ozone is formed. The reaction scheme just proposed is consistent with this observation. Figure 14-16 gives a typical result from a smog chamber.

To control smog, automobiles are now provided with *catalytic converters*. CO and hydrocarbons are oxidized to CO_2 and H_2O in the presence of an oxidation catalyst such as platinum or palladium metal. NO must be reduced to N_2, and this requires a reduction catalyst. A dual-catalyst system uses both types of catalysts. Alternatively, the air-fuel ratio of the engine is set to produce some CO and unburned hydrocarbons; these then act as reducing agents to reduce NO to N_2.

$$2\,CO(g) + 2\,NO(g) \longrightarrow 2\,CO_2(g) + N_2(g)$$

Next, the exhaust gases are passed through an oxidation catalyst to oxidize the remaining hydrocarbons and CO to CO_2 and H_2O. Future smog-control measures may include the use of alternative fuels, such as methanol or hydrogen, and the development of electric-powered automobiles.

14-11 Catalysis

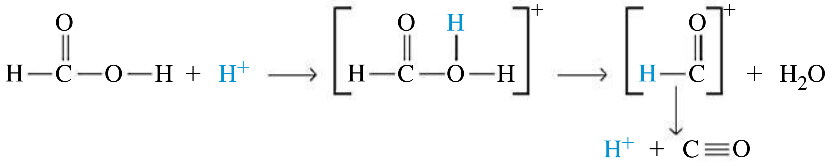
A reaction can generally be made to go faster by increasing the temperature. Another way to speed up a reaction is to use a catalyst. A **catalyst** provides an alternative reaction pathway of lower activation energy. The catalyst participates in a chemical reaction but does not itself undergo a permanent change. As a result, the formula of a catalyst does not appear in the overall chemical equation (its formula is generally placed over the reaction arrow).

The success of a chemical process often hinges on finding the right catalyst, as in the manufacture of nitric acid. By conducting the oxidation of $NH_3(g)$ very quickly (less than 1 ms) in the presence of a Pt–Rh catalyst, $NO(g)$ can be obtained as a product instead of $N_2(g)$. The formation of $HNO_3(aq)$ from $NO(g)$ then follows easily.

In this section, the two basic types of catalysis—homogeneous and heterogeneous—are described first. This is followed by discussions of the catalyzed decomposition of $H_2O_2(aq)$ and the biological catalysts called enzymes.

Homogeneous Catalysis

Figure 14-17 shows reaction profiles for the decomposition of formic acid (HCOOH). In the uncatalyzed reaction, a H atom must be transferred from one part of the formic acid molecule to another, shown by the arrow. Then a C—O bond breaks. Because the energy requirement for this atom transfer is high, the activation energy is high and the reaction is slow. In the acid-catalyzed decomposition of formic acid, a hydrogen ion from solution attaches itself to the O atom that is singly bonded to the C atom to form $[HCOOH_2]^+$. The C—O bond breaks, and a H atom attached to a carbon atom in the intermediate species $[HCO]^+$ is released to the solution as H^+.

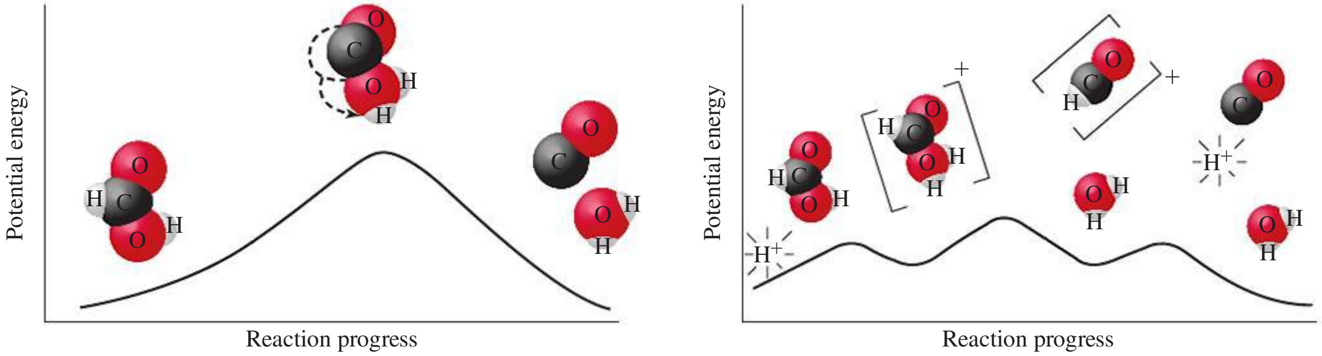


$$\mathrm{H-\overset{\overset{O}{\|}}{C}-O-H} + \mathrm{H^+} \longrightarrow \left[\mathrm{H-\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{O}-H}\right]^+ \longrightarrow \left[\mathrm{H-\overset{\overset{O}{\|}}{C}}\right]^+ + \mathrm{H_2O}$$

$$\downarrow$$

$$\mathrm{H^+} + \mathrm{C\equiv O}$$

This catalyzed reaction pathway does not require a H atom to be transferred within the formic acid molecule. It has a lower activation energy than does the uncatalyzed reaction and proceeds at a faster rate. Because the reactants and products of this reaction are all present throughout the solution, or homogeneous mixture, this type of catalysis is called **homogeneous catalysis**.



(a) Uncatalyzed reaction **(b)** Catalyzed reaction

▲ FIGURE 14-17
An example of homogeneous catalysis
The activation energy is lowered in the presence of H^+, a catalyst for the decomposition of HCOOH.

Heterogeneous Catalysis

Many reactions can be catalyzed by allowing them to occur on an appropriate solid surface. Essential reaction intermediates are found on the surface. This type of catalysis is called **heterogeneous catalysis** because the catalyst is present in a different phase of matter than are the reactants and products. Catalytic activity is associated with many transition elements and their compounds. The precise mechanism of heterogeneous catalysis is not totally understood, but in many cases the availability of electrons in *d* orbitals in surface atoms may play a role.

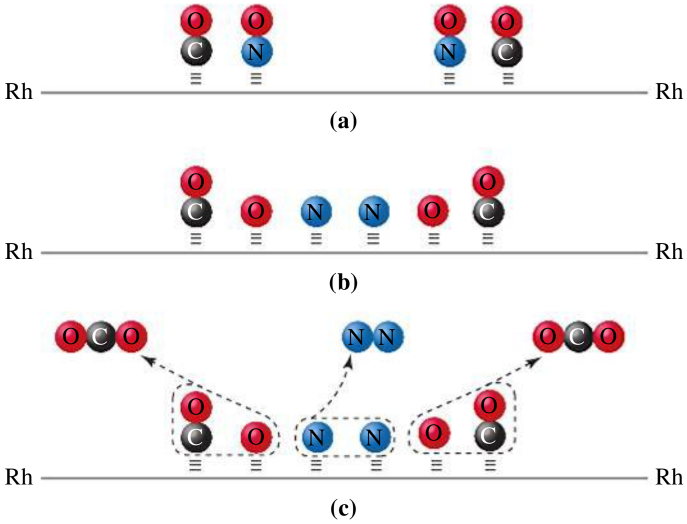
A key feature of heterogeneous catalysis is that reactants from a gaseous or solution phase are adsorbed, or attached, to the surface of the catalyst. Not all surface atoms are equally effective for catalysis; those that are effective are called **active sites**. Basically, heterogeneous catalysis involves (1) *adsorption* of reactants; (2) *diffusion* of reactants along the surface; (3) *reaction* at an active site to form adsorbed product; and (4) *desorption* of the product.

An interesting reaction is the oxidation of CO to CO_2 and the reduction of NO to N_2 in automotive exhaust gases as a smog-control measure. Figure 14-18 shows how this reaction is thought to occur on the surface of rhodium metal in a catalytic converter. In general, the reaction profile for a surface–catalyzed reaction resembles that shown in Figure 14-19.

The Catalyzed Decomposition of Hydrogen Peroxide

As previously noted (see the footnote on page 605), the decomposition of $H_2O_2(aq)$ is a slow reaction and generally must be catalyzed. Iodide ion is a good catalyst that seems to function by means of the following two-step mechanism.

$$\begin{array}{lrcl} \textit{Slow:} & H_2O_2 + I^- & \longrightarrow & OI^- + H_2O \\ \textit{Fast:} & H_2O_2 + OI^- & \longrightarrow & H_2O + I^- + O_2(g) \\ \hline \textit{Overall:} & 2\,H_2O_2 & \longrightarrow & 2\,H_2O + O_2(g) \end{array}$$



▲ FIGURE 14-18
Heterogeneous catalysis in the reaction

$$2\,CO + 2\,NO \xrightarrow{Rh} 2\,CO_2 + N_2$$

(a) Molecules of CO and NO are adsorbed on the rhodium surface. **(b)** The adsorbed NO molecules dissociate into adsorbed N and O atoms. **(c)** Adsorbed CO molecules and O atoms combine to a form CO_2 molecules, which desorb into the gaseous state. Two N atoms combine and are desorbed as a N_2 molecule.

▲ FIGURE 14-19
Reaction profile for a surface-catalyzed reaction
In the reaction profile (blue) for the surface-catalyzed reaction, the activation energy for the reaction step, E_s, is considerably less than in the reaction profile (red) for the uncatalyzed gas-phase reaction, E_g.

As required for a catalyzed reaction, the formula of the catalyst does not appear in the overall equation. Neither does the intermediate species OI^-. The rate of reaction of H_2O_2 is determined by the rate of the slow first step.

$$\text{rate of reaction } H_2O_2 = k[H_2O_2][I^-] \qquad \textbf{(14.33)}$$

◀ Although catalysts are not in the overall chemical equation, they do participate in the chemical reaction and do appear in the mechanism.

◀ The decomposition of hydrogen peroxide, H_2O_2, to H_2O and O_2 is a highly exothermic reaction that is catalyzed by platinum metal.

Because I^- is constantly regenerated, its concentration is constant throughout a given reaction. If the product of the constant terms $k[I^-]$ is replaced by a new constant, k', the rate law can be rewritten as

$$\text{rate of reaction of } H_2O_2 = k'[H_2O_2] \tag{14.34}$$

Equation (14.33) indicates that the rate of decomposition of $H_2O_2(aq)$ is affected by the initial concentration of I^-. For each initial concentration of I^-, we obtain a different rate constant, k', in equation (14.34).

We have just described the homogeneous catalysis of the decomposition of hydrogen peroxide. The decomposition can also be catalyzed by heterogeneous catalysis, as seen at the bottom of page 639.

14-8 CONCEPT ASSESSMENT

In the production of ammonia from nitrogen and hydrogen, the rate of reaction can be increased by using a catalyst or by increasing the temperature. Is the means by which these two different methods increase the rate of reaction the same? Explain.

Enzymes as Catalysts

Unlike platinum, which catalyzes a wide variety of reactions, the catalytic action of high-molar-mass proteins known as **enzymes** is very specific. For example, in the digestion of milk, lactose, a more complex sugar, breaks down into two simpler ones, glucose and galactose. This occurs in the presence of the enzyme *lactase*.

$$\underset{\text{"Milk sugar"}}{\text{lactose}} \xrightarrow{\text{lactase}} \text{glucose} + \text{galactose}$$

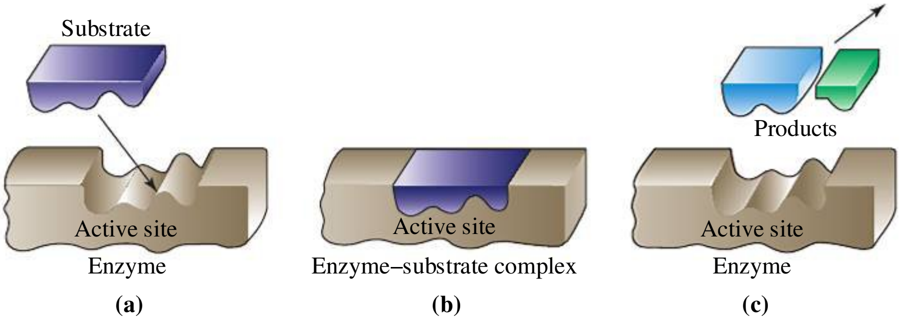
▶ Many people lose the ability to produce lactase when they become adults. In such cases, lactose passes through the small intestine into the colon, where it ferments and may cause severe gastric disturbances.

Biochemists describe enzyme activity with the "lock-and-key" model (Fig. 14-20). The reacting substance, the **substrate** (S), attaches itself to the enzyme (E) at a particular point called an *active site* to form the enzyme–substrate complex (ES). The complex decomposes to form products (P) and regenerate the enzyme.

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES$$

$$ES \xrightarrow{k_2} E + P$$

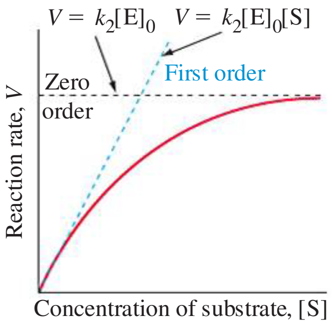
▲ A computer graphics representation of the enzyme phosphoglycerate kinase (carbon backbone shown as blue ribbon). A molecule of ATP, the substrate, is shown in green.



▲ FIGURE 14-20
Lock-and-key model of enzyme action
(a) The substrate attaches itself to an active site on an enzyme molecules. **(b)** Reaction occurs. **(c)** Product molecules detach themselves from the site, freeing the enzyme molecule to attach another molecule of substrate. The substrate and enzyme must have complementary structures to produce a complex, hence the term *lock and key*.

Most human enzyme-catalyzed reactions proceed fastest at about 37 °C (body temperature). If the temperature is raised much higher than that, the structure of the enzyme changes, the active sites become distorted, and the catalytic activity is lost.

Determining the rates of enzyme-catalyzed reactions is an important part of enzyme studies. Figure 14-21, a plot of reaction rate against substrate concentration, illustrates what we generally observe. Along the rising portion of the graph, the rate of reaction is proportional to the substrate concentration, $[S]$. The reaction is first order: rate of reaction $= k[S]$. At high substrate concentrations, the rate is independent of $[S]$. The reaction follows a zero-order rate equation: rate of reaction $= k$.



▲ FIGURE 14-21
Effect of substrate concentration on the rate of an enzyme reaction

This behavior can be understood in terms of the three-step mechanism given above. The rate at which the product appears, which is often called the velocity (V) of the reaction by biochemists, is given by

$$\text{rate of production of P} = V = k_2[ES]$$

To proceed further, we need an expression for the enzyme–substrate complex, and we can get this by applying the steady-state approximation to the concentration of the enzyme–substrate complex.

$$\text{rate of formation of ES} = \text{rate of destruction of ES}$$

$$k_1[E][S] = (k_{-1} + k_2)[ES] \qquad \textbf{(14.35)}$$

We can solve this equation for $[ES]$, but the solution contains the concentration of free enzyme E, which is unknown. However, we do know the *total* concentration of enzyme in an experiment, $[E]_0$. Then, by the condition known as *material balance*, we have

$$[E]_0 = [E] + [ES]$$

Solving this equation for $[E]$ and substituting the result into equation (14.35), we get

$$k_1[S([E]_0 - [ES]) = (k_{-1} + k_2)[ES]$$

$$[ES] = \frac{k_1[E]_0[S]}{(k_{-1} + k_2) + k_1[S]}$$

for the concentration of the enzyme–substrate complex. Substituting this value into the rate of reaction, we get

$$V = \frac{k_2 k_1[E]_0[S]}{(k_{-1} + k_2) + k_1[S]}$$

This equation can be put into a more convenient form by dividing the numerator and denominator by k_1 and replacing a ratio of rate constants by the single constant K_M.

$$K_M = \frac{k_{-1} + k_2}{k_1}$$

Our final result is

$$V = \frac{k_2[E]_0[S]}{K_M + [S]} \qquad \textbf{(14.36)}$$

◀ The reaction mechanism outlined here was proposed by Michaelis and Menten in 1913, accounting for the subscript M in the constant K_M.

Now, let's test whether the reaction velocity V, given by equation (14.36), depends on the substrate concentration in the manner suggested by Figure 14-21. At sufficiently low concentrations of S, we have the inequality

$$K_M \gg [S]$$

We can ignore [S] with respect to K_M in the denominator and obtain the following for the reaction velocity.

$$V = \frac{k_2}{K_M}[\text{E}]_0[\text{S}]$$

Because the total enzyme concentration is constant, the rate law is first order with respect to substrate, as observed experimentally.

The other limiting case is that in which the velocity of the reaction becomes independent of substrate concentration. At sufficiently high concentrations of substrate,

$$[\text{S}] \gg K_M$$

and

$$V = k_2[\text{E}]_0$$

Here, for a chosen concentration of enzyme, the reaction velocity is constant and is the maximum reaction velocity attainable for the particular enzyme. This velocity corresponds to the experimentally observed plateau at high substrate concentrations in a plot such as Figure 14-21. Thus, there is a satisfactory agreement between the predictions of the postulated mechanism and the experimental results. As is typical of the scientific method, postulated mechanisms are continually tested by subsequent experiment and modified when necessary.

MasteringCHEMISTRY www.masteringchemistry.com

A typical explosion is a combustion reaction that proceeds at an ever-increasing rate. For a discussion of how combustion reactions can become explosive and ways to prevent such occurrences, go to the Focus On feature for Chapter 14, Combustion and Explosions, on the MasteringChemistry site.

Summary

14-1 Rate of a Chemical Reaction—The **rate of reaction** reflects the rate of change in the concentrations of the reactants and products of a reaction. A *general rate of reaction* (equation 14.2) is defined so that the same value is obtained no matter which reactant or product serves as the basis of kinetic measurements.

14-2 Measuring Reaction Rates—An **initial rate of reaction** is the rate measured over a short time interval at the start of a reaction. An **instantaneous rate of reaction** is assessed over an infinitesimal time interval at any point in the reaction, often through the slope of a tangent line to a graph of concentration versus time (Fig. 14-2). Reaction rates measured over longer time intervals are simply *average* rates, since in almost all cases reaction rates continuously decrease as a reaction proceeds.

14-3 Effect of Concentration on Reaction Rates: The Rate Law—The relationship between the rate of a reaction and the concentrations of the reactants is called the **rate law (rate equation)** (equation 14.6); it has the form: rate of reaction $= k[\text{A}]^m[\text{B}]^n \cdots$. The **order of a reaction** refers to the exponents $m, n, \ldots$ in the rate law. If $m = 2$, the reaction is second order in A; if $n = 1$, the reaction is first order in B; and so on. The *overall order* of a reaction is given by the sum $m + n + \cdots$. One method of establishing the rate law of a reaction is by the *method of initial* rates. The **rate constant** relates the rate of reaction to reactant concentrations.

14-4 Zero-Order Reactions—A reaction having $m + n + \cdots = 0$ is a **zero-order reaction** (equation 14.9). A useful equation expressing concentration of a reactant as a function of time is called an **integrated rate law** (equation 14.10). A plot of concentration as a function of time for the zero-order reaction $\text{A} \longrightarrow$ products is a straight line with a slope of $-k$ (Fig. 14-3).

14-5 First-Order Reactions—A reaction having $m + n + \cdots = 1$ is a **first-order reaction** (equations 14.12 and 14.13). A graph of ln[A] versus time for the first-order reaction $\text{A} \longrightarrow$ products is a straight line with a slope of $-k$ (Fig. 14-4). The **half-life** of a reaction is the time required for the amount of a reactant to be reduced to one-half its initial value. For a first-order reaction, the half-life is a constant (equation 14.14). Many important reactions are first-order processes, including the decay of radioactive nuclides (Table 14.4).

14-6 Second-Order Reactions—A reaction having $m + n + \cdots = 2$ is a **second-order reaction** (equations 14.17 and 14.18). A graph of 1/[A] versus time for the second-order reaction, $\text{A} \longrightarrow$ products, is a straight line with a slope of k (Fig. 14-6). For a second-order reaction, the half-life is *not* constant; each successive half-life period is twice as long as the one preceding it (equation 14.19a and 14.19b).

Some second-order reactions, called pseudo-first-order reactions, can be treated as first-order if one of the reactants is present at such a high concentration that its concentration remains essentially constant during the reaction.

14-7 Reaction Kinetics: A Summary—A helpful summary of some basic ideas of reaction kinetics can be found on pages 620 to 622 and in Table 14.5.

14-8 Theoretical Models for Chemical Kinetics—The rate of reaction depends on the number of molecular collisions per unit volume per unit time, the proportion of molecules having energies in excess of the **activation energy** (Fig. 14-8) and proper orientation of molecules for effective collisions (Fig. 14-9). **A reaction profile** (Fig. 14-10) traces the progress of a reaction, highlighting the energy states of the reactants, the products, and the **activated complex**, a hypothetical transitory species that exists in a high-energy **transition state** between reactants and products.

14-9 The Effect of Temperature on Reaction Rates—The principal basis for describing the effect of temperature on the rate of a chemical reaction is the Arrhenius equation (14.21) or a variant of it (14.22). A graph of ln k versus $1/T$ is linear, with the slope of the line equal to $-E_a/R$ (Fig. 14-12).

14-10 Reaction Mechanisms—A **reaction mechanism** is a step-by-step description of a chemical reaction consisting of a series of **elementary processes**. Rate laws are written for the elementary processes and combined into a rate law for the overall reaction. To be plausible, the reaction mechanism must be consistent with the stoichiometry of the overall reaction and its experimentally determined rate law.

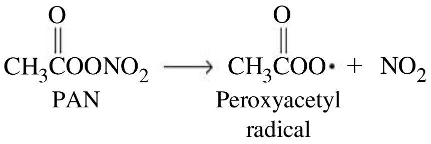
The most common elementary processes are **unimolecular** (one molecule dissociates) and **bimolecular** (two molecules collide). Some of the species in elementary processes may be **reaction intermediates**, species produced in one elementary process and consumed in another. One of the elementary processes may be the **rate-determining step**. When a single rate-determining step cannot be identified, the mechanism can often be established by the *steady-state approximation.* Reaction mechanisms can also be depicted through reaction profiles (Fig. 14-14).

Photochemical **smog** forms through the action of sunlight on the combustion products of internal combustion engines. The mechanism of its formation has been extensively studied by the methods of chemical kinetics.

14-11 Catalysis—**A catalyst** changes a reaction mechanism to one with a lower activation energy, thereby speeding up the overall reaction, but the catalyst is not itself changed by the reaction. In **homogeneous catalysis**, the catalytic reaction occurs within a single phase (Fig. 14-17). In **heterogeneous catalysis**, the catalytic action occurs on a surface separating two phases (Figs. 14-18 and 14-19). In biochemical reactions, the catalysts are high-molecular-mass proteins called **enzymes**. The reactant, called the **substrate**, attaches to the **active site** on the enzyme, where reaction occurs (Fig. 14-20). The rate of an enzyme-catalyzed reaction can be calculated with an equation (14.36) based on a generally accepted mechanism of enzyme catalysis.

Integrative Example

Peroxyacetyl nitrate (PAN) is an air pollutant produced in photochemical smog by the reaction of hydrocarbons, oxides of nitrogen, and sunlight. PAN is unstable and dissociates into peroxyacetyl radicals and $NO_2(g)$. Its presence in polluted air is like a reservoir for NO_2 storage.



$$\underset{\text{PAN}}{CH_3\overset{\overset{\displaystyle O}{\|}}{C}OONO_2} \longrightarrow \underset{\text{Peroxyacetyl radical}}{CH_3\overset{\overset{\displaystyle O}{\|}}{C}OO\cdot} + NO_2$$

The first-order decomposition of PAN has a half-life of 35 h at 0 °C and 30.0 min at 25 °C. At what temperature will a sample of air containing 5.0×10^{14} PAN molecules per liter decompose at the rate of 1.0×10^{12} PAN molecules per liter per minute?

Analyze

This problem, which requires four principal tasks, is centered on the relationship between rate constants and temperature (equation 14.22) and between a rate constant and the rate of a reaction (equation 14.6). Specifically, we will need to (1) convert the two half-lives to values of k; (2) use those values of k and their related temperatures to determine the activation energy of the reaction; (3) find the value of k corresponding to the decomposition rate specified; and (4) calculate the temperature at which k has the value determined in (3).

Solve

Determine the value of k at 0 °C for the first-order reaction.

$$k = 0.693/t_{1/2}$$

$$k = \frac{0.693}{35\ \text{h}} \times \frac{1\ \text{h}}{60\ \text{min}} = 3.3 \times 10^{-4}\ \text{min}^{-1}$$

At 25 °C,

$$k = \frac{0.693}{30.0\ \text{min}} = 2.31 \times 10^{-2}\ \text{min}^{-1}$$

To determine the activation energy of the reaction, substitute these data

$$k_2 = 2.31 \times 10^{-2}\ \text{min}^{-1};\ T_2 = 25\ °\text{C} = 298\ \text{K}$$

$$k_1 = 3.3 \times 10^{-4}\ \text{min}^{-1};\ T_1 = 0\ °\text{C} = 273\ \text{K}$$

into equation (14.22)

$$\ln\frac{k_2}{k_1} = \frac{E_a}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

$$\ln\frac{2.31 \times 10^{-2}\ \text{min}^{-1}}{3.3 \times 10^{-4}\ \text{min}^{-1}} = \frac{E_a}{8.3145\ \text{J mol}^{-1}\ \text{K}^{-1}} \times \left(\frac{1}{273\ \text{K}} - \frac{1}{298\ \text{K}}\right)$$

$$= \frac{E_a}{8.3145\ \text{J mol}^{-1}}(0.00366 - 0.00336) = 4.25$$

$$E_a = \frac{8.3145\ \text{J mol}^{-1} \times 4.25}{0.00030} = 1.2 \times 10^5\ \text{J mol}^{-1}$$

Because the reaction is first order, the rate law is rate = k[PAN], which can be rearranged to give

$$k = \text{rate}/[\text{PAN}]$$

Because mol/L and molecules/L are related through the Avogadro constant, [PAN] can be expressed as molecules/L.

$$k = \frac{\text{rate of reaction}}{[\text{PAN}]} = \frac{1.0 \times 10^{12}\ \text{molecules L}^{-1}\ \text{min}^{-1}}{5.0 \times 10^{14}\ \text{molecules L}^{-1}}$$

$$= 2.0 \times 10^{-3}\ \text{min}^{-1}$$

To determine the unknown temperature, choose one of the known combinations of k and T as k_2 and T_2. For example,

$$k_2 = 2.31 \times 10^{-2}\ \text{min}^{-1};\ T_2 = 298\ \text{K}$$

The unknown combination is

$$k_1 = 2.0 \times 10^{-3}\ \text{min}^{-1};\ T_1 = ?$$

Substitute these values into equation (14.22), together with the known value, $E_a = 1.2 \times 10^5$ J mol^{-1} to obtain

$$\ln\frac{2.31 \times 10^{-2}\ \text{min}^{-1}}{2.0 \times 10^{-3}\ \text{min}^{-1}} = \frac{1.2 \times 10^5\ \text{J mol}^{-1}}{8.3145\ \text{J mol}^{-1}\ \text{K}^{-1}} \times \left(\frac{1}{T_1} - \frac{1}{298}\right)\text{K}^{-1}$$

$$\ln 12 = 1.4 \times 10^4\left(\frac{1}{T_1} - 3.36 \times 10^{-3}\right)$$

$$2.5 = \frac{1.4 \times 10^4}{T_1} - 47$$

$$50T_1 = 1.4 \times 10^4$$

$$T_1 = 2.8 \times 10^2\ \text{K}$$

Assess

The best check on the reasonableness of the final answer is to note that based on the values $k = 3.3 \times 10^{-4}\ \text{min}^{-1}$ at 273 K and $k = 2.31 \times 10^{-2}\ \text{min}^{-1}$ at 298 K, the temperature at which $k = 2.0 \times 10^{-3}\ \text{min}^{-1}$ should be somewhere between 273 K and 298 K. Our result is just that: 2.8×10^2 K.

PRACTICE EXAMPLE A: At room temperature (20 °C), milk turns sour in about 64 hours. In a refrigerator at 3 °C, milk can be stored three times as long before it sours. **(a)** Estimate the activation energy of the reaction that causes the souring of milk. **(b)** How long should it take milk to sour at 40 °C?

PRACTICE EXAMPLE B: The following mechanism can be used to account for the change in apparent order of unimolecular reactions, such as the conversion of cyclopropane (A) into propene (P), where A* is an energetic form of cyclopropane that can either react or return to unreacted cyclopropane.

$$\mathrm{A} + \mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{A}^* + \mathrm{A}$$

$$\mathrm{A}^* \xrightarrow{k_2} \mathrm{P}$$

Show that at low pressures of cyclopropane, the rate law is second order in A and at high pressures, it is first order in A.

MasteringCHEMISTRY

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

Exercises

Rates of Reactions

1. In the reaction $2\,\mathrm{A} + \mathrm{B} \longrightarrow \mathrm{C} + 3\,\mathrm{D}$, reactant A is found to disappear at the rate of $6.2 \times 10^{-4}\ \mathrm{M\,s^{-1}}$. **(a)** What is the rate of reaction at this point? **(b)** What is the rate of disappearance of B? **(c)** What is the rate of formation of D?
2. From Figure 14-2 estimate the rate of reaction at **(a)** $t = 800\ \mathrm{s}$; **(b)** the time at which $[\mathrm{H_2O_2}] = 0.50\ \mathrm{M}$.
3. In the reaction $\mathrm{A} \longrightarrow$ products, [A] is found to be 0.485 M at $t = 71.5\ \mathrm{s}$ and 0.474 M at $t = 82.4\ \mathrm{s}$. What is the average rate of the reaction during this time interval?
4. In the reaction $\mathrm{A} \longrightarrow$ products, at $t = 0$, $[\mathrm{A}] = 0.1565\ \mathrm{M}$. After 1.00 min, $[\mathrm{A}] = 0.1498\ \mathrm{M}$, and after 2.00 min, $[\mathrm{A}] = 0.1433\ \mathrm{M}$.
   (a) Calculate the average rate of the reaction during the first minute and during the second minute.
   (b) Why are these two rates not equal?
5. In the reaction $\mathrm{A} \longrightarrow$ products, 4.40 min after the reaction is started, $[\mathrm{A}] = 0.588\ \mathrm{M}$. The rate of reaction at this point is rate $= -\Delta[\mathrm{A}]/\Delta t = 2.2 \times 10^{-2}\mathrm{M\,min^{-1}}$. Assume that this rate remains constant for a short period of time.
   (a) What is [A] 5.00 min after the reaction is started?
   (b) At what time after the reaction is started will $[\mathrm{A}] = 0.565\ \mathrm{M}$?
6. Refer to Experiment 2 of Table 14.3 and to reaction (14.7) and rate law (14.8). Exactly 1.00 h after the reaction is started, what are **(a)** $[\mathrm{HgCl_2}]$ and **(b)** $[\mathrm{C_2O_4}^{2-}]$ in the mixture?
7. For the reaction $\mathrm{A} + 2\,\mathrm{B} \longrightarrow 2\,\mathrm{C}$, the rate of reaction is $1.76 \times 10^{-5}\ \mathrm{M\,s^{-1}}$ at the time when $[\mathrm{A}] = 0.3580\ \mathrm{M}$.
   (a) What is the rate of formation of C?
   (b) What will [A] be 1.00 min later?
   (c) Assume the rate remains at $1.76 \times 10^{-5}\ \mathrm{M\,s^{-1}}$. How long would it take for [A] to change from 0.3580 to 0.3500 M?
8. If the rate of reaction (14.3) is $5.7 \times 10^{-4}\ \mathrm{M\,s^{-1}}$, what is the rate of production of $\mathrm{O_2(g)}$ from 1.00 L of the $\mathrm{H_2O_2(aq)}$, expressed as **(a)** mol $\mathrm{O_2 s^{-1}}$; **(b)** mol $\mathrm{O_2\ min^{-1}}$; **(c)** mL $\mathrm{O_2(STP)\ min^{-1}}$?
9. In the reaction $\mathrm{A(g)} \longrightarrow 2\,\mathrm{B(g)} + \mathrm{C(g)}$, the *total* pressure increases while the *partial* pressure of A(g) decreases. If the initial pressure of A(g) in a vessel of constant volume is 1.000×10^3 mmHg,
   (a) What will be the total pressure when the reaction has gone to completion?
   (b) What will be the total gas pressure when the partial pressure of A(g) has fallen to 8.00×10^2 mmHg?
10. At 65 °C, the half-life for the first-order decomposition of $\mathrm{N_2O_5(g)}$ is 2.38 min.

$$\mathrm{N_2O_5(g)} \longrightarrow 2\,\mathrm{NO_2(g)} + \frac{1}{2}\mathrm{O_2(g)}$$

If 1.00 g of $\mathrm{N_2O_5}$ is introduced into an evacuated 15 L flask at 65 °C,

(a) What is the initial partial pressure, in mmHg, of $\mathrm{N_2O_5(g)}$?

(b) What is the partial pressure, in mmHg, of $\mathrm{N_2O_5(g)}$ after 2.38 min?

(c) What is the total gas pressure, in mmHg, after 2.38 min?

Method of Initial Rates

11. The initial rate of the reaction $A + B \longrightarrow C + D$ is determined for different initial conditions, with the results listed in the table.
(a) What is the order of reaction with respect to A and to B?
(b) What is the overall reaction order?
(c) What is the value of the rate constant, *k*?

Expt	[A], M	[B], M	Initial Rate, M s^{-1}
1	0.185	0.133	3.35×10^{-4}
2	0.185	0.266	1.35×10^{-3}
3	0.370	0.133	6.75×10^{-4}
4	0.370	0.266	2.70×10^{-3}

12. For the reaction $A + B \longrightarrow C + D$, the following initial rates of reaction were found. What is the rate law for this reaction?

Expt	[A], M	[B], M	Initial Rate, M min^{-1}
1	0.50	1.50	4.2×10^{-3}
2	1.50	1.50	1.3×10^{-2}
3	3.00	3.00	5.2×10^{-2}

13. The following rates of reaction were obtained in three experiments with the reaction $2\,NO(g) + Cl_2(g) \longrightarrow 2\,NOCl(g)$.

Expt	Initial [NO], M	Initial [Cl$_2$], M	Initial Rate of Reaction, M s^{-1}
1	0.0125	0.0255	2.27×10^{-5}
2	0.0125	0.0510	4.55×10^{-5}
3	0.0250	0.0255	9.08×10^{-5}

What is the rate law for this reaction?

14. The following data are obtained for the initial rates of reaction in the reaction $A + 2\,B + C \longrightarrow 2\,D + E$.

Expt	Initial [A], M	Initial [B], M	[C], M	Initial Rate
1	1.40	1.40	1.00	R_1
2	0.70	1.40	1.00	$R_2 = \frac{1}{2} \times R_1$
3	0.70	0.70	1.00	$R_3 = \frac{1}{4} \times R_2$
4	1.40	1.40	0.50	$R_4 = 16 \times R_3$
5	0.70	0.70	0.50	$R_5 = ?$

(a) What are the reaction orders with respect to A, B, and C?
(b) What is the value of R_5 in terms of R_1?

First-Order Reactions

15. One of the following statements is true and the other is false regarding the first-order reaction $2A \longrightarrow B + C$. Identify the true statement and the false one, and explain your reasoning.
(a) The rate of the reaction decreases as more and more of B and C form.
(b) The time required for one-half of substance A to react is directly proportional to the quantity of A present initially.

16. One of the following statements is true and the other is false regarding the first-order reaction $2A \longrightarrow B + C$. Identify the true statement and the false one, and explain your reasoning.
(a) A graph of [A] versus time is a straight line.
(b) The rate of the reaction is one-half the rate of disappearance of A.

17. The first-order reaction $A \longrightarrow$ products has $t_{1/2} = 180$ s.
(a) What percent of a sample of A remains *unreacted* 900 s after a reaction has been started?
(b) What is the rate of reaction when $[A] = 0.50$ M?

18. The reaction $A \longrightarrow$ products is first order in A. Initially, $[A] = 0.800$ M; and after 54 min, $[A] = 0.100$ M.
(a) At what time is $[A] = 0.025$ M?
(b) What is the rate of reaction when $[A] = 0.025$ M?

19. The reaction $A \longrightarrow$ products is first order in A.
(a) If 1.60 g A is allowed to decompose for 38 min, the mass of A remaining undecomposed is found to be 0.40 g. What is the half-life, $t_{1/2}$, of this reaction?
(b) Starting with 1.60 g A, what is the mass of A remaining undecomposed after 1.00 h?

20. In the first-order reaction $A \longrightarrow$ products, $[A] = 0.816$ M initially and 0.632 M after 16.0 min.
(a) What is the value of the rate constant, *k*?
(b) What is the half-life of this reaction?
(c) At what time will $[A] = 0.235$ M?
(d) What will [A] be after 2.5 h?

21. In the first-order reaction $A \longrightarrow$ products, it is found that 99% of the original amount of reactant A decomposes in 137 min. What is the half-life, $t_{1/2}$, of this decomposition reaction?

22. The half-life of the radioactive isotope phosphorus-32 is 14.3 days. How long does it take for a sample of phosphorus-32 to lose 99% of its radioactivity?

23. Acetoacetic acid, CH_3COCH_2COOH, a reagent used in organic synthesis, decomposes in acidic solution, producing acetone and $CO_2(g)$.

$$CH_3COCH_2COOH(aq) \longrightarrow CH_3COCH_3(aq) + CO_2(g)$$

This first-order decomposition has a half-life of 144 min.

(a) How long will it take for a sample of acetoacetic acid to be 65% decomposed?
(b) How many liters of $CO_2(g)$, measured at 24.5 °C and 748 Torr, are produced as a 10.0 g sample of CH_3COCH_2COOH decomposes for 575 min? [Ignore the aqueous solubility of $CO_2(g)$.]

24. The following first-order reaction occurs in $CCl_4(l)$ at 45 °C: $N_2O_5 \longrightarrow N_2O_4 + \frac{1}{2}O_2(g)$. The rate constant is $k = 6.2 \times 10^{-4}\ s^{-1}$. An 80.0 g sample of N_2O_5 in $CCl_4(l)$ is allowed to decompose at 45 °C.
(a) How long does it take for the quantity of N_2O_5 to be reduced to 2.5 g?
(b) How many liters of O_2, measured at 745 mmHg and 45 °C, are produced up to this point?

25. For the reaction $A \longrightarrow$ products, the following data give [A] as a function of time: $t = 0\ s$, $[A] = 0.600\ M$; 100 s, 0.497 M; 200 s, 0.413 M; 300 s, 0.344 M; 400 s, 0.285 M; 600 s, 0.198 M; 1000 s, 0.094 M.
(a) Show that the reaction is first order.
(b) What is the value of the rate constant, k?
(c) What is [A] at $t = 750\ s$?

26. The decomposition of dimethyl ether at 504 °C is

$$(CH_3)_2O(g) \longrightarrow CH_4(g) + H_2(g) + CO(g)$$

The following data are partial pressures of dimethyl ether (DME) as a function of time: $t = 0\ s$, $P_{DME} = 312\ mmHg$; 390 s, 264 mmHg; 777 s, 224 mmHg; 1195 s, 187 mmHg; 3155 s, 78.5 mmHg.
(a) Show that the reaction is first order.
(b) What is the value of the rate constant, k?
(c) What is the total gas pressure at 390 s?
(d) What is the total gas pressure when the reaction has gone to completion?
(e) What is the total gas pressure at $t = 1000\ s$?

Reactions of Various Orders

Three different sets of data of [A] versus time are given in the following table for the reaction $A \longrightarrow$ products. [*Hint:* There are several ways of arriving at answers for each of the following six questions.]

Data for Exercises 27–32

I		II		III	
Time, s	[A], M	Time, s	[A], M	Time, s	[A], M
0	1.00	0	1.00	0	1.00
25	0.78	25	0.75	25	0.80
50	0.61	50	0.50	50	0.67
75	0.47	75	0.25	75	0.57
100	0.37	100	0.00	100	0.50
150	0.22			150	0.40
200	0.14			200	0.33
250	0.08			250	0.29

27. Which of these sets of data corresponds to a **(a)** zero-order, **(b)** first-order, **(c)** second-order reaction?

28. What is the value of the rate constant k of the zero-order reaction?

29. What is the approximate half-life of the first-order reaction?

30. What is the approximate initial rate of the second-order reaction?

31. What is the approximate rate of reaction at $t = 75\ s$ for the **(a)** zero-order, **(b)** first-order, **(c)** second-order reaction?

32. What is the approximate concentration of A remaining after 110 s in the **(a)** zero-order, **(b)** first-order, **(c)** second-order reaction?

33. The reaction $A + B \longrightarrow C + D$ is second order in A and zero order in B. The value of k is $0.0103\ M^{-1}\ min^{-1}$. What is the rate of this reaction when $[A] = 0.116\ M$ and $[B] = 3.83\ M$?

34. A reaction is 50% complete in 30.0 min. How long after its start will the reaction be 75% complete if it is **(a)** first order; **(b)** zero order?

35. The decomposition of HI(g) at 700 K is followed for 400 s, yielding the following data: at $t = 0$, $[HI] = 1.00\ M$; at $t = 100\ s$, $[HI] = 0.90\ M$; at $t = 200\ s$, $[HI] = 0.81\ M$; $t = 300\ s$, $[HI] = 0.74\ M$; at $t = 400\ s$, $[HI] = 0.68\ M$. What are the reaction order and the rate constant for the reaction:

$$HI(g) \longrightarrow \frac{1}{2}H_2(g) + \frac{1}{2}I_2(g)?$$

Write the rate law for the reaction at 700 K.

36. For the disproportionation of *p*-toluenesulfinic acid,

$$3\ ArSO_2H \longrightarrow ArSO_2SAr + ArSO_3H + H_2O$$

(where Ar = *p*-$CH_3C_6H_4$—), the following data were obtained: $t = 0\ min$, $[ArSO_2H] = 0.100\ M$; 15 min, 0.0863 M; 30 min, 0.0752 M; 45 min, 0.0640 M; 60 min, 0.0568 M; 120 min, 0.0387 M; 180 min, 0.0297 M; 300 min, 0.0196 M.
(a) Show that this reaction is second order.
(b) What is the value of the rate constant, k?
(c) At what time would $[ArSO_2H] = 0.0500\ M$?
(d) At what time would $[ArSO_2H] = 0.0250\ M$?
(e) At what time would $[ArSO_2H] = 0.0350\ M$?

37. For the reaction $A \longrightarrow$ products, the following data were obtained: $t = 0\ s$, $[A] = 0.715\ M$; 22 s, 0.605 M; 74 s, 0.345 M; 132 s, 0.055 M. **(a)** What is the order of this reaction? **(b)** What is the half-life of the reaction?

38. The following data were obtained for the dimerization of 1,3-butadiene, $2\,C_4H_6(g) \longrightarrow C_8H_{12}(g)$, at 600 K: $t = 0\ min$, $[C_4H_6] = 0.0169\ M$; 12.18 min, 0.0144 M; 24.55 min, 0.0124 M; 42.50 min, 0.0103 M; 68.05 min, 0.00845 M.
(a) What is the order of this reaction?
(b) What is the value of the rate constant, k?
(c) At what time would $[C_4H_6] = 0.00423\ M$?
(d) At what time would $[C_4H_6] = 0.0050\ M$?

39. For the reaction $A \longrightarrow$ products, the data tabulated below are obtained.
(a) Determine the initial rate of reaction (that is, $-\Delta[A]/\Delta t$) in each of the two experiments.
(b) Determine the order of the reaction.

First Experiment	
$[A] = 1.512\ M$	$t = 0$ min
$[A] = 1.490\ M$	$t = 1.0$ min
$[A] = 1.469\ M$	$t = 2.0$ min

Second Experiment	
$[A] = 3.024\ M$	$t = 0$ min
$[A] = 2.935\ M$	$t = 1.0$ min
$[A] = 2.852\ M$	$t = 2.0$ min

40. For the reaction $A \longrightarrow 2\,B + C$, the following data are obtained for $[A]$ as a function of time: $t = 0$ min, $[A] = 0.80$ M; 8 min, 0.60 M; 24 min, 0.35 M; 40 min, 0.20 M.
(a) By suitable means, establish the order of the reaction.
(b) What is the value of the rate constant, k?
(c) Calculate the rate of formation of B at $t = 30$ min.

41. In three different experiments, the following results were obtained for the reaction $A \longrightarrow$ products: $[A]_0 = 1.00\ M$, $t_{1/2} = 50$ min; $[A]_0 = 2.00\ M$, $t_{1/2} = 25$ min; $[A]_0 = 0.50\ M$, $t_{1/2} = 100$ min. Write the rate equation for this reaction, and indicate the value of k.

42. Ammonia decomposes on the surface of a hot tungsten wire. Following are the half-lives that were obtained at 1100 °C for different initial concentrations of NH_3: $[NH_3]_0 = 0.0031\ M$, $t_{1/2} = 7.6$ min; 0.0015 M, 3.7 min; 0.00068 M, 1.7 min. For this decomposition reaction, what is **(a)** the order of the reaction; **(b)** the rate constant, k?

43. The half-lives of both zero-order and second-order reactions depend on the initial concentration, as well as on the rate constant. In one case, the half-life gets longer as the initial concentration increases, and in the other it gets shorter. Which is which, and why isn't the situation the same for both?

44. Consider three hypothetical reactions, $A \longrightarrow$ products, all having the same numerical value of the rate constant k. One of the reactions is zero order, one is first order, and one is second order. What must be the initial concentration $[A]_0$ if **(a)** the zero- and first-order; **(b)** the zero- and second-order; **(c)** the first- and second-order reactions are to have the same half-life?

Collision Theory; Activation Energy

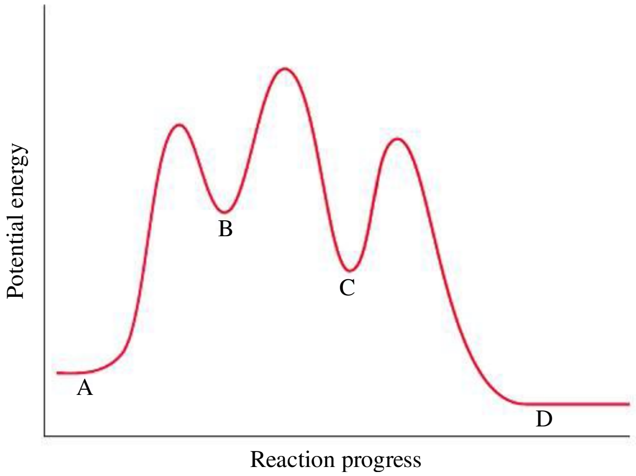
45. Explain why
(a) A reaction rate cannot be calculated from the collision frequency alone.
(b) The rate of a chemical reaction may increase dramatically with temperature, whereas the collision frequency increases much more slowly.
(c) The addition of a catalyst to a reaction mixture can have such a pronounced effect on the rate of a reaction, even if the temperature is held constant.

46. If even a tiny spark is introduced into a mixture of $H_2(g)$ and $O_2(g)$, a highly exothermic explosive reaction occurs. Without the spark, the mixture remains unreacted indefinitely.
(a) Explain this difference in behavior.
(b) Why is the nature of the reaction independent of the size of the spark?

47. For the reversible reaction $A + B \rightleftharpoons C + D$, the enthalpy change of the forward reaction is +21 kJ/mol. The activation energy of the forward reaction is 84 kJ/mol.
(a) What is the activation energy of the reverse reaction?
(b) In the manner of Figure 14-10, sketch the reaction profile of this reaction.

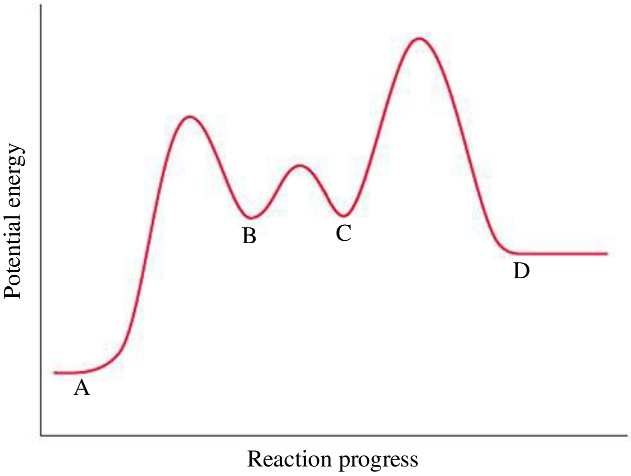
48. By an appropriate sketch, indicate why there is some relationship between the enthalpy change and the activation energy for an endothermic reaction but not for an exothermic reaction.

49. By inspection of the reaction profile for the reaction A to D given below, answer the following questions.



(a) How many intermediates are there in the reaction?
(b) How many transition states are there?
(c) Which is the fastest step in the reaction?
(d) Which step has the smallest rate constant?
(e) Is the first step of the reaction exothermic or endothermic?
(f) Is the overall reaction exothermic or endothermic?

50. By inspection of the reaction profile for the reaction A to D given, answer the following questions.
(a) How many intermediates are there in the reaction?
(b) How many transition states are there?
(c) Which is the fastest step in the reaction?
(d) Which step has the smallest rate constant?
(e) Is the first step of the reaction exothermic or endothermic?
(f) Is the overall reaction exothermic or endothermic?



Effect of Temperature on Rates of Reaction

51. The rate constant for the reaction $H_2(g) + I_2(g) \longrightarrow 2\,HI(g)$ has been determined at the following temperatures: 599 K, $k = 5.4 \times 10^{-4}\,M^{-1}\,s^{-1}$; 683 K, $k = 2.8 \times 10^{-2}\,M^{-1}\,s^{-1}$. Calculate the activation energy for the reaction.

52. At what temperature will the rate constant for the reaction in Exercise 51 have the value $k = 5.0 \times 10^{-3}\,M^{-1}\,s^{-1}$?

53. A treatise on atmospheric chemistry lists the following rate constants for the decomposition of PAN described in the Integrative Example on page 643: 0 °C, $k = 5.6 \times 10^{-6}\,s^{-1}$; 10 °C, $k = 3.2 \times 10^{-5}\,s^{-1}$; 20 °C, $k = 1.6 \times 10^{-4}\,s^{-1}$; 30 °C, $k = 7.6 \times 10^{-4}\,s^{-1}$.
(a) Construct a graph of ln k versus $1/T$.
(b) What is the activation energy, E_a, of the reaction?
(c) Calculate the half–life of the decomposition reaction at 40 °C.

54. The reaction $C_2H_5I + OH^- \longrightarrow C_2H_5OH + I^-$ was studied in an ethanol (C_2H_5OH) solution, and the following rate constants were obtained: 15.83 °C, $k = 5.03 \times 10^{-5}$; 32.02 °C, 3.68×10^{-4}; 59.75 °C, 6.71×10^{-3}; 90.61 °C, $0.119\,M^{-1}\,s^{-1}$.
(a) Determine E_a for this reaction by a graphical method.
(b) Determine E_a by the use of equation (14.22).
(c) Calculate the value of the rate constant k at 100.0 °C.

55. The first-order reaction $A \longrightarrow$ products has a half-life, $t_{1/2}$, of 46.2 min at 25 °C and 2.6 min at 102 °C.
(a) Calculate the activation energy of this reaction.
(b) At what temperature would the half-life be 10.0 min?

56. For the first-order reaction

$$N_2O_5(g) \longrightarrow 2\,NO_2(g) + \frac{1}{2}O_2(g)$$

$t_{1/2} = 22.5$ h at 20 °C and 1.5 h at 40 °C.
(a) Calculate the activation energy of this reaction.
(b) If the Arrhenius constant $A = 2.05 \times 10^{13}\,s^{-1}$, determine the value of k at 30 °C.

57. A commonly stated rule of thumb is that reaction rates double for a temperature increase of about 10 °C. (This rule is very often wrong.)
(a) What must be the approximate activation energy for this statement to be true for reactions at about room temperature?
(b) Would you expect this rule of thumb to apply at room temperature for the reaction profiled in Figure 14-10? Explain.

58. Concerning the rule of thumb stated in Exercise 57, estimate how much faster cooking occurs in a pressure cooker with the vapor pressure of water at 2.00 atm instead of in water under normal boiling conditions. [*Hint:* Refer to Table 12.2.]

Catalysis

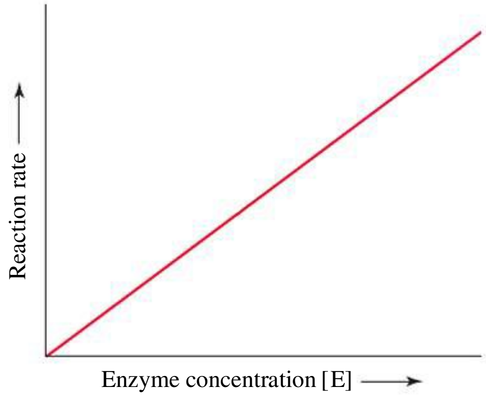
59. The following statements about catalysis are not stated as carefully as they might be. What slight modifications would you make in them?
(a) A catalyst is a substance that speeds up a chemical reaction but does not take part in the reaction.
(b) The function of a catalyst is to lower the activation energy for a chemical reaction.

60. The following substrate concentration [S] versus time data were obtained during an enzyme-catalyzed reaction: $t = 0$ min, $[S] = 1.00$ M; 20 min, 0.90 M; 60 min, 0.70 M; 100 min, 0.50 M; 160 min, 0.20 M. What is the order of this reaction with respect to S in the concentration range studied?

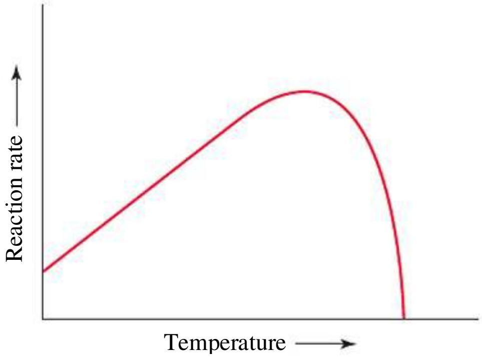
61. What are the similarities and differences between the catalytic activity of platinum metal and of an enzyme?

62. Certain gas-phase reactions on a heterogeneous catalyst are first order at low gas pressures and zero order at high pressures. Can you suggest a reason for this?

63. The graph shows the effect of enzyme concentration on the rate of an enzyme reaction. What reaction conditions are necessary to account for this graph?



64. The graph shows the effect of temperature on enzyme activity. Explain why the graph has the general shape shown. For human enzymes, at what temperature would you expect the maximum in the curve to appear?



Reaction Mechanisms

65. We have used the terms *order of a reaction* and *molecularity of an elementary process* (that is, unimolecular, bimolecular). What is the relationship, if any, between these two terms?

66. According to collision theory, chemical reactions occur through molecular collisions. A unimolecular elementary process in a reaction mechanism involves dissociation of a *single* molecule. How can these two ideas be compatible? Explain.

67. The reaction $2\,NO + 2\,H_2 \longrightarrow N_2 + 2\,H_2O$ is second order in $[NO]$ and first order in $[H_2]$. A *three-step* mechanism has been proposed. The first, fast step is the elementary process given as equation (14.25) on page 632. The third step, also fast, is $N_2O + H_2 \longrightarrow N_2 + H_2O$. Propose an entire three-step mechanism, and show that it conforms to the experimentally determined reaction order.

68. The mechanism proposed for the reaction of $H_2(g)$ and $I_2(g)$ to form $HI(g)$ consists of a fast reversible first step involving $I_2(g)$ and $I(g)$, followed by a slow step. Propose a two-step mechanism for the reaction $H_2(g) + I_2(g) \longrightarrow 2\,HI(g)$, which is known to be first order in H_2 and first order in I_2.

69. The reaction $2\,NO + Cl_2 \longrightarrow 2\,NOCl$ has the rate law: rate of reaction $= k[NO]^2[Cl_2]$. Propose a two-step mechanism for this reaction consisting of a fast reversible first step, followed by a slow step.

70. A simplified rate law for the reaction $2\,O_3(g) \longrightarrow 3\,O_2(g)$ is

$$\text{rate} = k = \frac{[O_3]^2}{[O_2]}$$

For this reaction, propose a two-step mechanism that consists of a fast, reversible first step, followed by a slow second step.

71. One proposed mechanism for the formation of a double helix in DNA is given by

$$(S_1 + S_2) = (S_1\!:\!S_2)^* \qquad \text{(fast)}$$
$$(S_1\!:\!S_2)^* \longrightarrow S_1\!:\!S_2 \qquad \text{(slow)}$$

where S_1 and S_2 represent strand 1 and 2, and $(S_1\!:\!S_2)^*$ represents an unstable helix. Write the rate of reaction expression for the formation of the double helix.

72. One proposed mechanism for the condensation of propanone, $(CH_3)_2CO$, is as follows:

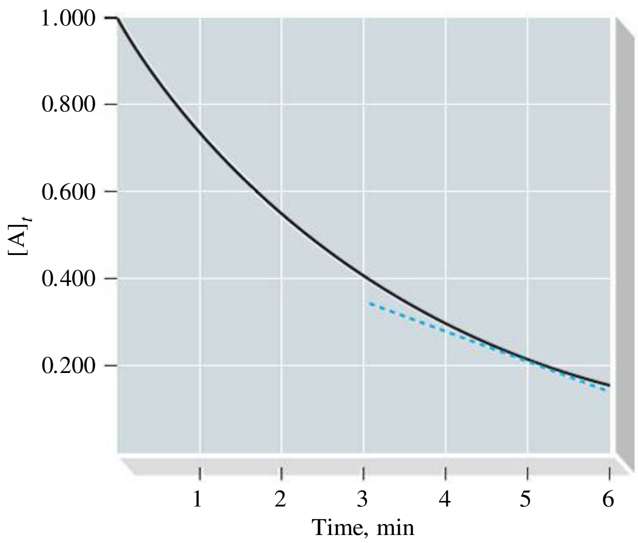
$$(CH_3)_2CO(aq) + OH^-(aq) = CH_3C(O)CH_2^-(aq) + H_2O(l)$$
$$CH_3C(O)CH_2^-(aq) + (CH_3)_2CO(aq) \longrightarrow \text{product}$$

Use the steady-state approximation to determine the rate of formation for the product.

Integrative and Advanced Exercises

73. Suppose that the reaction in Example 14-8 is first order with a rate constant of $0.12\ \text{min}^{-1}$. Starting with $[A]_0 = 1.00$ M, will the curve for $[A]$ versus t for the first-order reaction cross the curve for the second-order reaction at some time after $t = 0$? Will the two curves cross if $[A]_0 = 2.00$ M? In each case, if the curves are found to cross, at what time will this happen?

74. $[A]_t$ as a function of time for the reaction $A \longrightarrow$ products is plotted in the following graph. Use data from this graph to determine **(a)** the order of the reaction; **(b)** the rate constant, k; **(c)** the rate of the reaction at $t = 3.5$ min, using the results of parts (a) and (b); **(d)** the rate of the reaction at $t = 5.0$ min, from the slope of the tangent line; **(e)** the initial rate of the reaction.



75. Exactly 300 s after decomposition of $H_2O_2(aq)$ begins (reaction 14.3), a 5.00 mL sample is removed and immediately titrated with 37.1 mL of 0.1000 M $KMnO_4$. What is $[H_2O_2]$ at this 300 s point in the reaction?

76. Use the method of Exercise 75 to determine the volume of 0.1000 M $KMnO_4$ required to titrate 5.00 mL samples of $H_2O_2(aq)$ for each of the entries in Table 14.1. Plot these volumes of $KMnO_4(aq)$ as a function of time, and show that from this graph you can get the same rate of reaction at 1400 s as that obtained in Figure 14-2.

77. The initial rate of reaction (14.3) is found to be $1.7 \times 10^{-3}\ \text{M s}^{-1}$. Assume that this rate holds for 2 minutes. Start with 175 mL of 1.55 M $H_2O_2(aq)$ at $t = 0$. How many milliliters of $O_2(g)$, measured at 24 °C and 757 mmHg, are released from solution in the first minute of the reaction?

78. We have seen that the unit of k depends on the overall order of a reaction. Derive a general expression for the units of k for a reaction of any overall order, based on the order of the reaction (o) and the units of concentration (M) and time (s).

79. Hydroxide ion is involved in the mechanism of the following reaction but is not consumed in the overall reaction.

$$OCl^- + I^- \xrightarrow{OH^-} OI^- + Cl^-$$

(a) From the data given, determine the order of the reaction with respect to OCl^-, I^-, and OH^-.
(b) What is the overall reaction order?
(c) Write the rate equation, and determine the value of the rate constant, k.

$[OCl^-]$, M	$[I^-]$, M	$[OH^-]$, M	Rate Formation OI^-, M s^{-1}
0.0040	0.0020	1.00	4.8×10^{-4}
0.0020	0.0040	1.00	5.0×10^{-4}
0.0020	0.0020	1.00	2.4×10^{-4}
0.0020	0.0020	0.50	4.6×10^{-4}
0.0020	0.0020	0.25	9.4×10^{-4}

80. The half-life for the first-order decomposition of nitramide, $NH_2NO_2(aq) \longrightarrow N_2O(g) + H_2O(l)$, is 123 min at 15 °C. If 165 mL of a 0.105 M NH_2NO_2 solution is allowed to decompose, how long must the reaction proceed to yield 50.0 mL of $N_2O(g)$ collected over water at 15 °C and a barometric pressure of 756 mmHg? (The vapor pressure of water at 15 °C is 12.8 mmHg.)

81. The decomposition of ethylene oxide at 690 K is monitored by measuring the *total* gas pressure as a function of time. The data obtained are $t = 10$ min, $P_{\text{tot}} =$ 139.14 mmHg; 20 min, 151.67 mmHg; 40 min, 172.65 mmHg; 60 min, 189.15 mmHg; 100 min, 212.34 mmHg; 200 min, 238.66 mmHg; ∞, 249.88 mmHg. What is the order of the reaction $(CH_2)_2O(g) \longrightarrow CH_4(g) + CO(g)$?

82. Refer to Example 14-7. For the decomposition of di-*t*-butyl peroxide (DTBP), determine the time at which the *total* gas pressure is 2100 mmHg.

83. The following data are for the reaction $2\,A + B \longrightarrow$ products. Establish the order of this reaction with respect to A and to B.

Expt 1, [B] = 1.00 M		Expt 2, [B] = 0.50 M	
Time, min	[A], M	Time, Min	[A], M
0	1.000×10^{-3}	0	1.000×10^{-3}
1	0.951×10^{-3}	1	0.975×10^{-3}
5	0.779×10^{-3}	5	0.883×10^{-3}
10	0.607×10^{-3}	10	0.779×10^{-3}
20	0.368×10^{-3}	20	0.607×10^{-3}

84. Show that the following mechanism is consistent with the rate law established for the iodide–hypochlorite reaction in Exercise 79.

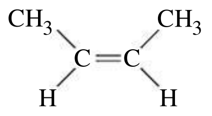
Fast: $OCl^- + H_2O \underset{k_1}{\overset{k_1}{\rightleftharpoons}} HOCl + OH^-$

Slow: $I^- + HOCl \xrightarrow{k_2} HOI + Cl^-$

Fast: $HOI + OH^- \underset{k_3}{\overset{k_3}{\rightleftharpoons}} H_2O + OI^-$

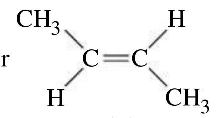
85. In the hydrogenation of a compound containing a carbon-to-carbon triple bond, two products are possible, as in the reaction

$$CH_3-C\equiv C-CH_3 + H_2 \longrightarrow$$



(I)

or



(II)

The amount of each product can be controlled by using an appropriate catalyst. The Lindlar catalyst is a *heterogeneous* catalyst that produces only one of these products. Which product, I or II, do you think is produced and why? Draw a sketch of how the reaction might occur.

86. Derive a plausible mechanism for the following reaction in aqueous solution, $Hg_2^{2+} + Tl^{3+} \longrightarrow 2\,Hg^{2+} + Tl^{+}$, for which the observed rate law is: rate $= k[Hg_2^{2+}][Tl^{3+}]/[Hg^{2+}]$.

87. The following three-step mechanism has been proposed for the reaction of chlorine and chloroform.

(1) $Cl_2(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2\,Cl(g)$

(2) $Cl(g) + CHCl_3(g) \xrightarrow{k_2} HCl(g) + CCl_3(g)$

(3) $CCl_3(g) + Cl(g) \xrightarrow{k_3} CCl_4(g)$

The numerical values of the rate constants for these steps are $k_1 = 4.8 \times 10^3$; $k_{-1} = 3.6 \times 10^3$; $k_2 = 1.3 \times 10^{-2}$; $k_3 = 2.7 \times 10^2$. Derive the rate law and the magnitude of k for the overall reaction.

88. For the reaction $A \longrightarrow$ products, derive the integrated rate law and an expression for the half-life if the reaction is third order.

89. The reaction $A + B \longrightarrow$ products is first order in A, first order in B, and second order overall. Consider that the starting concentrations of the reactants are $[A]_0$ and $[B]_0$, and that x represents the decrease in these concentrations at the time t. That is, $[A]_t = [A]_0 - x$ and $[B]_t = [B]_0 - x$. Show that the integrated rate law for this reaction can be expressed as shown below.

$$\ln\frac{[A]_0 \times [B]_t}{[B]_0 \times [A]_t} = ([B]_0 - [A]_0) \times kt$$

90. The rate of the reaction

$$2\,CO(g) \longrightarrow CO_2(g) + C(s)$$

was studied by injecting CO(g) into a reaction vessel and measuring the total pressure at constant volume.

P_{total} (Torr)	Time (s)
250	0
238	398
224	1002
210	1801

What is the rate constant of this reaction?

91. The kinetics of the decomposition of phosphine at 950 K

$$4\,PH_3(g) \longrightarrow P_4(g) + 6\,H_2(g)$$

was studied by injecting $PH_3(g)$ into a reaction vessel and measuring the total pressure at constant volume.

P_{total} (Torr)	Time (s)
100	0
150	40
167	80
172	120

What is the rate constant of this reaction?

92. The rate of an enzyme-catalyzed reaction can be slowed down by the presence of an inhibitor (I) that reacts with the enzyme in a rapid equilibrium process.

$$E + I \rightleftharpoons EI$$

By adding this step to the mechanism for enzyme catalysis on page 641, determine the effect of adding the concentration $[I_0]$ on the rate of an enzyme-catalyzed reaction.

93. By taking the reciprocal of both sides of equation 14.36, obtain an expression for $1/V$. Using the resulting equation, suggest a strategy for determining the Michaelis–Menten constant, K_M, and the value of k_2.

94. You want to test the following proposed mechanism for the oxidation of HBr.

$$HBr + O_2 \xrightarrow{k_1} HOOBr$$
$$HOOBr + HBr \xrightarrow{k_2} 2\,HOBr$$
$$HOBr + HBr \xrightarrow{k_3} H_2O + Br_2$$

You find that the rate is first order with respect to HBr and to O_2. You cannot detect HOBr among the products.
(a) If the proposed mechanism is correct, which must be the rate-determining step?
(b) Can you prove the mechanism from these observations?
(c) Can you disprove the mechanism from these observations?

95. The decomposition of nitric oxide occurs through two parallel reactions:

$$NO(g) \longrightarrow \frac{1}{2}N_2(g) + \frac{1}{2}O_2(g) \qquad k_1 = 25.7\ s^{-1}$$

$$NO(g) \longrightarrow \frac{1}{2}N_2O(g) + \frac{1}{4}O_2(g) \qquad k_2 = 18.2\ s^{-1}$$

(a) What is the reaction order for these reactions?
(b) Which reaction is the slow reaction?
(c) If the initial concentration of NO(g) is 2.0 M, what is the concentration of $N_2(g)$ after 0.1 seconds?
(d) If the initial concentration of NO(g) is 4.0 M, what is the concentration of $N_2O(g)$ after 0.025 seconds?

Feature Problems

96. Benzenediazonium chloride decomposes by a first-order reaction in water, yielding $N_2(g)$ as one product.

$$C_6H_5N_2Cl \longrightarrow C_6H_5Cl + N_2(g)$$

The reaction can be followed by measuring the volume of $N_2(g)$ as a function of time. The data in the table were obtained for the decomposition of a 0.071 M solution at 50 °C, where $t = \infty$ corresponds to the completed reaction.

Time, min	$N_2(g)$, mL	Time, min	$N_2(g)$, mL
0	0	18	41.3
3	10.8	21	44.3
6	19.3	24	46.5
9	26.3	27	48.4
12	32.4	30	50.4
15	37.3	∞	58.3

(a) Convert the information given here into a table with one column for time and the other for $[C_6H_5N_2Cl]$.
(b) Construct a table similar to Table 14.2, in which the time interval is $\Delta t = 3$ min.
(c) Plot graphs similar to Figure 14-2, showing both the formation of $N_2(g)$ and the disappearance of $C_6H_5N_2Cl$ as a function of time.
(d) From the graph of part (c), determine the rate of reaction at $t = 21$ min, and compare your result with the reported value of $1.1 \times 10^{-3}\ \text{M min}^{-1}$.
(e) Determine the initial rate of reaction.
(f) Write the rate law for the first-order decomposition of $C_6H_5N_2Cl$, and estimate a value of k based on the rate determined in parts (d) and (e).
(g) Determine $t_{1/2}$ for the reaction by estimation from the graph of the rate data and by calculation.
(h) At what time would the decomposition of the sample be three-fourths complete?
(i) Plot $\ln[C_6H_5N_2Cl]$ versus time, and show that the reaction is indeed first order.
(j) Determine k from the slope of the graph of part (i).

97. The object is to study the kinetics of the reaction between peroxodisulfate and iodide ions.

(a) $S_2O_8{}^{2-}(aq) + 3\,I^-(aq) \longrightarrow 2\,SO_4{}^{2-}(aq) + I_3{}^-(aq)$

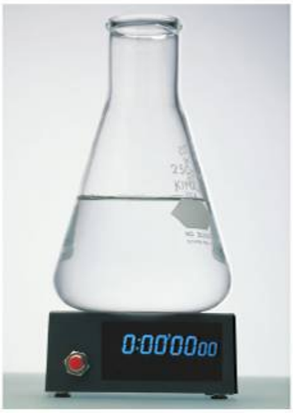
The $I_3{}^-$ formed in reaction (a) is actually a complex of iodine, I_2, and iodide ion, I^-. Thiosulfate ion, $S_2O_3{}^{2-}$, also present in the reaction mixture, reacts with $I_3{}^-$ just as fast as it is formed.

(b) $2\,S_2O_3{}^{2-}(aq) + I_3{}^-(aq) \longrightarrow S_4O_6{}^{2-} + 3\,I^-(aq)$

When all of the thiosulfate ion present initially has been consumed by reaction (b), a third reaction occurs between $I_3{}^-(aq)$ and starch, which is also present in the reaction mixture.

(c) $I_3{}^-(aq) + \text{starch} \longrightarrow \text{blue complex}$

The rate of reaction (a) is inversely related to the time required for the blue color of the starch–iodine complex to appear. That is, the faster reaction (a) proceeds, the more quickly the thiosulfate ion is consumed in reaction (b), and the sooner the blue color appears in reaction (c). One of the photographs shows the initial colorless solution and an electronic timer set at $t = 0$; the other photograph shows the very first appearance of the blue complex (after 49.89 s). Tables I and II list some actual student data obtained in this study.



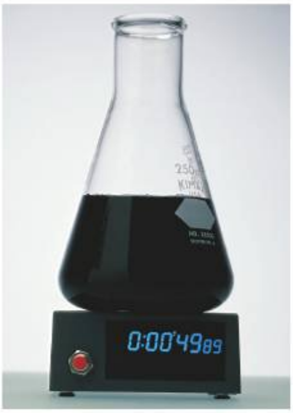


TABLE I

Reaction conditions at 24 °C: 25.0 mL of the $(NH_4)_2S_2O_8(aq)$ listed, 25.0 mL of the KI(aq) listed, 10.0 mL of 0.010 M $Na_2S_2O_3(aq)$, and 5.0 mL starch solution are mixed. The time is that of the first appearance of the starch–iodine complex.

	Initial Concentrations, M		
Experiment	$(NH_4)_2S_2O_8$	KI	Time, s
1	0.20	0.20	21
2	0.10	0.20	42
3	0.050	0.20	81
4	0.20	0.10	42
5	0.20	0.050	79

TABLE II

Reaction conditions: those listed in Table I for Experiment 4, but at the temperatures listed.

Experiment	Temperature, °C	Time, s
6	3	189
7	13	88
8	24	42
9	33	21

(a) Use the data in Table I to establish the order of reaction (a) with respect to $S_2O_8{}^{2-}$ and to I^-. What is the overall reaction order? [*Hint:* How are the times required for the blue complex to appear related to the actual rates of reaction?]
(b) Calculate the initial rate of reaction in Experiment 1, expressed in M s^{-1}. [*Hint:* You must take into account the dilution that occurs when the various solutions are mixed, as well as the reaction stoichiometry indicated by equations (a), (b), and (c).]
(c) Calculate the value of the rate constant, k, based on experiments 1 and 2.
(d) Calculate the rate constant, k, for the four different temperatures in Table II.
(e) Determine the activation energy, E_a, of the peroxodisulfate–iodide ion reaction.
(f) The following mechanism has been proposed for reaction (a). The first step is slow, and the others are fast.

$$\begin{aligned} I^- + S_2O_8{}^{2-} &\longrightarrow IS_2O_8{}^{3-} \\ IS_2O_8{}^{3-} &\longrightarrow 2\,SO_4{}^{2-} + I^+ \\ I^+ + I^- &\longrightarrow I_2 \\ I_2 + I^- &\longrightarrow I_3{}^- \end{aligned}$$

Show that this mechanism is consistent with both the stoichiometry and the rate law of reaction (a). Explain why it is reasonable to expect the first step in the mechanism to be slower than the others.

Self-Assessment Exercises

98. In your own words, define or explain the following terms or symbols: **(a)** $[A]_0$; **(b)** k; **(c)** $t_{1/2}$; **(d)** zero-order reaction; **(e)** catalyst.

99. Briefly describe each of the following ideas, phenomena, or methods: **(a)** the method of initial rates; **(b)** activated complex; **(c)** reaction mechanism; **(d)** heterogeneous catalysis; **(e)** rate-determining step.

100. Explain the important distinctions between each pair of terms: **(a)** first-order and second-order reactions; **(b)** rate law and integrated rate law; **(c)** activation energy and enthalpy of reaction; **(d)** elementary process and overall reaction; **(e)** enzyme and substrate.

101. The rate equation for the reaction $2\,A + B \longrightarrow C$ is found to be rate $= k[A][B]$. For this reaction, we can conclude that **(a)** the unit of $k = s^{-1}$; **(b)** $t_{1/2}$ is constant; **(c)** the value of k is independent of the values of $[A]$ and $[B]$; **(d)** the rate of formation of C is twice the rate of disappearance of A.

102. A first-order reaction, $A \longrightarrow$ products, has a half-life of 75 s, from which we can draw two conclusions. Which of the following are those two **(a)** the reaction goes to completion in 150 s; **(b)** the quantity of A remaining after 150 s is half of what remains after 75 s; **(c)** the same quantity of A is consumed for every 75 s of the reaction; **(d)** one-quarter of the original quantity of A is consumed in the first 37.5 s of the reaction; **(e)** twice as much A is consumed in 75 s when the initial amount of A is doubled; **(f)** the amount of A consumed in 150 s is twice as much as is consumed in 75 s.

103. A first order reaction $A \longrightarrow$ products has a half-life of 13.9 min. The rate at which this reaction proceeds when $[A] = 0.40\,M$ is **(a)** $0.020\,mol\,L^{-1}\,min^{-1}$; **(b)** $5.0 \times 10^{-2}\,mol\,L^{-1}\,min^{-1}$; **(c)** $8.0\,mol\,L^{-1}\,min^{-1}$; **(d)** $0.125\,mol\,L^{-1}\,min^{-1}$.

104. The reaction $A \longrightarrow$ products is second order. The initial rate of decomposition of A when $[A]_0 = 0.50\,M$ is **(a)** the same as the initial rate for any other value of $[A]_0$; **(b)** half as great as when $[A]_0 = 1.00\,M$; **(c)** five times as great as when $[A]_0 = 0.10\,M$; **(d)** four times as great as when $[A]_0 = 0.25\,M$.

105. The rate of a chemical reaction generally increases rapidly, even for small increases in temperature, because of a rapid increase in **(a)** collision frequency; **(b)** fraction of reactant molecules with very high kinetic energies; **(c)** activation energy; **(d)** average kinetic energy of the reactant molecules.

106. For the reaction $A + B \longrightarrow 2\,C$, which proceeds by a single-step bimolecular elementary process, **(a)** $t_{1/2} = 0.693/k$; **(b)** rate of appearance of C = −rate of disappearance of A; **(c)** rate of reaction $= k[A][B]$; **(d)** $\ln[A]_t = -kt + \ln[A]_0$.

107. In the first-order decomposition of substance A the following concentrations are found at the indicated times: $t = 0\,s, [A] = 0.88\,M; t = 50\,s, [A] = 0.62\,M; t = 100\,s, [A] = 0.44\,M; t = 150\,s, [A] = 0.31\,M$. Calculate the instantaneous rate of decomposition at $t = 100\,s$.

108. A reaction is 50% complete in 30.0 min. How long after its start will the reaction be 75% complete if it is **(a)** first order; **(b)** zero order?

109. A kinetic study of the reaction $A \longrightarrow$ products yields the data: $t = 0\,s, [A] = 2.00\,M$; 500 s, 1.00 M; 1500 s, 0.50 M; 3500 s, 0.25 M. *Without performing detailed calculations*, determine the order of this reaction and indicate your method of reasoning.

110. For the reaction $A \longrightarrow$ products the following data are obtained.

Experiment 1		Experiment 2	
$[A] = 1.204\,M$	$t = 0\,min$	$[A] = 2.408\,M$	$t = 0\,min$
$[A] = 1.180\,M$	$t = 1.0\,min$	$[A] = ?$	$t = 1.0\,min$
$[A] = 0.602\,M$	$t = 35\,min$	$[A] = ?$	$t = 30\,min$

(a) Determine the initial rate of reaction in Experiment 1.

(b) If the reaction is second order, what will be $[A]$ at $t = 1.0$ min in Experiment 2?

(c) If the reaction is first order, what will be $[A]$ at 30 min in Experiment 2?

111. For the reaction $A + 2\,B \longrightarrow C + D$, the rate law is rate of reaction $= k[A][B]$.

(a) Show that the following mechanism is consistent with the stoichiometry of the overall reaction and with the rate law.

$$A + B \longrightarrow I \quad (\text{slow})$$
$$I + B \longrightarrow C + D \quad (\text{fast})$$

(b) Show that the following mechanism is consistent with the stoichiometry of the overall reaction, but *not* with the rate law.

$$2\,B \underset{k_1}{\overset{k_1}{\rightleftharpoons}} B_2 \quad (\text{fast})$$
$$A + B_2 \xrightarrow{k_2} C + D \quad (\text{slow})$$

112. If the plot of the reactant concentration versus time is nonlinear, but the concentration drops by 50% every 10 seconds, then the order of the reaction is **(a)** zero order; **(b)** first order; **(c)** second order; **(d)** third order.

113. If the plot of the reactant concentration versus time is linear, then the order of the reaction is **(a)** zero order; **(b)** first order; **(c)** second order; **(d)** third order.

114. For a given reaction, doubling the temperature will increase the reaction rate by **(a)** 2; **(b)** 0.61; **(c)** 2.7; **(d)** 1.6.

115. One example of a zero-order reaction is the decomposition of ammonia on a hot platinum wire, $2\,NH_3(g) \longrightarrow N_2(g) + 3\,H_2(g)$. If the concentration of ammonia is doubled, the rate of the reaction will **(a)** be zero; **(b)** double; **(c)** remain the same; **(d)** exponentially increase.

116. Using the method presented in Appendix E, construct a concept map illustrating the concepts in Sections 14-8 and 14-9.

15

Principles of Chemical Equilibrium

A vital natural reaction is in progress in the lightning bolt seen here: $N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$. Usually this reversible reaction does not occur to any significant extent in the forward direction, but in the high-temperature lightning bolt it does. At equilibrium at high temperatures, measurable conversion of $N_2(g)$ and $O_2(g)$ to $NO(g)$ occurs. In this chapter we study the equilibrium condition in a reversible reaction and the factors affecting it.

CONTENTS

15-1 Dynamic Equilibrium
15-2 The Equilibrium Constant Expression
15-3 Relationships Involving Equilibrium Constants
15-4 The Magnitude of an Equilibrium Constant
15-5 The Reaction Quotient, Q: Predicting the Direction of Net Change
15-6 Altering Equilibrium Conditions: Le Châtelier's Principle
15-7 Equilibrium Calculations: Some Illustrative Examples

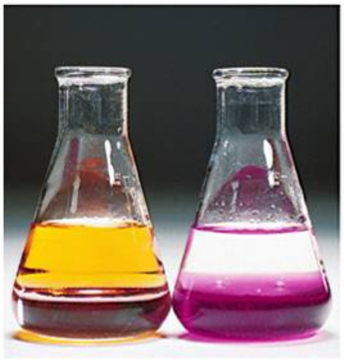
Until now, we have stressed reactions that go to completion and the concepts of stoichiometry that allow us to calculate the outcomes of such reactions. We have made occasional references to situations involving both a forward and a reverse reaction—*reversible reactions*—but in this chapter, we will look at them in a detailed and systematic way.

Our emphasis will be on the equilibrium condition reached when forward and reverse reactions proceed at the same rate. Our main tool in dealing with equilibrium will be the equilibrium constant. We will begin with some key relationships involving equilibrium constants; then we will make qualitative predictions about the condition of equilibrium; and finally we will do various equilibrium calculations. As we will discover throughout the remainder of the text, the equilibrium condition plays a role in numerous natural phenomena and affects the methods used to produce many important industrial chemicals.

15-1 Dynamic Equilibrium

Let's begin by describing three simple physical and one chemical phenomena that will help us to establish the core attribute of a system at **equilibrium**—two opposing processes take place at equal rates.

1. When a liquid vaporizes within a closed container, after a time, vapor molecules condense to the liquid state at the same rate at which liquid molecules vaporize. Even though molecules continue to pass back and forth between liquid and vapor (a *dynamic* process), the pressure exerted by the vapor remains constant with time. *The vapor pressure of a liquid is a property resulting from an equilibrium condition.*
2. When a solute is added to a solvent, the system may reach a point at which the rate of dissolution is just matched by the rate at which dissolved solute crystallizes—that is, the solution is saturated. Even though solute particles continue to pass back and forth between the saturated solution and the undissolved solute, the concentration of dissolved solute remains constant. *The solubility of a solute is a property resulting from an equilibrium condition.*
3. When an aqueous solution of iodine, I_2, is shaken with pure carbon tetrachloride, $CCl_4(l)$, the I_2 molecules move into the CCl_4 layer. As the concentration of I_2 builds up in the CCl_4, the rate of return of I_2 to the water layer becomes significant. When I_2 molecules pass between the two liquids at equal rates—a condition of dynamic equilibrium—the concentration of I_2 in each layer remains constant. At this point, the concentration of I_2 in the CCl_4 is about 85 times as great as in the H_2O (Fig. 15-1). The ratio of concentrations of a solute in two immiscible solvents is called the distribution coefficient. *The distribution coefficient, which represents the partitioning of a solute between two immiscible solvents, is a property resulting from an equilibrium condition.*
4. When gaseous phosphorus pentachloride is heated, it decomposes to phosphorus trichloride and chlorine gases: $PCl_5(g) \longrightarrow PCl_3(g) + Cl_2(g)$. Consider a sample of $PCl_5(g)$ initially exerting a pressure of 1.0 atm in a closed container at 250 °C. The gas pressure in the container first rises rapidly and then ever more slowly, reaching a maximum, unchanging pressure of 1.7 atm. Because two moles of gas are produced for each mole of $PCl_5(g)$ that decomposes, if the reaction went to completion the final pressure would have been 2.0 atm. We conclude that *the decomposition of* PCl_5 *is a reversible reaction that reaches an equilibrium condition.*



(a) (b)

▲ FIGURE 15-1
Dynamic equilibrium in a physical process
(a) A yellow-brown saturated solution of I_2 in water (top layer) is brought into contact with colorless $CCl_4(l)$ (bottom layer), **(b)** I_2 molecules distribute themselves between the H_2O and CCl_4. When equilibrium is reached, $[I_2]$ in the CCl_4 (violet, bottom layer) is about 85 times as great as in the water (colorless, top layer).

The properties in the first three situations just described—vapor pressure, solubility, and distribution coefficient—are examples of physical equilibria. The fourth situation is an example of chemical equilibrium. All four are described through a general quantity known as an *equilibrium constant*, the subject of the next section.

15-1 CONCEPT ASSESSMENT

For each chemical equation state whether it represents physical or chemical equilibrium: **(a)** $CaCO_3(s) \rightleftharpoons Ca^{2+}(aq) + CO_3{}^{2-}(aq)$; **(b)** $I_2(s) \rightleftharpoons I_2(g)$; **(c)** $Fe(s) + 4H_2O(l) \rightleftharpoons Fe_3O_4(s) + 4H_2(g)$.

15-2 The Equilibrium Constant Expression

The oxidation–reduction reaction of copper(II) and tin(II) in aqueous solution is a reversible reaction, which means that at the same time as copper(I) and tin(IV) are being formed,

$$2\,Cu^{2+}(aq) + Sn^{2+}(aq) \longrightarrow 2\,Cu^{+}(aq) + Sn^{4+}(aq) \qquad \textbf{(15.1)}$$

copper(I) and tin(IV) ions elsewhere in the solution are being consumed to form copper(II) and tin(II):

$$2\,\mathrm{Cu}^{+}(\mathrm{aq}) + \mathrm{Sn}^{4+}(\mathrm{aq}) \longrightarrow 2\,\mathrm{Cu}^{2+}(\mathrm{aq}) + \mathrm{Sn}^{2+}(\mathrm{aq}) \qquad \textbf{(15.2)}$$

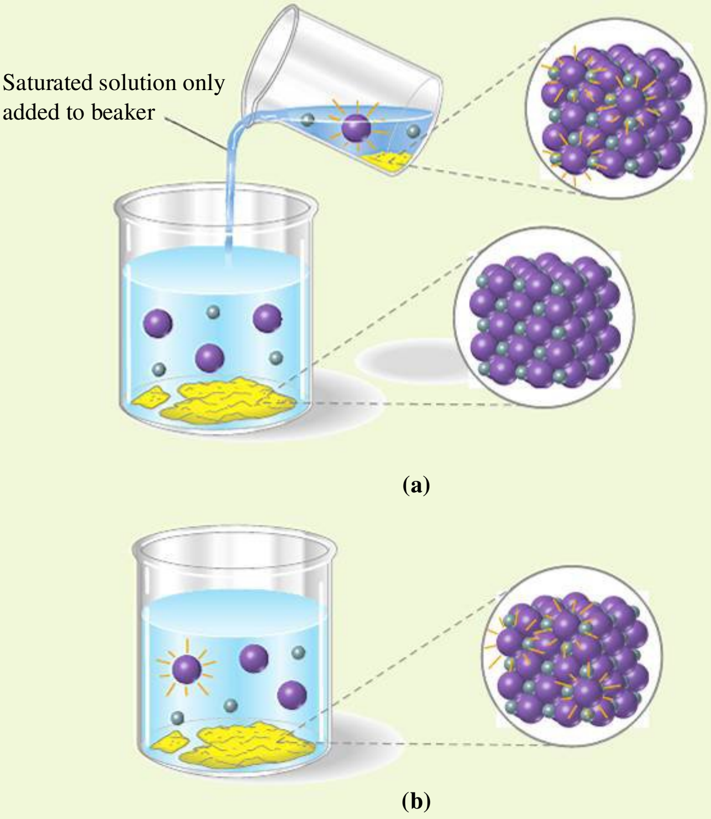
15-1 ARE YOU WONDERING...

How we know that an equilibrium is dynamic—that forward and reverse reactions continue even after equilibrium is reached?

Suppose we have an equilibrium mixture of AgI(s) and its saturated aqueous solution.

$$\mathrm{AgI(s)} \rightleftharpoons \mathrm{Ag}^{+}(\mathrm{aq}) + \mathrm{I}^{-}(\mathrm{aq})$$

Now let's add to this mixture some saturated solution of AgI made from AgI containing radioactive iodine-131 as iodide ion, as illustrated in Figure 15-2. If both the forward and reverse processes stopped at equilibrium, radioactivity would be confined to the solution. What we find, though, is that radioactivity shows up in the solid in contact with the saturated solution. Over time, the radioactive "hot" spots distribute themselves throughout the solution and undissolved solid. The only way this can happen is if the dissolving of the solid solute and its crystallization from the saturated solution continue indefinitely. The equilibrium condition is *dynamic*.



Saturated solution only added to beaker
(a)
(b)

▲ FIGURE 15-2
Dynamic equilibrium illustrated
(a) A saturated solution of radioactive AgI is added to a saturated solution of AgI. **(b)** The radioactive iodide ions distribute themselves throughout the solution and the solid AgI, showing that the equilibrium is dynamic.

▶ The equilibrium state can be obtained by starting with any combination of reactants and products.

TABLE 15.1 Three Approaches to Equilibrium in the Reaction[a] $2\,Cu^{2+}(aq) + Sn^{2+}(aq) \rightleftharpoons 2\,Cu^{+}(aq) + Sn^{4+}(aq)$

	$Cu^{2+}(aq)$	$Sn^{2+}(aq)$	$Cu^{+}(aq)$	$Sn^{4+}(aq)$
Experiment 1				
Initial amounts, mol	0.100	0.100	0.000	0.000
Equilibrium amounts, mol	0.0360	0.0680	0.0640	0.0320
Equilibrium concentrations, mol/L	0.0360	0.0680	0.0640	0.0320
Experiment 2				
Initial amounts, mol	0.000	0.000	0.100	0.100
Equilibrium amounts, mol	0.0567	0.0283	0.0433	0.0717
Equilibrium concentrations, mol/L	0.0567	0.0283	0.0433	0.0717
Experiment 3				
Initial amounts, mol	0.100	0.100	0.100	0.100
Equilibrium amounts, mol	0.0922	0.0961	0.1078	0.1039
Equilibrium concentrations, mol/L	0.0922	0.0961	0.1078	0.1039

The concentrations printed in blue are used in the calculations in Table 15.2.

[a] Reaction carried out in 1.00 L of solution at 298 K.

▶ The rates of reactions (forward and reverse) are affected by the concentration of reactants.

Initially, only the forward reaction (15.1) occurs, but as soon as some Cu^{+} and Sn^{4+} form, the reverse reaction (15.2) begins. With passing time, the forward reaction slows because of the decreasing concentrations of Cu^{2+} and Sn^{2+} and the reverse reaction speeds up as more Cu^{+} and Sn^{4+} accumulate. Eventually, the forward and reverse reactions proceed at equal rates, and the reaction mixture reaches a condition of dynamic equilibrium, which we can represent with a double arrow $\rightleftharpoons$.

$$2\,Cu^{2+}(aq) + Sn^{2+}(aq) \rightleftharpoons 2\,Cu^{+}(aq) + Sn^{4+}(aq) \qquad \textbf{(15.3)}$$

One consequence of the equilibrium condition is that the amounts of the reactants and products remain constant with time. These equilibrium amounts, however, depend on the quantities of reactants and products present initially. For example, Table 15.1 lists data for three hypothetical experiments. All experiments are conducted by using 1.00 L of solution at 298 K. In the first experiment, only $Cu^{2+}(aq)$ and $Sn^{2+}(aq)$ are present initially; in a second experiment, only $Cu^{+}(aq)$ and $Sn^{4+}(aq)$; and in the third experiment, $Cu^{2+}(aq)$, $Sn^{2+}(aq)$, $Cu^{+}(aq)$, and $Sn^{4+}(aq)$. The data from Table 15.1 are plotted in Figure 15-3, and from these graphs we see that

- in no case is any reacting species completely consumed.
- in all three cases the equilibrium amounts of reactants and products appear to have nothing in common.

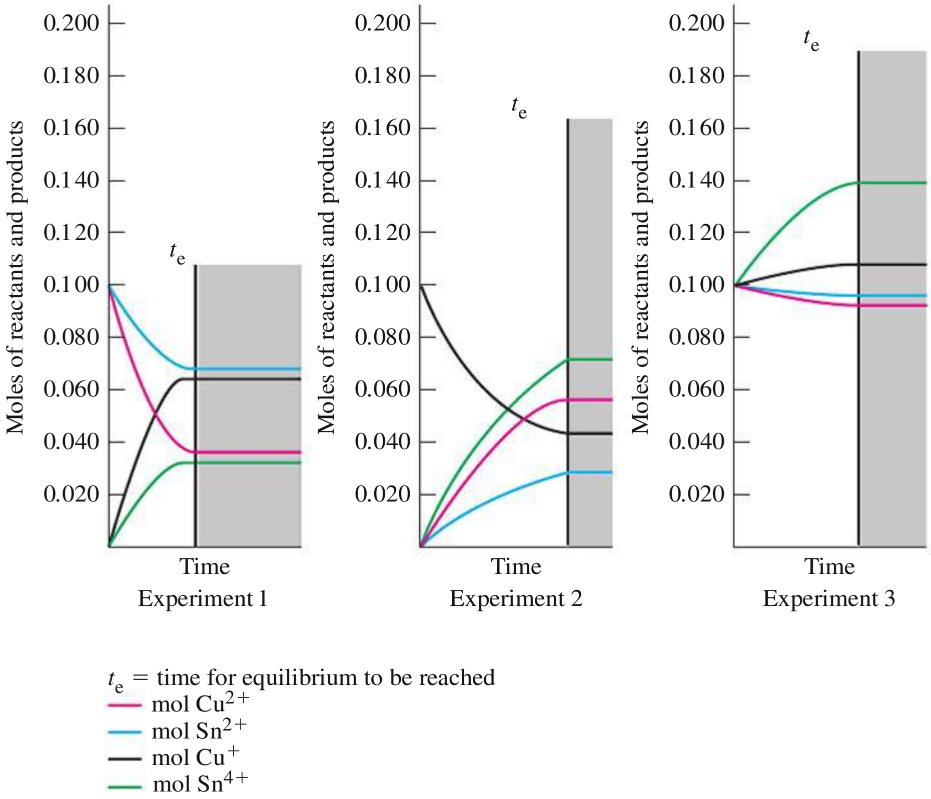
Although it is not obvious from a cursory inspection of the data, a particular ratio involving equilibrium concentrations of product and reactants has a constant value, independent of how the equilibrium is reached. This ratio, which is central to the study of chemical equilibrium, can be derived theoretically using concepts presented later in the text, but it can also be established empirically, that is, by trial and error. Three reasonable attempts at formulating the desired ratio for reaction (15.3) are outlined in Table 15.2, and the ratio that works is identified.

For the copper–tin oxidation–reduction reaction, the ratio of equilibrium concentrations in the following equation has a constant value of 1.48 at 300 K.

▶ The representation of the equilibrium expression in terms of concentrations is valid only at low concentrations, usually less than a few moles per liter.

$$K = \frac{[Cu^{+}]^2_{eq}[Sn^{4+}]_{eq}}{[Cu^{2+}]^2_{eq}[Sn^{2+}]_{eq}} = 1.48 \qquad \textbf{(15.4)}$$

This ratio is called the **equilibrium constant expression** and its numerical value is the **equilibrium constant**.



▲ FIGURE 15-3

Three approaches to equilibrium in the reaction

$$2\ Cu^{2+}(aq) + Sn^{2+}(aq) \rightleftharpoons 2\ Cu^{+}(aq) + Sn^{4+}(aq)$$

The initial and equilibrium amounts for each of these three cases are listed in Table 15.1. t_e = time for equilibrium to be reached.

The Equilibrium Constant and Activities

We have discovered that the equilibrium constant expression is written as a ratio of the product concentrations divided by the reactant concentrations. G. N. Lewis* proposed a more appropriate way to represent the equilibrium constant expression that uses the activities of the reactants and products. **Activity** is a thermodynamic concept that we will see again in Chapter 19.

◀ "Equilibrium" means equal rates of forward and reverse reactions, *not* equal concentrations of reactants and products.

TABLE 15.2

Expt	Trial 1: $\dfrac{[Cu^+][Sn^{4+}]}{[Cu^{2+}][Sn^{2+}]}$	Trial 2: $\dfrac{(2 \times [Cu^+])[Sn^{4+}]}{(2 \times [Cu^{2+}])[Sn^{2+}]}$	Trial 3: $\dfrac{[Cu^+]^2[Sn^{4+}]}{[Cu^{2+}]^2[Sn^{2+}]}$
1	$\dfrac{0.0640 \times 0.0320}{0.0360 \times 0.0680} = 0.837$	$\dfrac{(2 \times 0.0640) \times 0.0320}{(2 \times 0.0360) \times 0.0680} = 0.837$	$\dfrac{0.0640^2 \times 0.0320}{0.0360^2 \times 0.0680} = 1.49$
2	$\dfrac{0.0433 \times 0.0717}{0.0567 \times 0.0283} = 1.93$	$\dfrac{(2 \times 0.0433) \times 0.0717}{(2 \times 0.0567) \times 0.0283} = 1.93$	$\dfrac{0.0433^2 \times 0.0717}{0.0567^2 \times 0.0283} = 1.48$
3	$\dfrac{0.1078 \times 0.1039}{0.0922 \times 0.0961} = 1.26$	$\dfrac{(2 \times 0.1078) \times 0.1039}{(2 \times 0.0922) \times 0.0961} = 1.26$	$\dfrac{0.1078^2 \times 0.1039}{0.0922^2 \times 0.0961} = 1.48$

Equilibrium concentration data are from Table 15.1. In Trial 1, the equilibrium concentration of Cu^+ and Sn^{2+} are placed in the numerator and the equilibrium concentration of Cu^{2+} and Sn^{4+}, in the denominator. In Trial 2, each concentration is multiplied by its stoichiometric coefficient. In Trial 3, each concentration is raised to a power equal to its stoichiometric coefficient. Trial 3 has essentially the same value for each experiment. This value is the equilibrium constant *K*.

---

*G. N. Lewis and M. Randall, *Thermodynamics*, McGraw Hill, New York, 1923.

Here, we summarize only a few important points. For a substance in solution, activity is equal to the dimensionless ratio $\gamma[X]/c^\circ$, where γ is referred to as the *activity coefficient*, $[X]$ represents a particular concentration and c° corresponds to the concentration in a chosen reference state. Our usual choice of reference state for a substance in solution is a concentration of one mole per liter (1 mol L^{-1}). For gases, activity is equal to the dimensionless ratio $\gamma P/P^\circ$, where P is a particular partial pressure and P° is the partial pressure in the reference state; our usual choice of P° is 1 bar (essentially equal to 1 atm). Pure solids and pure liquids are usually assigned activities of 1.

▶Because of interactions between particles, the "effective" or "active" concentration (activity) of a substance is usually different from the stoichiometric concentration (see page 587). The activity coefficient, γ, takes into account the effect of particle interactions.

Why base equilibrium constants on activities? Under conditions where gases do not obey the ideal gas law (Section 6-9) or solutions depart from ideal behavior (Section 13-3), equilibrium constant values may vary with total concentration or pressure. This problem is eliminated when activities are used. As we learned in Section 13-9, activities are "effective" or "active" concentrations. In this text we will generally assume that systems are ideal, and that activities can be replaced by the numerical values of concentrations or partial pressures. Later on in this text we will establish the relationship between equilibrium and thermodynamic quantities.

Let us reconsider expression (15.4), this time by using activities. We will replace equation (15.4) with the following expression:

$$K = \frac{a^2_{Cu^+}a_{Sn^{4+}}}{a^2_{Cu^{2+}}a_{Sn^{2+}}} = 1.48 \qquad \textbf{(15.5)}$$

To establish the relationship between an equilibrium constant expressed in activities and the corresponding one expressed in concentration, we begin by writing the activity of each species, using the [ ] symbol for the equilibrium concentration and c° for the concentration in the reference state.

$$a_{Cu^+} = \frac{\gamma_{Cu^+}[Cu^+]}{c^\circ}; \qquad a_{Sn^{4+}} = \frac{\gamma_{Sn^{4+}}[Sn^{4+}]}{c^\circ}$$

$$a_{Cu^{2+}} = \frac{\gamma_{Cu^{2+}}[Cu^{2+}]}{c^\circ}; \qquad a_{Sn^{2+}} = \frac{\gamma_{Sn^{2+}}[Sn^{2+}]}{c^\circ}$$

Then we choose the value $c^\circ = 1\ \text{mol L}^{-1}$, we substitute these relationships into the equilibrium constant expression (15.5), and we have

$$K = \frac{\left(\dfrac{\gamma_{Cu^+}[Cu^+]_{eq}}{c^\circ}\right)^2 \dfrac{\gamma_{Sn^{4+}}[Sn^{4+}]_{eq}}{c^\circ}}{\left(\dfrac{\gamma_{Cu^{2+}}[Cu^{2+}]_{eq}}{c^\circ}\right)^2 \dfrac{\gamma_{Sn^{2+}}[Sn^{2+}]_{eq}}{c^\circ}} \approx \frac{[Cu^+]^2_{eq}[Sn^{4+}]_{eq}}{[Cu^{2+}]^2_{eq}[Sn^{2+}]_{eq}} = 1.48 \qquad \textbf{(15.6)}$$

The approximation made in writing expression (15.6) is that the values of all the γ are equal to one. This is equivalent to assuming that the ions behave ideally in solution (see page 587). Notice that we have arrived at exactly the expression in equation (15.4).

▶ The activity coefficients for ions will not be equal to 1 because the interactions between the ions are significant, even at low concentrations.

15-2 CONCEPT ASSESSMENT

How would you write the equilibrium constant expression for $Cu(s) + 2\,H^+(aq) \longrightarrow Cu^{+2}(aq) + H_2(g)$? Write this first in terms of activities and then convert to pressures and concentrations.

A General Expression for *K*

Before proceeding to other matters, let us emphasize that the equilibrium constant expression for the oxidation–reduction reaction of copper(II) and tin(II)

EXAMPLE 15-1 Relating Equilibrium Concentrations of Reactants and Products

These equilibrium concentrations are measured in reaction (15.3) at 300 K: $[Cu^+]_{eq} = 0.148$ M, $[Sn^{2+}]_{eq} = 0.124$ M, and $[Sn^{4+}]_{eq} = 0.176$ M. What is the equilibrium concentration of $Cu^{2+}(aq)$?

Analyze

First, we write the equilibrium constant expression for reaction (15.3) in terms of activities, along with the value of the equilibrium constant. Then, we convert the activities to concentrations and replace the concentrations with the given data.

Solve

Write the equilibrium constant expression.

$$K = \frac{a_{Cu^+}^2 a_{Sn^{4+}}}{a_{Cu^{2+}}^2 a_{Sn^{2+}}} = 1.48$$

Assume that the reaction conditions are such that the activities can be replaced by their concentration values, allowing concentration units to be canceled, as in expression (15.6).

$$K = \frac{[Cu^+]_{eq}^2[Sn^{4+}]_{eq}}{[Cu^{2+}]_{eq}^2[Sn^{2+}]_{eq}} = 1.48$$

Substitute the known equilibrium concentrations into the equilibrium constant expression.

$$K = \frac{[Cu^+]_{eq}^2[Sn^{4+}]_{eq}}{[Cu^{2+}]_{eq}^2[Sn^{2+}]_{eq}} = \frac{(0.148)^2(0.176)}{[Cu^{2+}]_{eq}^2(0.124)} = 1.48$$

Solve for the unknown concentration, $[Cu^{2+}]$. (An implicit calculation to restore the concentration unit is $[Cu^{2+}] = a_{Cu^{2+}} \times c^\circ = 0.145 \times 1.000\text{ M} = 0.145$ M.)

$$[Cu^{2+}]^2 = \frac{0.148^2 \times 0.176}{0.124 \times 1.48} = 0.0210$$

$$[Cu^{2+}] = \sqrt{0.0210} = 0.145\text{ M}$$

Assess

When solving equilibrium problems, we should examine the results to ensure they make sense. We can do this easily by placing the solution back into the equilibrium constant expression and calculating the equilibrium constant to see whether it agrees with the value stated in the problem, as shown below.

$$K = \frac{0.148^2 \times 0.176}{0.145^2 \times 0.124} = 1.48$$

PRACTICE EXAMPLE A: In another experiment, equal concentrations of $[Cu^+]$, $[Sn^{4+}]$, and $[Sn^{2+}]$ are found to be in equilibrium in reaction (15.3). What must be the equilibrium concentration of $[Cu^{2+}]$?

PRACTICE EXAMPLE B: At 25 °C, $K = 9.14 \times 10^{-6}$ for the reaction $2\,Fe^{3+}(aq) + Hg_2{}^{2+}(aq) \rightleftharpoons 2\,Fe^{2+}(aq) + 2\,Hg^{2+}(aq)$. If the equilibrium concentrations of Fe^{3+}, and Hg^{2+} are 0.015 M, 0.0025 M and 0.0018 M, Fe^{2+} respectively, what is the equilibrium concentration of $Hg_2{}^{2+}$?

summarized through expression (15.6) is just a specific example of a more general case. For the hypothetical, generalized reaction

$$aA(aq) + bB(aq) \cdots \rightleftharpoons gG(aq) + hH(aq) \cdots$$

The equilibrium constant expression has the form

$$K = \frac{(a_G)^g(a_H)^h \cdots}{(a_A)^a(a_B)^b \cdots} \approx \left(\frac{1}{c^\circ}\right)^{\Delta n}\frac{[G]^g[H]^h \cdots}{[A]^a[B]^b \cdots} = \left(\frac{1}{c^\circ}\right)^{\Delta n} K_c \qquad (15.7)$$

where $\Delta n = (g + h + \cdots) - (a + b + \cdots)$ and K_c is an equilibrium constant expression written in terms of concentrations. The factor $(1/c^\circ)^{\Delta n}$ ensures that K is a dimensionless quantity.

The *numerator* of an equilibrium constant expression is the product of the activities of the species on the *right* side of the equation $(a_G, a_H, \ldots)$, with each activity raised to a power given by the stoichiometric coefficient $(g, h, \ldots)$. The *denominator* is the product of the activities of the species on the *left* side of the

◀ In principle, when using equation (15.7), we can express concentrations in any unit. However, the use of a unit other than mol/L will require an "extra" calculation, that is, the calculation of the value of $(1/c^\circ)^{\Delta n}$. When we express concentrations, in mol/L, the factor $(1/c^\circ)^{\Delta n}$ has a numerical value of 1. For this reason, when using equation (15.7), we will express concentrations in mol/L and substitute their values (without units) into the expression to obtain the correct value of K.

15-3 CONCEPT ASSESSMENT

Consider a hypothetical reaction in which one molecule, A, is converted to its isomer, B, that is, the reversible reaction A $\rightleftharpoons$ B. Start with a flask containing 54 molecules of A, represented by open circles. Convert the appropriate number of open circles to filled circles to represent the isomer B and portray the equilibrium condition if $K = 0.02$. Repeat the process for $K = 0.5$ and then for $K = 1$.

equation ($a_A, a_B, \dots$), and again, with each activity raised to a power given by the stoichiometric coefficient ($a, b, \dots$). As previously noted, where equilibrium systems are sufficiently close to ideal in their behavior, equilibrium concentrations are acceptable approximations to true activities.

The numerical value of an equilibrium constant, K, depends on the particular reaction and on the temperature. We will explore the significance of these numerical values in Section 15-4.

Relationship Between the Equilibrium Constant and Rate Constants

Given the requirement that the rates of the forward and reverse reactions become equal at equilibrium, it seems that a relationship should exist between the equilibrium constant and the rate constants for the forward and reverse reactions. That such a relationship does exist can be demonstrated easily for elementary reactions. Consider again the hypothetical generalized reaction

$$a\text{A} + b\text{B} + \cdots \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} g\text{G} + h\text{H} + \cdots$$

k_1 and k_{-1} are the rate constants for the forward and reverse reactions. *With the assumption that both the forward and reverse reactions are elementary reactions*, we can write

$$\text{rate of forward reaction} = k_1[\text{A}]^a[\text{B}]^b \cdots$$
$$\text{rate of reverse reaction} = k_{-1}[\text{G}]^g[\text{H}]^h \ldots$$

At equilibrium, these two rates become equal; thus,

$$k_1[\text{A}]^a[\text{B}]^b \cdots = k_{-1}[\text{G}]^g[\text{H}]^h \cdots$$

which can be rearranged into an expression having rate constants on one side and concentrations on the other:

$$\frac{k_1}{k_{-1}} = \frac{[\text{G}]^g[\text{H}]^h \cdots}{[\text{A}]^a[\text{B}]^b \cdots}$$

Because the right side of the equation above is the equilibrium constant expression for the reaction, we arrive at the following result:

$$\frac{k_1}{k_{-1}} = K$$

Keep in mind that this result is based on the assumption that the forward and reverse reactions are elementary reactions. For reactions that involve a multistep mechanism, the relationship between K and the rate constants is more complicated. For a mechanism involving n steps, it can be demonstrated (in the manner described in Exercise 95) that the relationship between K and the rate constants is

$$\frac{k_1}{k_{-1}} \times \frac{k_2}{k_{-2}} \times \cdots \times \frac{k_n}{k_{-n}} = K$$

Although the expression above shows that there is indeed a relationship between the equilibrium constant and rate constants, it is generally easier to obtain K directly from measurements on equilibrium conditions than to attempt a calculation based on rate constants. In Chapters 19 and 20, we will learn about much more direct measurements and calculations leading to values of equilibrium constants.

15-3 Relationships Involving Equilibrium Constants

Before assessing an equilibrium situation, it may be necessary to make some preliminary calculations or decisions to get the appropriate equilibrium constant expression. This section presents some useful ideas in working with equilibrium constants.

Relationship of K to the Balanced Chemical Equation

We must always make certain that the expression for K matches the corresponding balanced equation. In doing so, the following hold true.

- When we *reverse* an equation, we *invert* the value of K.
- When we *multiply* the coefficients in a balanced equation by a common factor (2, 3, . . .), we raise the equilibrium constant to the *corresponding power* (2, 3, . . .).
- When we *divide* the coefficients in a balanced equation by a common factor (2, 3, . . .), we take the *corresponding root* of the equilibrium constant (square root, cube root, . . .).

To illustrate these points, let us consider the synthesis of methanol (methyl alcohol) from a carbon monoxide–hydrogen mixture called synthesis gas. This reaction is likely to become increasingly important as methanol and its mixtures with gasoline find greater use as motor fuels. The balanced reaction is

$$CO(g) + 2\,H_2(g) \rightleftharpoons CH_3OH(g) \qquad K = 9.23 \times 10^{-3}$$

▲ Methanol is actively being considered as an alternative fuel to gasoline.

Suppose that in discussing the synthesis of CH_3OH from CO and H_2, we had written the reverse reaction, that is,

$$CH_3OH(g) \rightleftharpoons CO(g) + 2\,H_2(g) \qquad K' = ?$$

Now, according to the generalized equilibrium constant expression (15.7), we should write

$$K' = \frac{a_{CO}\,a_{H_2}^2}{a_{CH_3OH}} = \frac{1}{\dfrac{a_{CH_3OH}}{a_{CO}\,a_{H_2}^2}} = \frac{1}{K} = \frac{1}{9.23 \times 10^{-3}} = 1.08 \times 10^2$$

In the preceding expression, the equilibrium constant expression and K value for the reaction, as originally written, are printed in blue. We see that $K' = 1/K$.

Suppose that for a certain application we want an equation based on synthesizing *two* moles of $CH_3OH(g)$.

$$2\,CO(g) + 4\,H_2(g) \rightleftharpoons 2\,CH_3OH(g) \qquad K'' = ?$$

Here, $K'' = K^2$. That is,

$$K'' = \frac{a_{CH_3OH}^2}{a_{CO}^2\,a_{H_2}^4} = \left(\frac{a_{CH_3OH}}{a_{CO}\,a_{H_2}^2}\right)^2 = (K)^2 = (9.23 \times 10^{-3})^2 = 8.52 \times 10^{-5}$$

15-4 CONCEPT ASSESSMENT

Can you conclude whether the numerical value of K for the reaction $2\,ICl(g) \rightleftharpoons I_2(g) + Cl_2(g)$ is greater or less than the numerical value of K for the reaction $ICl(g) \rightleftharpoons \frac{1}{2}I_2(g) + \frac{1}{2}Cl_2(g)$? Explain.

EXAMPLE 15-2 Relating *K* to the Balanced Chemical Equation

The following *K* value is given at 298 K for the synthesis of $NH_3(g)$ from its elements.

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g) \qquad K = 5.8 \times 10^5$$

What is the value of *K* at 298 *K* for the following reaction?

$$NH_3(g) \rightleftharpoons \frac{1}{2}N_2(g) + \frac{3}{2}H_2(g) \qquad K = ?$$

Analyze

The solution to this problem lies in recognizing that the reaction is the reverse and one-half of the given reaction. In this example we apply two of the rules given above that relate *K* to balanced chemical reactions.

Solve

First, reverse the given equation. This puts $NH_3(g)$ on the left side of the equation, where we need it.

$$2NH_3(g) \rightleftharpoons N_2(g) + 3H_2(g)$$

The equilibrium constant K' becomes

$$K' = 1/(5.8 \times 10^5) = 1.7 \times 10^{-6}$$

Then, to base the equation on 1 mol $NH_3(g)$, divide all coefficients by 2.

$$NH_3(g) \rightleftharpoons \frac{1}{2}N_2(g) + \frac{3}{2}H_2(g)$$

This requires the square root of K'.

$$K = \sqrt{1.7 \times 10^{-6}} = 1.3 \times 10^{-3}$$

Assess

Because the rules given on page 663 are used extensively throughout this book, memorizing them will be helpful.

PRACTICE EXAMPLE A: Use data from Example 15-2 to determine the value of *K* at 298 *K* for the reaction

$$\frac{1}{3}N_2(g) + H_2(g) \rightleftharpoons \frac{2}{3}NH_3(g)$$

PRACTICE EXAMPLE B: For the reaction $NO(g) + \frac{1}{2}O_2(g) \rightleftharpoons NO_2(g)$ at 184 °C, $K = 1.2 \times 10^2$. What is the value of *K* at 184 °C for the reaction $2\,NO_2(g) \rightleftharpoons 2\,NO(g) + O_2(g)$?

Combining Equilibrium Constant Expressions

In Section 7-7, through Hess's law, we showed how to combine a series of equations into a single overall equation. The enthalpy change of the overall reaction was obtained by adding together the enthalpy changes of the individual reactions. A similar procedure can be used with equilibrium constants, but with this important difference:

When individual equations are combined (that is, added), their equilibrium constants are *multiplied* to obtain the equilibrium constant for the overall reaction.

Suppose we need the equilibrium constant for the reaction

$$N_2O(g) + \frac{1}{2}O_2(g) \rightleftharpoons 2\,NO(g) \qquad K = ? \tag{15.8}$$

and know the *K* values of these two equilibria.

$$N_2(g) + \frac{1}{2}O_2(g) \rightleftharpoons N_2O(g) \qquad K = 5.4 \times 10^{-19} \tag{15.9}$$

$$N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g) \qquad K = 4.6 \times 10^{-31} \tag{15.10}$$

Equation (15.8) is obtained by reversing equation (15.9) and adding it to (15.10). This requires that we also take the *reciprocal* of the K value of equation (15.9).

$$\textbf{(a)} \qquad N_2O(g) \rightleftharpoons N_2(g) + \frac{1}{2}O_2(g) \qquad K(a) = 1/(5.4 \times 10^{-19}) = 1.9 \times 10^{18}$$

$$\textbf{(b)} \qquad N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g) \qquad K(b) = 4.6 \times 10^{-31}$$

$$\textit{Overall:} \qquad N_2O(g) + \frac{1}{2}O_2(g) \rightleftharpoons 2\,NO(g) \qquad K(\text{overall}) = ?$$

The overall equation is expression (15.8), and according to the general expression (15.7),

$$K(\text{overall}) = \frac{a_{NO}^2}{a_{N_2O}\,a_{O_2}^{1/2}} = \underbrace{\frac{a_{N_2}a_{O_2}^{1/2}}{a_{N_2O}}}_{K(a)} \times \underbrace{\frac{a_{NO}^2}{a_{N_2}\,a_{O_2}}}_{K(b)} = K(a) \times K(b)$$

$$= 1.9 \times 10^{18} \times 4.6 \times 10^{-31} = 8.5 \times 10^{-13}$$

15-5 CONCEPT ASSESSMENT

You want to calculate K for the reaction

$$CH_4(g) + 2\,H_2O(g) \rightleftharpoons CO_2(g) + 4\,H_2(g)$$

and you have available a K value for the reaction

$$CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g)$$

What additional K value do you need, assuming that all K values are at the same temperature?

Equilibria Involving Gases

Mixtures of gases are as much solutions as are mixtures in a liquid solvent. Thus, concentrations in a gaseous mixture can be expressed on a mole-per-liter basis. However, as mentioned on page 660, the activity of a gas is not defined in terms of its concentration, but rather, in terms of its partial pressure relative to a reference pressure of $P° = 1$ bar. Let us investigate equilibria involving gases by considering a specific gas-phase reaction.

A key step in the manufacture of sulfuric acid is the following reversible reaction.

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g) \qquad \textbf{(15.11)}$$

◀ The reaction of sulfur dioxide with oxygen gas to form sulfur trioxide is a reaction that takes place in the atmosphere. This results in the formation of sulfuric acid, which contributes to acid rain.

Since all the reaction species are in the gas phase it seems reasonable to use a partial-pressure reference state. We begin by writing the equilibrium constant expression in terms of activities

$$K = \left(\frac{(a_{SO_3})^2}{(a_{SO_2})^2 a_{O_2}}\right)_{eq} \qquad \textbf{(15.12)}$$

where the activities are

$$a_{SO_2} = \frac{\gamma_{SO_2} P_{SO_2}}{P^\circ_{SO_2}}; \qquad a_{O_2} = \frac{\gamma_{O_2} P_{O_2}}{P^\circ_{O_2}}; \qquad a_{SO_3} = \frac{\gamma_{SO_3} P_{SO_3}}{P^\circ_{SO_3}}$$

The reference-state partial pressure is $P° = 1$ bar, which we will take to be essentially the same as 1 atm. Substituting these relationships into equation (15.12) and setting all the γ values equal to 1, we obtain

$$K = \left(\frac{\left(\frac{P_{SO_3}}{P^\circ}\right)^2}{\left(\frac{P_{SO_2}}{P^\circ}\right)^2 \frac{P_{O_2}}{P^\circ}} \right)_{eq} = P^\circ \left(\frac{(P_{SO_3})^2}{(P_{SO_2})^2 P_{O_2}} \right)_{eq} = P^\circ \times K_p \qquad \textbf{(15.13)}$$

As always, the equilibrium constant, K, is dimensionless. The quantity multiplying P° on the right hand side of equation (15.13) is an equilibrium constant expressions written in terms of partial pressures; it is given the symbol K_p:

$$K_p = \left(\frac{(P_{SO_3})^2}{(P_{SO_2})^2 P_{O_2}} \right)_{eq}$$

To establish the equilibrium constant based on concentrations, we first use the ideal gas law, $PV = nRT$, to relate gas concentrations and partial pressures,

$$[SO_2] = \frac{n}{V} = \frac{P_{SO_2}}{RT}; \qquad [O_2] = \frac{n}{V} = \frac{P_{O_2}}{RT}; \qquad [SO_3] = \frac{n}{V} = \frac{P_{SO_3}}{RT}$$

and then substitute into the expression for K_p. We obtain

$$K_p = \left(\frac{(P_{SO_3})^2}{(P_{SO_2})^2 P_{O_2}} \right)_{eq} = \left(\frac{([SO_3]RT)^2}{([SO_2]RT)^2[O_2]RT} \right)_{eq} = \frac{1}{RT}\left(\frac{[SO_3]^2}{[SO_2]^2[O_2]} \right)_{eq} \qquad \textbf{(15.14)}$$

The final parenthetical factor in equation (15.14) is given the symbol K_c, where the subscript "c" emphasizes that this equilibrium constant expression is written in terms of concentrations. Equation (15.14) makes it clear that, in general, K_p and K_c have different values. This result is not wrong. It stems from the fact that for gases, we can choose to express the equilibrium constants in terms of either pressures or concentrations.

Thus, the relationship between K_p and K_c for reaction (15.11) is

$$K_p = K_c(RT)^{-1}$$

If we carried out a similar derivation for the general reaction,

$$a\text{A(g)} + b\text{B(g)} + \cdots \rightleftharpoons g\text{G(g)} + h\text{H(g)} + \cdots$$

the results would be

$$K = \frac{(a_G)^g (a_H)^h \cdots}{(a_A)^a (a_B)^b \cdots} \approx \left(\frac{1}{P^\circ}\right)^{\Delta n} \frac{P_G^g P_H^h \cdots}{P_A^a P_B^b \cdots} = \left(\frac{1}{P^\circ}\right)^{\Delta n} K_p \qquad \textbf{(15.15)}$$

and

$$K_p = K_c(RT)^{\Delta n_{gas}} \qquad \textbf{(15.16)}$$

where Δn_{gas} is the difference in the stoichiometric coefficients of *gaseous* products and reactants; that is, $\Delta n_{gas} = (g + h + \cdots) - (a + b + \cdots)$. In reaction (15.11), $\Delta n_{gas} = 2 - (2 + 1) = -1$, and thus, $K_p = K_c(RT)^{-1}$, as we established previously. It is important to note that, when applying equation (15.16), we must use $R = 0.08314472$ bar L K^{-1} mol^{-1}. This value of R is required because, as discussed previously, partial pressures are to be expressed in bar and concentrations in mol/L.

KEEP IN MIND

that $K_p = K_c$ only if $\Delta n_{gas} = 0$. That is, $K_p = K_c(RT)^0 = K_c$ because any number raised to the zero power equals one.

Let us address another very important fact concerning the equilibrium constants we have encountered. The equilibrium constant K, expressed in terms of activities, is a dimensionless quantity. Unlike K, the equilibrium constants K_p and K_c have units of $(\text{bar})^{\Delta n}$ and $(\text{mol/L})^{\Delta n}$, respectively. The factors $(1/c^\circ)^{\Delta n}$ and $(1/P^\circ)^{\Delta n}$ appearing in equations (15.7) and (15.15) ensure that K is a dimensionless quantity. Throughout this text, we will use K_p and K_c expressions in solving problems. To avoid the clutter of units in these calculations, and to simplify the

EXAMPLE 15-3 Illustrating the Dependence of K on the Reference State

Complete the calculation of K_p for reaction (15.11) knowing that $K_c = 2.8 \times 10^2$ (at 1000 K).

Analyze

We use equation (15.16), with $R = 0.08314$ bar L K^{-1} mol^{-1}. For reasons outlined on page 666, units are omitted from our calculations.

Solve

Write the equation relating the two equilibrium constants with different reference states.

$$K_c = RT \times K_p$$

Rearrange the expression to obtain the quantity desired, K_p.

$$K_p = \frac{K_c}{RT}$$

Substitute the given data and solve.

$$K_p = \frac{2.8 \times 10^2}{0.08314 \times 1000} = 3.4$$

Assess

In this example the equilibrium constant depends on the reference state used. When working this type of problem, keep in mind that Δn is equal to the sum of coefficients of products in the gas phase minus the sum of coefficients of reactants in the gas phase. That is, for the purposes of converting a K_p value to K_c value (or vice versa), Δn is obtained from the coefficients in the chemical equation, not from the actual amounts of gases present in an equilibrium mixture.

PRACTICE EXAMPLE A: For the reaction $2\,NH_3(g) \rightleftharpoons N_2(g) + 3\,H_2(g)$ at 298 K, $K_c = 2.8 \times 10^{-9}$. What is the value of K_p for this reaction?

PRACTICE EXAMPLE B: At 1065 °C, for the reaction $2\,H_2S(g) \rightleftharpoons 2\,H_2(g) + S_2(g)$, $K_p = 1.2 \times 10^{-2}$. What is the value of K_c for the reaction $H_2(g) + \frac{1}{2}S_2(g) \rightleftharpoons H_2S(g)$ at 1065 °C?

conversion of a K_c or K_p value to a K value, we will always use the numerical values of partial pressures or concentrations in the expressions without including the units bar or mol/L explicitly.

Equilibria Involving Pure Liquids and Solids

Up to this point in the chapter, all our examples have involved gas phase reactions or reactions occurring in aqueous solutions. Gas-phase reactions and reactions in aqueous solution are *homogeneous* reactions: They occur within a single phase. Let's extend our coverage now to include reactions involving one or more condensed phases—solids and liquids—in contact with a gas or solution phase. These are called *heterogeneous* reactions. One of the most important ideas about heterogeneous reactions is that

> Equilibrium constant expressions *do not* contain concentration terms for solid or liquid phases of a single component (that is, for pure solids and liquids).

We can think about this statement in either of two ways: (1) An equilibrium constant expression includes terms only for reactants and products whose concentrations and/or partial pressures *can change* during a chemical reaction. The concentration of the single component within a pure solid or liquid phase *cannot change.* (2) Alternatively, recall that the activities of pure liquids and solids are set equal to 1; thus the effect on the numerical value of the equilibrium constant is the same as not including terms for pure solids and liquids at all.

The water–gas reaction, used to make combustible gases from coal, has reacting species in both gaseous and solid phases.

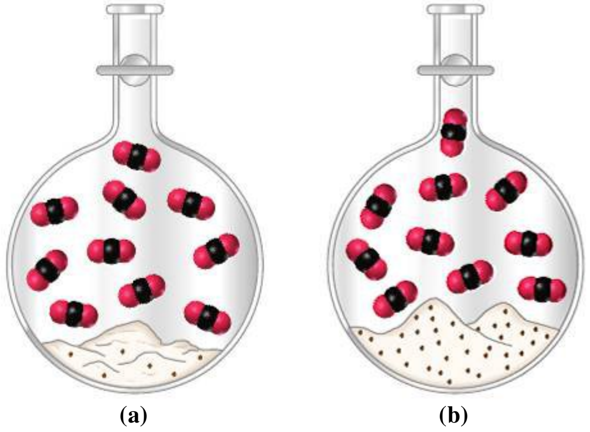
$$C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g)$$

◀ Still another way to think about solids and liquids is through their densities. Density, the mass per unit volume of a substance, can be expressed in moles per liter by converting the unit volume from milliliter to liter and dividing the mass in grams by the molar mass. The resultant molar density (mol/L) is a concentration term and, at a fixed temperature, is a constant that would be incorporated in the K_c value.

▶ FIGURE 15-4
Equilibrium in the reaction

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

(a) Decomposition of $CaCO_3(s)$ upon heating in a closed vessel yields a few granules CaO(s), together with $CO_2(g)$, which soon exerts its equilibrium partial pressure. **(b)** Introduction of additional $CaCO_3(s)$ and/or more CaO(s) has no effect on the partial pressure of the $CO_2(g)$, which remains the same as in (a).



Although solid carbon must be present for the reaction to occur, the equilibrium constant expression contains terms only for the species in the homogeneous gas phase: H_2O, CO, and H_2.

$$K = \frac{a_{CO}\, a_{H_2}}{a_{C(s)}\, a_{H_2O}} \approx \frac{P_{CO}\, P_{H_2}}{P_{H_2O}} = K_p$$

The activity of solid carbon is $a_{C(s)} = 1$, and we have implicitly divided through each of the remaining pressures by the reference-state pressure, $P° = 1$ bar, to obtain a dimensionless K.

The decomposition of calcium carbonate (limestone) is also a heterogeneous reaction. The equilibrium constant expression, K_c, contains just a single term.

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g) \qquad K_c = [CO_2] \qquad \textbf{(15.17)}$$

We can write K_p for reaction (15.17) by using equation (15.16), with $\Delta n_{gas} = 1$.

$$K_p = P_{CO_2} \qquad \text{and} \qquad K_p = K_c(RT) \qquad \textbf{(15.18)}$$

Equation (15.18) indicates that the equilibrium pressure of $CO_2(g)$ in contact with $CaCO_3(s)$ and CaO(s) is a constant equal to K_p. Its value is *independent* of the quantities of $CaCO_3$ and CaO (as long as both solids are present). Figure 15-4 offers a conceptualization of this decomposition reaction.

One of our examples in Section 15-1 was liquid–vapor equilibrium. This is a physical equilibrium because no chemical reactions are involved. Consider the liquid–vapor equilibrium for water.

$$H_2O(l) \rightleftharpoons H_2O(g)$$
$$K_c = [H_2O(g)] \qquad K_p = P_{H_2O} \qquad K_p = K_cRT$$

So, equilibrium vapor pressures such as P_{H_2O} are just values of K_p. As we have seen before, these values do *not* depend on the quantities of liquid or vapor at equilibrium, as long as some of each is present.

EXAMPLE 15-4 Writing Equilibrium Constant Expressions for Reactions Involving Pure Solids or Liquids

At equilibrium in the following reaction at 60 °C, the partial pressures of the gases are found to be $P_{HI} = 3.70 \times 10^{-3}$ bar and $P_{H_2S} = 1.01$ bar. What is the value of K for the reaction?

$$H_2S(g) + I_2(s) \rightleftharpoons 2\,HI(g) + S(s) \qquad K = ?$$

Analyze

We need to first write the equilibrium constant expression in terms of activities, and then eliminate the activities of pure solids and pure liquids by setting their activities to 1.

Solve

Write the equilibrium constant expression in terms of activities. Note that activities for the iodine and sulfur are not included, since the activity of a pure solid is 1.

$$K = \frac{(a_{HI})^2}{(a_{H_2S})}$$

The partial pressures are given in bar. The activity of each gas is equal to the numerical value of its partial pressure.

$$a_{HI} = 3.70 \times 10^{-3} \text{ and } a_{H_2S} = 1.01$$

Substitute the given equilibrium data into the equilibrium constant expression.

$$K = \frac{(3.70 \times 10^{-3})^2}{1.01} = 1.36 \times 10^{-5}$$

Assess

Note that the equilibrium constant, *K*, has no units. You must remember that activities are dimensionless quantities, and that when the partial pressure of a gas is expressed in bar, the activity is equal to the numerical value of its pressure.

PRACTICE EXAMPLE A: Teeth are made principally from the mineral hydroxyapatite, $Ca_5(PO_4)_3OH$, which can be dissolved in acidic solution such as that produced by bacteria in the mouth. The reaction that occurs is $Ca_5(PO_4)_3OH(s) + 4\,H^+(aq) \rightleftharpoons 5\,Ca^{2+}(aq) + 3\,HPO_4^{2-}(aq) + H_2O(l)$. Write the equilibrium constant expression K_c for this reaction.

PRACTICE EXAMPLE B: The steam–iron process is used to generate $H_2(g)$, mostly for use in hydrogenating oils. Iron metal and steam $[H_2O(g)]$ react to produce $Fe_3O_4(s)$ and $H_2(g)$. Write expressions for K_c and K_p for this reversible reaction. How are the values of K_c and K_p related to each other? Explain.

15-4 The Magnitude of an Equilibrium Constant

In principle, every chemical reaction has an equilibrium constant, but often the constants are not used. Why is this so? Table 15.3 lists equilibrium constants for several reactions mentioned in this chapter or previously in the text. The first of these reactions is the synthesis of H_2O from its elements. We have always assumed that this reaction goes to completion, that is, that the reverse reaction is negligible and the overall reaction proceeds only in the forward direction. If a reaction goes to completion, one (or more) of the reactants is used up. A term in the *denominator* of the equilibrium constant expression approaches *zero* and makes the value of the equilibrium constant very large. A very large numerical value of K signifies that the forward reaction, as written, *goes to completion* or very nearly so. Because the value of K_p for the water synthesis reaction is 1.4×10^{83}, we are entirely justified in saying that the reaction goes to completion at 298 K.

If the equilibrium constant is so large, why is a mixture of hydrogen and oxygen gases stable at room temperature? The value of the equilibrium constant

TABLE 15.3 Equilibrium Constants of Some Common Reactions

Reaction	Equilibrium Constant, K_p
$2\,H_2(g) + O_2(g) \rightleftharpoons 2\,H_2O(l)$	1.4×10^{83} at 298 K
$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$	1.9×10^{-23} at 298 K 1.0 at about 1200 K
$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$	3.4 at 1000 K
$C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g)$	1.6×10^{-21} at 298 K 10.0 at about 1100 K

relates to thermodynamic stability: $H_2O(l)$ is much more thermodynamically stable than a mixture of $H_2(g)$ and $O_2(g)$ because it lies at a lower energy state. As noted in Chapter 14, however, the rate of a chemical reaction is strongly governed by the activation energy, E_a. Because E_a is very high for the synthesis of $H_2O(l)$ from $H_2(g)$ and $O_2(g)$, the rate of reaction is inconsequential at 298 K. To get the reaction to occur at a measurable rate, we must either raise the temperature or use a catalyst. A chemist would say that the synthesis of $H_2O(l)$ at 298 K is a *kinetically* controlled reaction (as opposed to *thermodynamically* controlled).

▶ The products formed in a reaction under *kinetic control* are determined by reaction rates. The products formed in a reaction under *thermodynamic control* will depend on the stability of the products.

From Table 15.3, we see that K_p for the decomposition of $CaCO_3(s)$ (limestone) is very small at 298 K (only 1.9×10^{-23}). To account for a very small numerical value of an equilibrium constant, the *numerator* must be very small (approaching zero). A very small numerical value of K signifies that the forward reaction, as written, *does not occur to any significant extent*. Although limestone does not decompose at ordinary temperatures, the partial pressure of $CO_2(g)$ in equilibrium with $CaCO_3(s)$ and $CaO(s)$ increases with temperature. It becomes 1 atm at about 1200 K. An important application of this decomposition reaction is in the commercial production of quicklime (CaO).

The conversion of $SO_2(g)$ and $O_2(g)$ to $SO_3(g)$ at 1000 K has an equilibrium constant such that we expect significant amounts of both reactants and products to be present at equilibrium (see Table 15.3). Both the forward and reverse reactions are important. A similar situation exists for the reaction of $C(s)$ and $H_2O(g)$ at 1100 K, but not at 298 K where the forward reaction does not occur to any significant extent ($K_p = 1.6 \times 10^{-21}$).

In light of the several cases from Table 15.3, we can conclude the following:

We consider a reaction going to completion if $K > 10^{10}$ or a reaction not occurring in the forward direction if $K < 10^{-10}$.

Thus, we see that equilibrium calculations are not required for all reactions. At times, we can use simple stoichiometric calculations to determine the outcome of a reaction, and in some cases there may be no reaction at all.

15-6 CONCEPT ASSESSMENT

Why is having a balanced equation a necessary condition for predicting the outcome of a chemical reaction, but often not a sufficient condition?

15-5 The Reaction Quotient, Q: Predicting the Direction of Net Change

Let's return briefly to the set of three experiments that we discussed in Section 15-2, involving the reaction

$$2\,Cu^{2+}(aq) + Sn^{2+}(aq) \longrightarrow 2\,Cu^{+}(aq) + Sn^{4+}(aq) \qquad K_c = 1.48 \qquad \textbf{(15.19)}$$

Experiment 1 starts with just the reactants, Cu^{2+} and Sn^{2+}. An overall, or net, change has to occur in which some Cu^{+} and Sn^{4+} forms. Only in this way can an equilibrium condition be reached in which all reacting species are present. We say that a net change occurs in the *forward* direction (*to the right*).

Experiment 2 starts with just the product, Cu^{+} and Sn^{4+}. Here, some of the Cu^{+} and Sn^{4+} must decompose back to Cu^{2+} and Sn^{2+} before equilibrium can be established. We say that a net change occurs in the *reverse* direction (*to the left*).

Experiment 3 starts with all the reacting species present: Cu^{2+}, Sn^{2+}, Cu^{+}, and Sn^{4+}. In this system, it is not obvious in what direction a net change occurs to establish equilibrium.

The ability to predict the direction of net change in establishing equilibrium is important for two reasons.

- At times we do not need detailed equilibrium calculations. We may need only a qualitative description of the changes that occur in establishing equilibrium from a given set of initial conditions.
- In some equilibrium calculations, it is helpful to determine the direction of net change as a first step.

For any set of *initial* activities in a reaction mixture, we can set up a ratio of activities having the same form as the equilibrium constant expression. This ratio is called the **reaction quotient** and is designated Q. For a hypothetical generalized reaction, the reaction quotient, first written in terms of activities, and then as concentrations assuming a concentration reference state, is

$$Q_c = \frac{(a_{\text{init}})^g (a_{\text{init}})^h}{(a_{\text{init}})^a (a_{\text{init}})^b} \qquad Q_c = \frac{[G]_{\text{init}}^g [H]_{\text{init}}^h}{[A]_{\text{init}}^a [B]_{\text{init}}^b} \tag{15.20}$$

If $Q = K$, *a reaction is at equilibrium*, but our primary interest in the relationship between Q and K is for a reaction mixture that is not at equilibrium. To see what this relationship is, let's turn again to the experiments in Table 15.1.

In Experiment 1, the initial concentrations of Cu^{2+} and Sn^{2+} are 0.100 mol/1.00 L = 0.100 M. Initially there is no Cu^{+} and Sn^{4+}. The expression for Q_c is

$$Q_c = \frac{[Cu^{+}]_{\text{init}}^2 [Sn^{4+}]_{\text{init}}}{[Cu^{2+}]_{\text{init}}^2 [Sn^{2+}]_{\text{init}}} = \frac{0 \times 0}{(0.100)^2 (0.100)} = 0 \tag{15.21}$$

We know that a net reaction occurs *to the right*, producing some Cu^{+} and Sn^{4+}. As it does, the numerator in expression (15.21) increases, the denominator decreases, and the value of Q_c increases; eventually $Q_c = K_c$.

If $Q_c < K_c$, then a net change occurs from left to right (the direction of the forward reaction).

In Experiment 2, the initial concentrations of Cu^{+} and Sn^{4+} are 0.100 mol/1.00 L = 0.100 M. Initially, there is no Cu^{2+} and Sn^{2+}. The expression for Q_c is

$$Q_c = \frac{[Cu^{+}]_{\text{init}}^2 [Sn^{4+}]_{\text{init}}}{[Cu^{2+}]_{\text{init}}^2 [Sn^{4+}]_{\text{init}}} = \frac{(0.100)^2 (0.100)}{0 \times 0} = \infty \tag{15.22}$$

◀ Strictly speaking, we cannot evaluate Q_c in this case. Any value divided by zero is undefined. By writing $Q_c = \infty$, we mean the following: As the concentrations of reactants approach a value of zero, Q_c approaches ∞.

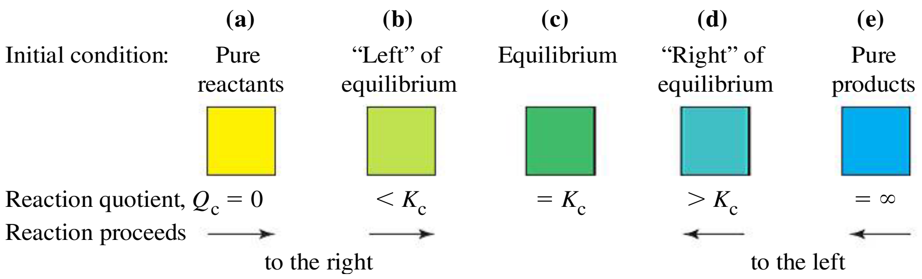
We know that a net reaction occurs *to the left*, producing some Cu^{2+} and Sn^{2+}. As it does, the numerator in expression (15.22) decreases, the denominator increases, and the value of Q_c decreases; eventually $Q_c = K_c$.

If $Q_c > K_c$, a net change occurs from right to left (the direction of the reverse reaction).

Now let us turn to a case where direction of net change is not immediately obvious. In Experiment 3, the initial concentrations of all four species are 0.100 mol/1.00 L = 0.100 M. The value of Q_c is

$$Q_c = \frac{[Cu^{+}]_{\text{init}}^2 [Sn^{4+}]_{\text{init}}}{[Cu^{2+}]_{\text{init}}^2 [Sn^{2+}]_{\text{init}}} = \frac{(0.100)^2 (0.100)}{(0.100)^2 (0.100)} = 1.00$$

Because $Q_c < K_c$ (1.00 compared with 1.48), a net change occurs in the *forward direction*. Note that you can verify this conclusion from Figure 15-3. The



▲ FIGURE 15-5
Predicting the direction of net change in a reversible reaction
Five possibilities for the relationship of initial and equilibrium conditions are shown. From Table 15.1 and Figure 15-3, Experiment 1 corresponds to initial condition (a); Experiment 2 to condition (e); and Experiment 3 to (d). The situation in Example 15-5 also corresponds to condition (d).

amounts of Cu^{2+} and Sn^{2+} at equilibrium are less than they were initially, and the amounts of Cu^{+} and Sn^{4+} are greater.

The criteria for predicting the direction of a net chemical change in a reversible reaction are summarized in Figure 15-5 and applied in Example 15-5.

EXAMPLE 15-5 Predicting the Direction of a Net Chemical Change in Establishing Equilibrium

To increase the yield of $H_2(g)$ in the water–gas reaction—the reaction of C(g) and $H_2O(g)$ to form CO(g) and $H_2(g)$—a follow-up reaction called the "water–gas shift reaction" is generally used. In this reaction, some of the CO(g) of the water gas is replaced by $H_2(g)$.

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

$K_c = 1.00$ at about 1100 K. The following amounts of substances are brought together and allowed to react at this temperature: 1.00 mol CO, 1.00 mol H_2O, 2.00 mol CO_2, and 2.00 mol H_2. Compared with their initial amounts, which of the substances will be present in a greater amount and which in a lesser amount when equilibrium is established?

Analyze

Our task is to determine the direction of net change by evaluating Q_c and comparing it to K_c.

Solve

Write down the expression for Q_c.

$$Q_c = \frac{[CO_2][H_2]}{[CO][H_2O]}$$

Substitute concentrations into the expression for Q_c, by assuming an arbitrary volume V (which cancels out in the calculation).

$$Q_c = \frac{(2.00/V)(2.00/V)}{(1.00/V)(1.00/V)} = 4.00$$

Compare Q_c to K_c.

$$4.00 > 1.00$$

Because $Q_c > K_c$ (that is, $4.00 > 1.00$), a net change occurs to the *left*. When equilibrium is established, the amounts of CO and H_2O will be greater than the initial quantities and the amounts of CO_2 and H_2 will be less.

Assess

It is important to be able to determine the direction of reaction. As we will see in Section 15-7, this step must be completed before we attempt to determine what the equilibrium amounts will be.

PRACTICE EXAMPLE A: In Example 15-5, equal masses of CO, H_2O, CO_2, and H_2 are mixed at a temperature of about 1100 K. When equilibrium is established, which substance(s) will show an increase in quantity and which will show a decrease compared with the initial quantities?

PRACTICE EXAMPLE B: For the reaction $PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$, $K_c = 0.0454$ at 261 °C. If a vessel is filled with these gases such that the initial partial pressures are $P_{PCl_3} = 2.19$ atm, $P_{Cl_2} = 0.88$ atm, $P_{PCl_5} = 19.7$ atm, in which direction will a net change occur?

15-7 CONCEPT ASSESSMENT

A mixture of 1.00 mol each of CO(g), $H_2O(g)$, and $CO_2(g)$ is placed in a 10.0 L flask at a temperature at which $K_p = 10.0$ in the reaction

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

When equilibrium is established, **(a)** the amount of $H_2(g)$ will be 1.00 mol; **(b)** the amounts of all reactants and products will be greater than 1.00 mol; **(c)** the amounts of all reactants and products will be less than 1.00 mol; **(d)** the amount of $CO_2(g)$ will be greater than 1.00 mol and the amounts of CO(g), $H_2O(g)$, and $H_2(g)$ will be less than 1.00 mol; **(e)** the amounts of reactants and products cannot be predicted and can only be determined by analyzing the equilibrium mixture.

KEEP IN MIND

that volumes cancel in a reaction quotient or equilibrium constant expression whenever the sum of the exponents in the numerator equals that in the denominator. This can simplify problem solving in some instances.

15-6 Altering Equilibrium Conditions: Le Châtelier's Principle

At times, we want only to make qualitative statements about a reversible reaction: the direction of a net change, whether the amount of a substance will have increased or decreased when equilibrium is reached, and so on. Also, we may not have the data needed for a quantitative calculation. In these cases, we can use a statement attributed to the French chemist Henri Le Châtelier (1884). **Le Châtelier's principle** is hard to state unambiguously, but its essential meaning is stated here.

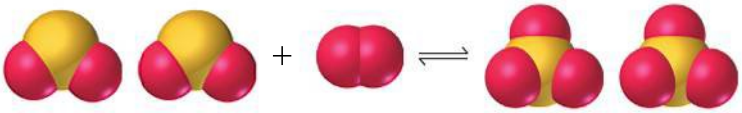
> When an equilibrium system is subjected to a change in temperature, pressure, or concentration of a reacting species, the system responds by attaining a new equilibrium that *partially* offsets the impact of the change.

As we will see in the examples that follow, it is generally not difficult to predict the outcome of changing one or more variables in a system at equilibrium.

Effect of Changing the Amounts of Reacting Species on Equilibrium

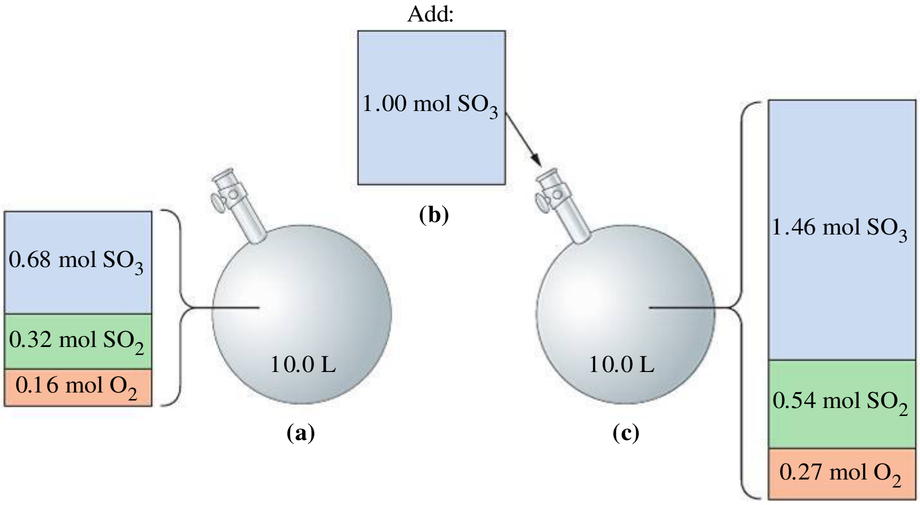
Let's return to reaction (15.11)

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g) \qquad K_c = 2.8 \times 10^2 \text{ at } 1000\text{ K}$$



Suppose we start with certain equilibrium amounts of SO_2, O_2, and SO_3, as suggested by Figure 15-6(a). Now let's create a disturbance in the equilibrium mixture by forcing an additional 1.00 mol SO_3 into the 10.0 L flask (Fig. 15-6b). How will the amounts of the reacting species change to re-establish equilibrium?

According to Le Châtelier's principle, if the system is to partially offset an action that increases the equilibrium concentration of one of the reacting species, it must do so by favoring the reaction in which that species is consumed. In this case, this is the *reverse* reaction—conversion of some of the added SO_3 to SO_2 and O_2. In the new equilibrium, there are greater amounts of all the substances than in the original equilibrium, but the additional amount of SO_3 is less than the 1.00 mol that was added.



▲ FIGURE 15-6
Changing equilibrium conditions by changing the amount of a reactant

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g),\ K_c = 2.8 \times 10^2 \text{ at } 1000\text{ K}$$

(a) The original equilibrium condition. **(b)** Disturbance caused by adding 1.00 mol SO_3. **(c)** The new equilibrium condition. The amount of SO_3 in the new equilibrium mixture, 1.46 mol, is greater than the original 0.68 mol but it is not as great as immediately after the addition of 1.00 mol SO_3. The effect of adding SO_3 to an equilibrium mixture is *partially* offset when equilibrium is restored.

Another way to look at the matter is to evaluate the reaction quotient immediately after adding the SO_3.

Original equilibrium

$$Q_c = \frac{[SO_3]}{[SO_2]^2[O_2]} = K_c$$

Immediately following disturbance

$$Q_c = \frac{[SO_3]}{[SO_2]^2[O_2]} > K_c$$

EXAMPLE 15-6 Applying Le Châtelier's Principle: Effect of Adding More of a Reactant to an Equilibrium Mixture

Predict the effect of adding more $H_2(g)$ to a constant-volume equilibrium mixture of N_2, H_2, and NH_3.

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$$

Analyze

When a system at equilibrium is disturbed by adding more of one reactant, the system responds by using up (consuming) some of the added reactant.

Solve

Increasing $[H_2]$ stimulates the forward reaction and a shift in the equilibrium condition to the right. However, only a portion of the added H_2 is consumed in this reaction.

Assess

When equilibrium is re-established, there will be more H_2 than was present originally, and also more NH_3, but the amount of N_2 will be *smaller*. Some of the original N_2 must be consumed in converting some of the added H_2 to NH_3.

PRACTICE EXAMPLE A: Given the reaction $2\,CO(g) + O_2(g) \rightleftharpoons 2\,CO_2(g)$, what is the effect of adding $O_2(g)$ to a constant-volume equilibrium mixture?

PRACTICE EXAMPLE B: Calcination of limestone (decomposition by heating), $CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$, is the commercial source of quicklime, $CaO(s)$. After this equilibrium has been established in a constant-temperature, constant-volume container, what is the effect on the equilibrium amounts of materials caused by *adding* some **(a)** $CaO(s)$; **(b)** $CO_2(g)$; **(c)** $CaCO_3(s)$?

Adding any quantity of SO_3 to a constant-volume equilibrium mixture makes Q_c larger than K_c. A net change occurs in the direction that reduces $[SO_3]$, that is, to the left, or in the reverse direction. Notice that reaction in the reverse direction increases $[SO_2]$ and $[O_2]$, further decreasing the value of Q_c.

Effect of Changes in Pressure or Volume on Equilibrium

There are three ways to change the pressure of a constant-temperature equilibrium mixture.

1. **Add or remove a gaseous reactant or product.** The effect of these actions on the equilibrium condition is simply that caused by adding or removing a reaction component, as described previously.
2. **Add an inert gas to the constant-volume reaction mixture.** This has the effect of increasing the *total* pressure, but the partial pressures of the reacting species are all unchanged. An inert gas added to a constant-volume equilibrium mixture has no effect on the equilibrium condition.
3. **Change the pressure by changing the volume of the system.** Decreasing the volume of the system increases the pressure, and increasing the system volume decreases the pressure. Thus, the effect of this type of pressure change is simply that of a volume change.

Let's explore the third situation first. Consider, again, the formation of $SO_3(g)$ from $SO_2(g)$ and $O_2(g)$.

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g) \qquad K_c = 2.8 \times 10^2 \text{ at } 1000\text{ K}$$

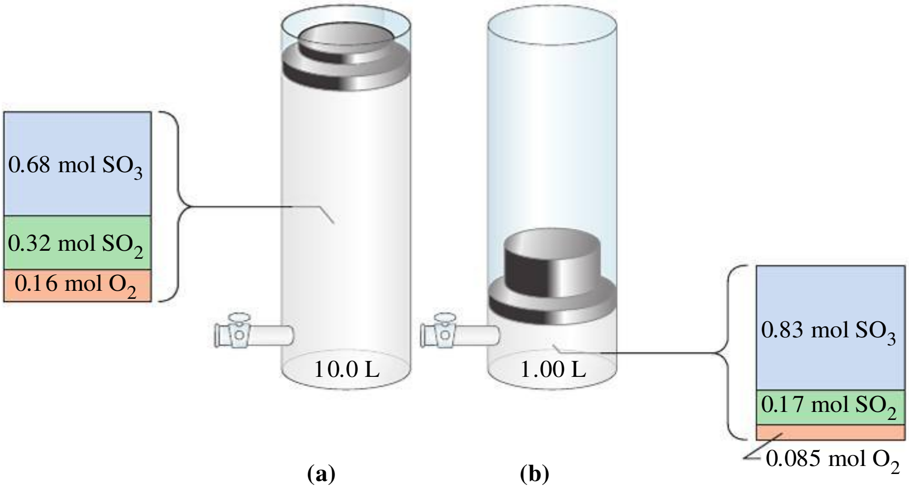
The equilibrium mixture in Figure 15-7(a) has its volume reduced to one-tenth of its original value by increasing the external pressure. To see how the equilibrium amounts of the gases change, let's first rearrange the equilibrium constant expression to the form

$$K_c = \frac{[SO_3]^2}{[SO_2]^2[O_2]} = \frac{(n_{SO_3}/V)^2}{(n_{SO_2}/V)^2(n_{O_2}/V)} = \frac{(n_{SO_3})^2}{(n_{SO_2})^2(n_{O_2})} \times V = 2.8 \times 10^2 \qquad \textbf{(15.23)}$$

From equation (15.23), we see that if V is *reduced* by a factor of 10, the ratio

$$\frac{(n_{SO_3})^2}{(n_{SO_2})^2(n_{O_2})}$$

must *increase* by a factor of 10. In this way, the value of K_c is restored, as it must be to restore equilibrium. There is only one way in which the ratio of moles of gases will increase in value: The number of moles of SO_3 must increase, and



◀ FIGURE 15-7
Effect of pressure change on equilibrium in the reaction
$2SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$
An increase in external pressure causes a decrease in the reaction volume and a shift in equilibrium "to the right." (See Exercise 77 for a calculation of the new equilibrium amounts.)

the numbers of moles of SO_2 and O_2 must decrease. The equilibrium shifts in the direction producing more SO_3—to the right.

Notice that three moles of *gas* on the left produce two moles of *gas* on the right in reaction (15.11). When compared at the same temperature and pressure, two moles of $SO_3(g)$ occupy a smaller volume than does a mixture of two moles of $SO_2(g)$ and one mole of $O_2(g)$. Given this fact and the observation from equation (15.23) that a decrease in volume favors the production of additional SO_3, we can formulate a statement that is especially easy to apply.

When the volume of an equilibrium mixture of gases is *reduced*, a net change occurs in the direction that produces *fewer moles of gas*. When the volume is *increased*, a net change occurs in the direction that produces *more moles of gas.*

KEEP IN MIND

that an inert gas has no effect on an equilibrium condition if the gas is added to a system maintained at constant volume, but it can have an effect if added at constant pressure.

Figure 15-7 suggests a way of decreasing the volume of gaseous mixture at equilibrium—by increasing the external pressure. One way to increase the volume is to lower the external pressure. Another way is to transfer the equilibrium mixture from its original container to one of larger volume. A third method is to add an inert gas at *constant pressure*; the volume of the mixture must increase to make room for the added gas. The effect on the equilibrium, however, is the same for all three methods: Equilibrium shifts in the direction of the reaction producing the greater number of moles of gas.

Equilibria between condensed phases are not affected much by changes in external pressure because solids and liquids are not easily compressible. Also, we cannot assess whether the forward or reverse reaction is favored by these changes by examining only the chemical equation.

15-8 CONCEPT ASSESSMENT

To the hypothetical reaction $A(g) + B(g) \rightleftharpoons C(g)$ 0.100 mol of the inert gas argon is added. In addition, the volume of the container is decreased. According to Le Châtelier's principle, will the reaction shift to the right or left? Explain.

EXAMPLE 15-7 Applying Le Châtelier's Principle: The Effect of Changing Volume

An equilibrium mixture of $N_2(g)$, $H_2(g)$, and $NH_3(g)$ is transferred from a 1.50 L flask to a 5.00 L flask. In which direction does a net change occur to restore equilibrium?

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$$

Analyze

Because the volume has increased, the reaction will move in the direction that increases the number of moles of gas.

Solve

When the gaseous mixture is transferred to the larger flask, the partial pressure of each gas and the total pressure drop. Whether we think in terms of a decrease in pressure or an increase in volume, we reach the same conclusion. Equilibrium shifts in such a way as to produce a larger number of moles of gas. Some of the NH_3 originally present decomposes back to N_2 and H_2. A net change occurs in the direction of the reverse reaction—to the left—in restoring equilibrium.

Assess

Whether we think in terms of a decrease in pressure or an increase in volume, the conclusion is the same.

PRACTICE EXAMPLE A: The reaction $N_2O_4(g) \rightleftharpoons 2\,NO_2(g)$ is at equilibrium in a 3.00 L cylinder. What would be the effect on the concentrations of $N_2O_4(g)$ and $NO_2(g)$ if the pressure were doubled (that is, cylinder volume decreased to 1.50 L)?

PRACTICE EXAMPLE B: How is the equilibrium amount of $H_2(g)$ produced in the water–gas shift reaction affected by changing the total gas pressure or the system volume? Explain.

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

15-9 CONCEPT ASSESSMENT

The following reaction is brought to equilibrium at 700 °C.

$$2\,H_2S(g) + CH_4(g) \rightleftharpoons CS_2(g) + 4\,H_2(g)$$

Indicate whether each of the following statements is true, false, or not possible to evaluate from the information given.

(a) If the equilibrium mixture is allowed to expand into an evacuated larger container, the mole fraction of H_2 will increase.

(b) If several moles of Ar(g) are forced into the reaction container, the amounts of H_2S and CH_4 will increase.

(c) If the equilibrium mixture is cooled to 100 °C, the mole fractions of the four gases will likely change.

(d) If the equilibrium mixture is forced into a slightly smaller container, the partial pressures of the four gases will all increase.

Effect of Temperature on Equilibrium

We can think of changing the temperature of an equilibrium mixture in terms of adding heat (raising the temperature) or removing heat (lowering the temperature). According to Le Châtelier's principle, adding heat favors the reaction in which heat is absorbed (*endothermic* reaction). Removing heat favors the reaction in which heat is evolved (*exothermic* reaction). Stated in terms of changing temperature,

> *Raising the temperature* of an equilibrium mixture shifts the equilibrium condition in the direction of the *endothermic* reaction. *Lowering the temperature* causes a shift in the direction of the *exothermic* reaction.

The principal effect of temperature on equilibrium is in changing the value of the equilibrium constant. In Chapter 19, we will learn how to calculate equilibrium constants as a function of temperature. For now, we will limit ourselves to making qualitative predictions.

EXAMPLE 15-8 Applying Le Châtelier's Principle: Effect of Temperature on Equilibrium

Consider the reaction

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g) \qquad \Delta H^\circ = -197.8\text{ kJ}$$

Will the amount of $SO_3(g)$ formed from given amounts of $SO_2(g)$ and $O_2(g)$ be greater at high or low temperatures?

Analyze

We must think of the impact made by changing the temperature. In general, an increase in temperature causes a shift in the direction of the endothermic reaction.

Solve

The sign of ΔH° tells us that the forward reaction is exothermic. Thus, the reverse reaction is endothermic. In this case, increasing the temperature will favor the reverse reaction and lowering the temperature will favor the forward reaction. The conversion of SO_2 to SO_3 is favored at *low* temperatures.

(continued)

Assess

Be sure not to confuse shifts in equilibrium with changes in reaction rates that result from temperature changes. That is, equilibria of exothermic and endothermic reactions will shift *differently* when temperatures are increased, but the rates of exothermic and endothermic reactions *both increase* with increasing temperature. Changing the temperature is somewhat different than other changes we have discussed in this section. Changing the temperature causes a shift in the equilibrium position and changes the value of the equilibrium constant. We will discuss the temperature dependence of K in Chapter 19.

PRACTICE EXAMPLE A: The reaction $N_2O_4(g) \rightleftharpoons 2\,NO_2(g)$ has $\Delta H° = +57.2$ kJ. Will the amount of $NO_2(g)$ formed from $N_2O_4(g)$ be greater at high or low temperatures?

PRACTICE EXAMPLE B: The enthalpy of formation of NH_3 is $\Delta H_f^\circ[NH_3(g)] = -46.11$ kJ/mol NH_3. Will the concentration of NH_3 in an equilibrium mixture with its elements be greater at 100 or at 300 °C? Explain.

▲ **Sulfuric acid is produced from SO_3**

$$SO_3(g) + H_2O(l) \rightleftharpoons H_2SO_4(aq)$$

The catalyst used to speed up the conversion of SO_2 to SO_3 in the commercial production of sulfuric acid is $V_2O_5(s)$. What appears to be smoke coming from the cooling tower (in the rear) is in fact just water vapor.

Effect of a Catalyst on Equilibrium

Adding a catalyst to a reaction mixture speeds up both the forward and reverse reactions. Equilibrium is achieved more rapidly, but the equilibrium amounts are unchanged by the catalyst. Consider again reaction (15.11)

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g) \qquad K_c = 2.8 \times 10^2 \text{ at } 1000 \text{ K}$$

For a given set of reaction conditions, the equilibrium amounts of SO_2, O_2, and SO_3 have fixed values. This is true whether the reaction is carried out by a slow homogeneous reaction, catalyzed in the gas phase, or conducted as a heterogeneous reaction on the surface of a catalyst. Stated another way, the presence of a catalyst does not change the numerical value of the equilibrium constant.

We now have two thoughts about a catalyst to reconcile: one from the preceding chapter and one from this discussion.

- A catalyst changes the mechanism of a reaction to one with a lower activation energy.
- A catalyst has no effect on the condition of equilibrium in a reversible reaction.

Taken together, these two statements must mean that an equilibrium condition is *independent* of the reaction mechanism. Thus, even though equilibrium has been described in terms of opposing reactions occurring at equal rates, we do not have to be concerned with the kinetics of chemical reactions to work with the equilibrium concept. This observation is still another indication that the equilibrium constant is a thermodynamic quantity, as we shall describe more fully in Chapter 19.

15-10 CONCEPT ASSESSMENT

Two students are performing the same experiment in which an endothermic reaction rapidly attains a condition of equilibrium. Student A does the reaction in a beaker resting on the surface of the lab bench while student B holds the beaker in which the reaction occurs. Assuming that all other environmental variables are the same, which student should end up with more product? Explain.

15-7 Equilibrium Calculations: Some Illustrative Examples

We are now ready to tackle the problem of describing, in quantitative terms, the condition of equilibrium in a reversible reaction. Part of the approach we use may seem unfamiliar at first—it has an algebraic look to it. But as you adjust to this "new look," do not lose sight of the fact that we continue to use some familiar and important ideas—molar masses, molarities, and stoichiometric factors from the balanced equation, for example.

The five numerical examples that follow apply the general equilibrium principles described earlier in the chapter. The first four involve gases, while the fifth deals with equilibrium in an aqueous solution. (The study of equilibria in aqueous solutions is the principal topic of the next three chapters.) Each example includes an assessment that summarizes the essential features of equilibrium calculations exemplified by that type of problem. You may find it helpful to return to these assessments from time to time as you encounter new equilibrium situations in later chapters.

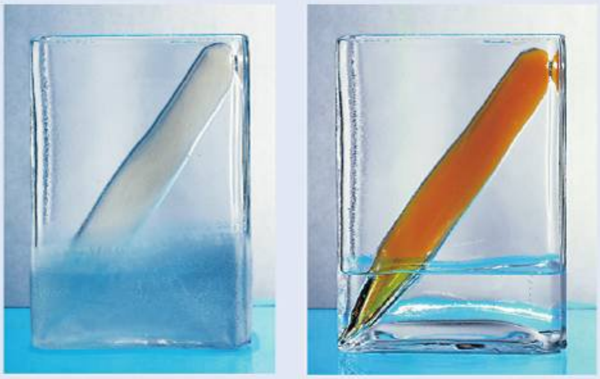
Example 15-9 is relatively straightforward. It demonstrates how to determine the equilibrium constant of a reaction when the equilibrium concentrations of the reactants and products are known.

Example 15-10 is somewhat more involved than Example 15-9. We are still interested in determining the equilibrium constant for a reaction, but we do not have the same sort of information as in Example 15-9. We are given the initial concentrations of all the reactants and products, but the equilibrium concentration of only one substance. This case requires a little algebra and some careful bookkeeping. We will introduce a tabular system, sometimes called an **ICE table**, for keeping track of changing concentrations of reactants and products. The table contains the *initial*, *change in*, and *equilibrium concentration* of each species. It is a helpful device that we will use throughout the next three chapters.

EXAMPLE 15-9 Determining a Value of K_c from the Equilibrium Quantities of Substances

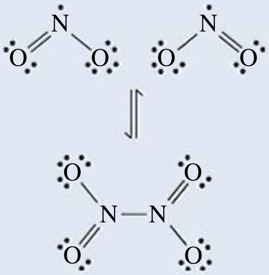
Dinitrogen tetroxide, $N_2O_4(l)$, is an important component of rocket fuels—for example, as an oxidizer of liquid hydrazine in the Titan rocket. At 25 °C, N_2O_4 is a colorless gas that partially dissociates into NO_2, a red-brown gas. The color of an equilibrium mixture of these two gases depends on their relative proportions, which in turn depends on the temperature (Fig. 15-8).

(continued)



(a) (b)

▲ FIGURE 15-8
The equilibrium $N_2O_4(g) \rightleftharpoons 2\ NO_2(g)$
(a) At dry ice temperatures, N_2O_4 exists as a solid. The gas in equilibrium with the solid is mostly colorless N_2O_4, with only a trace of brown NO_2. **(b)** When warmed to room temperature and above, the N_2O_4 melts and vaporizes. The proportion of $NO_2(g)$ at equilibrium increases over that at low temperatures, and the equilibrium mixture of $N_2O_4(g)$ and $NO_2(g)$ has a red-brown color.



▲ **The Lewis structures of N_2O_4 and $NO_2(g)$**
Nitrogen dioxide is a free radical that combines exothermically to form dinitrogen tetroxide.

Equilibrium is established in the reaction $N_2O_4(g) \rightleftharpoons 2\ NO_2(g)$ at 25 °C. The quantities of the two gases present in a 3.00 L vessel are 7.64 g N_2O_4 and 1.56 g NO_2. What is the value of K_c for this reaction?

Analyze

We are given the equilibrium amounts (in terms of mass) of the reactants and products, along with the volume of the reaction vessel. We use these values to determine the equilibrium concentrations and plug them into the equilibrium constant expression.

Solve

Convert the mass of N_2O_4 to moles.

$$\text{mol } N_2O_4 = 7.64 \text{ g } N_2O_4 \times \frac{1 \text{ mol } N_2O_4}{92.01 \text{ g } N_2O_4} = 8.303 \times 10^{-2} \text{ mol}$$

Convert moles of N_2O_4 to mol/L.

$$[N_2O_4] = \frac{8.303 \times 10^{2} \text{ mol}}{3.00 \text{ L}} = 0.0277 \text{ M}$$

Convert the mass of NO_2 to moles.

$$\text{mol } NO_2 = 1.56 \text{ g } NO_2 \times \frac{1 \text{ mol } NO_2}{46.01 \text{ g } NO_2} = 3.391 \times 10^{-2} \text{ mol}$$

Convert moles of NO_2 to mol/L.

$$[NO_2] = \frac{3.391 \times 10^{-2}}{3.00 \text{ L}} = 0.0113 \text{ M}$$

Write the equilibrium constant expression, substitute the equilibrium concentrations, and solve for K_c.

$$K_c = \frac{[NO_2]^2}{[N_2O_4]} = \frac{(0.0113)^2}{(0.0277)} = 4.61 \times 10^{-3}$$

Assess

The quantities required in an equilibrium constant expression, K_c, are equilibrium *concentrations in moles per liter*, not simply equilibrium amounts in moles or masses in grams. It is helpful to organize all the equilibrium data and carefully label each item.

PRACTICE EXAMPLE A: Equilibrium is established in a 3.00 L flask at 1405 K for the reaction $2\ H_2S(g) \rightleftharpoons 2\ H_2(g) + S_2(g)$. At equilibrium, there is 0.11 mol $S_2(g)$, 0.22 mol $H_2(g)$, and 2.78 mol $H_2S(g)$. What is the value of K_c for this reaction?

PRACTICE EXAMPLE B: Equilibrium is established at 25 °C in the reaction $N_2O_4(g) \rightleftharpoons 2\ NO_2(g)$, $K_c = 4.61 \times 10^{-3}$. If $[NO_2] = 0.0236$ M in a 2.26 L flask, how many grams of N_2O_4 are also present?

EXAMPLE 15-10 Determining a Value of K_p from Initial and Equilibrium Amounts of Substances: Relating K_c and K_p

The equilibrium condition for $SO_2(g)$, $O_2(g)$, and $SO_3(g)$ is important in sulfuric acid production. When a 0.0200 mol sample of SO_3 is introduced into an evacuated 1.52 L vessel at 900 K, 0.0142 mol SO_3 is present at equilibrium. What is the value of K_p for the dissociation of $SO_3(g)$ at 900 K?

$$2\,SO_3(g) \rightleftharpoons 2\,SO_2(g) + O_2(g) \qquad K_p = ?$$

Analyze

Let's first determine K_c and then convert to K_p by using equation (15.16). In the ICE table below, the key term leading to the other data is the change in amount of SO_3: In progressing from 0.0200 mol SO_3 to 0.0142 mol SO_3, 0.0058 mol SO_3 is dissociated. The *negative sign* (−0.0058 mol) indicates that this amount of SO_3 is consumed in establishing equilibrium. In the row labeled "changes," the changes in amounts of SO_2 and O_2 must be related to the change in amount of SO_3. For this, we use the stoichiometric coefficients from the balanced equation: 2, 2, and 1. That is, *two* moles of SO_2 and *one* mole of O_2 are produced for every *two* moles of SO_3 that dissociate.

Solve

The reaction:	**$2\,SO_3(g)$**	**$\rightleftharpoons$**	**$2\,SO_2(g)$**	**+**	**$O_2(g)$**
initial amounts:	0.0200 mol		0.00 mol		0.00 mol
changes:	−0.0058 mol		+0.0058 mol		+0.0029 mol
equil amounts:	0.0142 mol		0.0058 mol		0.0029 mol
equil concns:	$[SO_3] = \dfrac{0.0142\text{ mol}}{1.52\text{ L}}$;		$[SO_2] = \dfrac{0.0058\text{ mol}}{1.52\text{ L}}$;		$[O_2] = \dfrac{0.0029\text{ mol}}{1.52\text{ L}}$
	$[SO_3] = 9.34 \times 10^{-3}\text{ M}$;		$[SO_2] = 3.8 \times 10^{-3}\text{ M}$;		$[O_2] = 1.9 \times 10^{-3}\text{ M}$

$$K_c = \frac{[SO_2]^2[O_2]}{[SO_3]^2} = \frac{(3.8 \times 10^{-3})^2(1.9 \times 10^{-3})}{(9.34 \times 10^{-3})^2} = 3.1 \times 10^{-4}$$

$$\begin{aligned} K_p &= K_c(RT)^{\Delta n_{gas}} = 3.1 \times 10^{-4}(0.0821 \times 900)^{(2+1)-2} \\ &= 3.1 \times 10^{-4}(0.0821 \times 900)^1 = 2.3 \times 10^{-2} \end{aligned}$$

Assess

The chemical equation for a reversible reaction serves both to establish the form of the equilibrium constant expression and to provide the conversion factors (stoichiometric factors) to relate the equilibrium quantity of one species to equilibrium quantities of the others.

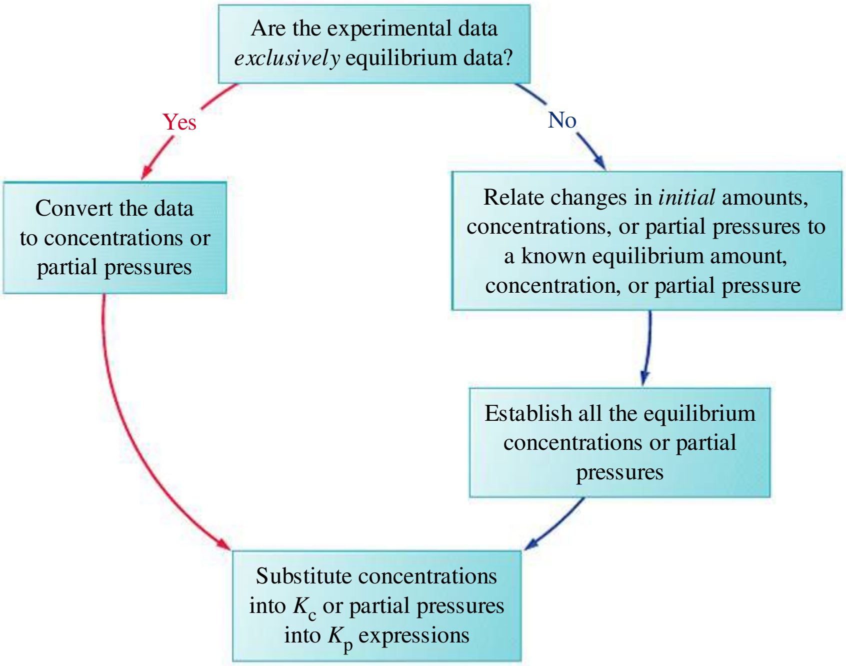
For equilibria involving gases, we can use either K_c or K_p. In general, if the data given involve amounts of substances and volumes, it is easier to work with K_c. If data are given as partial pressures, then work with K_p. Whether working with K_c or K_p or the relationship between them, we must always base these expressions on the given chemical equation, not on equations we may have used in other situations.

PRACTICE EXAMPLE A: A 5.00 L evacuated flask is filled with 1.86 mol NOBr. At equilibrium at 25 °C, there is 0.082 mol of Br_2 present. Determine K_c and K_p for the reaction $2\,NOBr(g) \rightleftharpoons 2\,NO(g) + Br_2(g)$.

PRACTICE EXAMPLE B: 0.100 mol SO_2 and 0.100 mol O_2 are introduced into an evacuated 1.52 L flask at 900 K. When equilibrium is reached, the amount of SO_3 found is 0.0916 mol. Use these data to determine K_p for the reaction $2\,SO_3(g) \rightleftharpoons 2\,SO_2(g) + O_2(g)$.

The methods used in Examples 15-9 and 15-10 are summarized in Figure 15-9. Example 15-11 demonstrates that we can often determine several pieces of useful information about an equilibrium system from just the equilibrium constant and the reaction equation.

Example 15-12 brings back the ICE format, but with a twist. This time the known values include the equilibrium constant and an initial amount of the reactant, but no information is given about the equilibrium amount of the reactant or the product. That means that we do not know how much the initial value will change. We show this by using an "*x*" in that part of the table. The setup will be quite algebraic; in fact, we must use the quadratic formula to obtain a solution.



Are the experimental data *exclusively* equilibrium data?
Yes
No
Convert the data to concentrations or partial pressures
Relate changes in *initial* amounts, concentrations, or partial pressures to a known equilibrium amount, concentration, or partial pressure
Establish all the equilibrium concentrations or partial pressures
Substitute concentrations into K_c or partial pressures into K_p expressions

▲ FIGURE 15-9
Determining K_c or K_p from experimental data

EXAMPLE 15-11 Determining Equilibrium Partial and Total Pressures from a Value of K_p

Ammonium hydrogen sulfide, $NH_4HS(s)$, used as a photographic developer, is unstable and dissociates at room temperature.

$$NH_4HS(s) \rightleftharpoons NH_3(g) + H_2S(g) \qquad K_p = 0.108 \text{ at } 25\,°C$$

A sample of $NH_4HS(s)$ is introduced into an evacuated flask at 25 °C. What is the total gas pressure at equilibrium?

Analyze

We begin by writing the equilibrium constant expression in terms of pressure. The key step is to recognize that the pressure of ammonia is equal to the pressure of hydrogen sulfide. This will then allow us to determine the pressure of ammonia and hydrogen sulfide.

Solve

K_p for this reaction is just the product of the equilibrium partial pressures of $NH_3(g)$ and $H_2S(g)$, each stated in atmospheres. (There is no term for NH_4HS because it is a solid.) Because these gases are produced in equimolar amounts, $P_{NH_3} = P_{H_2S}$.

$$K_p = (P_{NH_3})(P_{H_2S}) = 0.108$$
$$K_p = (P_{NH_3})(P_{H_2S}) = (P_{NH_3})(P_{NH_3}) = (P_{NH_3})^2 = 0.108$$

Find P_{NH_3}. (Note that the unit atm appears because in the equilibrium expression the reference pressure $P°$ was implicitly included.)

$$P_{NH_3} = \sqrt{0.108} = 0.329 \text{ atm} \qquad P_{H_2S} = P_{NH_3} = 0.329 \text{ atm}$$

The total pressure is

$$P_{tot} = P_{NH_3} + P_{H_2S} = 0.329 \text{ atm} + 0.329 \text{ atm} = 0.658 \text{ atm}$$

Assess

When using K_p expressions, look for relationships among partial pressures of the reactants. If we need to relate the total pressure to the partial pressures of the reactants, we should be able to do this with some equations presented in Chapter 6 (for example, equations 6.15, 6.16, and 6.17).

PRACTICE EXAMPLE A: Sodium hydrogen carbonate (baking soda) decomposes at elevated temperatures and is one of the sources of $CO_2(g)$ when this compound is used in baking.

$$2\,NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + H_2O(g) + CO_2(g) \qquad K_p = 0.231 \text{ at } 100\,°C$$

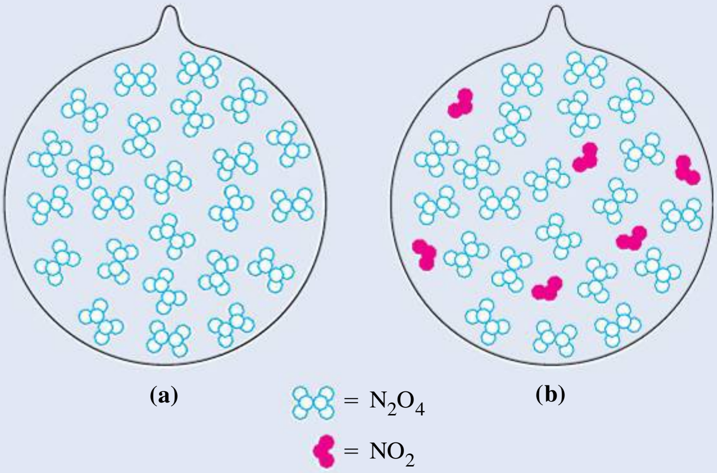
What is the partial pressure of $CO_2(g)$ when this equilibrium is established starting with $NaHCO_3(s)$?

PRACTICE EXAMPLE B: If enough additional $NH_3(g)$ is added to the flask in Example 15-11 to raise its partial pressure to 0.500 atm at equilibrium, what will be the *total* gas pressure when equilibrium is re-established?

EXAMPLE 15-12 Calculating Equilibrium Concentrations from Initial Conditions

A 0.0240 mol sample of $N_2O_4(g)$ is allowed to come to equilibrium with $NO_2(g)$ in a 0.372 L flask at 25 °C. Calculate the amount of N_2O_4 present at equilibrium (Fig. 15-10).

$$N_2O_4(g) \rightleftharpoons 2\,NO_2(g) \qquad K_c = 4.61 \times 10^{-3} \text{ at } 25\ °C$$



◀ FIGURE 15-10
Equilibrium in the reaction

$$N_2O_4(g) \rightleftharpoons 2\,NO_2(g)$$

at 25 °C—Example 15-12 illustrated
Each "molecule" illustrated represents 0.001 mol. **(a)** Initially, the bulb contains 0.024 mol N_2O_4, represented by 24 "molecules." **(b)** At equilibrium, some "molecules" of N_2O_4 have dissociated to NO_2. The 21 "molecules" of N_2O_4 and 6 of NO_2 correspond to 0.021 mol N_2O_4 and 0.006 mol NO_2 at equilibrium.

Analyze

We need to determine the amount of N_2O_4 that dissociates to establish equilibrium. For the first time, we introduce an algebraic unknown, x. Suppose we let $x =$ the number of moles of N_2O_4 that dissociate. In the following ICE table, we enter the value $-x$ into the row labeled "changes." The amount of NO_2 produced is $+2x$ because the stoichiometric coefficient of NO_2 is *2* and that of N_2O_4 is *1*.

Solve

The reaction:	**$N_2O_4(g)$**	$\rightleftharpoons$	**$2\,NO_2(g)$**
initial amounts:	0.0240 mol		0.00 mol
changes:	$-x$ mol		$+2x$ mol
equil amounts:	$(0.0240 - x)$ mol		$2x$ mol
equil concns:	$[N_2O_4] = (0.0240 - x)$ mol/0.372 L		$[NO_2] = 2x$ mol/0.372 L

$$K_c = \frac{[NO_2]^2}{[N_2O_4]} = \frac{\left(\dfrac{2x}{0.372}\right)^2}{\left(\dfrac{0.0240 - x}{0.372}\right)} = \frac{4x^2}{0.372(0.0240 - x)} = 4.61 \times 10^{-3}$$

$$4x^2 = 4.12 \times 10^{-5} - (1.71 \times 10^{-3})x$$

$$x^2 + (4.28 \times 10^{-4})x - 1.03 \times 10^{-5} = 0$$

$$x = \frac{-4.28 \times 10^{-4} \pm \sqrt{(4.28 \times 10^{-4})^2 + 4 \times 1.03 \times 10^{-5}}}{2}$$

$$= \frac{-4.28 \times 10^{-4} \pm \sqrt{(1.83 \times 10^{-7}) + 4.12 \times 10^{-5}}}{2}$$

$$x = \frac{-4.28 \times 10^{-4} \pm \sqrt{4.14 \times 10^{-5}}}{2}$$

$$= \frac{-4.28 \times 10^{-4} \pm 6.43 \times 10^{-3}}{2}$$

(continued)

$$= \frac{-4.28 \times 10^{-4} + 6.43 \times 10^{-3}}{2} = \frac{6.00 \times 10^{-3}}{2}$$

$$= 3.00 \times 10^{-3}\ \text{mol } N_2O_4$$

The amount of N_2O_4 at equilibrium is $(0.0240 - x) = (0.0240 - 0.0030) = 0.0210\ \text{mol } N_2O_4$.

Assess

When we need to introduce an algebraic unknown, x, into an equilibrium calculation, we follow these steps.

- Introduce x into the ICE setup in the row labeled "changes."
- Decide which change to label as x, that is, the amount of a reactant consumed or of a product formed. Usually, we base this on the species that has the smallest stoichiometric coefficient in the balanced chemical equation.
- Use stoichiometric factors to relate the other changes to x (that is, $2x$, $3x$, . . .).
- Consider that equilibrium amounts = initial amounts + "changes." (If you have assigned the correct signs to the changes, equilibrium amounts will also be correct.)
- After substitutions have been made into the equilibrium constant expression, the equation will often be a quadratic equation in x, which you can solve by the quadratic formula. Occasionally you may encounter a higher-degree equation. Appendix A-3 outlines a straightforward method of dealing with these.

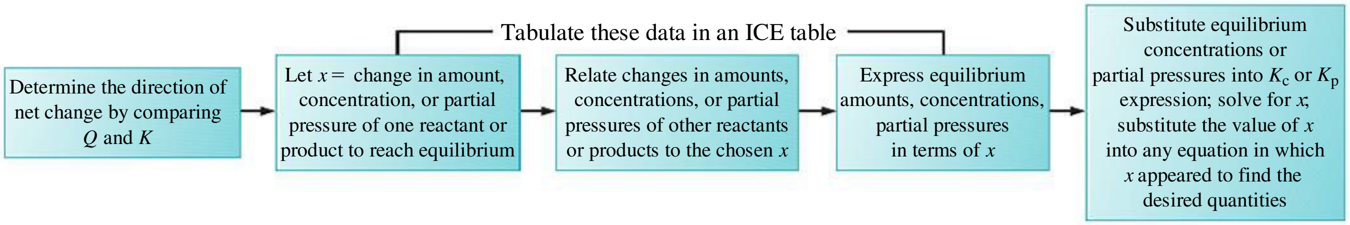
Most of us can solve quadratic equations, but few can solve polynomials greater than a quadratic. If you get an equation that is a cubic or higher degree equation, it is likely that it will simplify by using an approximation.

PRACTICE EXAMPLE A: If 0.150 mol $H_2(g)$ and 0.200 mol $I_2(g)$ are introduced into a 15.0 L flask at 445 °C and allowed to come to equilibrium, how many moles of HI(g) will be present?

$$H_2(g) + I_2(g) \rightleftharpoons 2\,HI(g) \qquad K_c = 50.2 \text{ at } 445\ °C$$

PRACTICE EXAMPLE B: Suppose the equilibrium mixture of Example 15-12 is transferred to a 10.0 L flask. **(a)** Will the equilibrium amount of N_2O_4 increase or decrease? Explain. **(b)** Calculate the number of moles of N_2O_4 in the new equilibrium condition.

Our final example is similar to the previous one, but with this slight complication: Initially, we don't know whether a net change occurs to the right or to the left to establish equilibrium. We can find out, though, by using the reaction quotient, Q_c, and proceeding in the manner suggested in Figure 15-11. Also, because the reactants and products are in solution, we can work exclusively with concentrations in formulating the K_c expression.



Tabulate these data in an ICE table
Determine the direction of net change by comparing Q and K
Let x = change in amount, concentration, or partial pressure of one reactant or product to reach equilibrium
Relate changes in amounts, concentrations, or partial pressures of other reactants or products to the chosen x
Express equilibrium amounts, concentrations, partial pressures in terms of x
Substitute equilibrium concentrations or partial pressures into K_c or K_p expression; solve for x; substitute the value of x into any equation in which x appeared to find the desired quantities

▲ FIGURE 15-11
Determining equilibrium concentrations and partial pressures

EXAMPLE 15-13 Using the Reaction Quotient, Q_c, in an Equilibrium Calculation

Solid silver is added to a solution with these initial concentrations: $[Ag^+] = 0.200$ M, $[Fe^{2+}] = 0.100$ M, and $[Fe^{3+}] = 0.300$ M. The following reversible reaction occurs.

$$Ag^+(aq) + Fe^{2+}(aq) \rightleftharpoons Ag(s) + Fe^{3+}(aq) \qquad K_c = 2.98$$

What are the ion concentrations when equilibrium is established?

(continued)

Analyze

Because all reactants and products are present initially, we need to use the reaction quotient Q_c to determine the direction in which a net change occurs.

$$Q_c = \frac{[Fe^{3+}]}{[Ag^+][Fe^{2+}]} = \frac{0.300}{(0.200)(0.100)} = 15.0$$

Because Q_c (15.0) is larger than K_c (2.98), a net change must occur in the direction of the reverse reaction, *to the left*. Let's define x as the change in molarity of Fe^{3+}. Because the net change occurs *to the left*, we designate the changes for the species on the left side of the equation as positive and those on the right side as negative.

Solve

The reaction:	$Ag^+(aq)$ +	$Fe^{2+}(aq)$ $\rightleftharpoons$	$Ag(s) + Fe^{3+}(aq)$
initial concns:	0.200 M	0.100 M	0.300 M
changes:	$+x$ M	$+x$ M	$-x$ M
equil concns:	$(0.200 + x)$ M	$(0.100 + x)$ M	$(0.300 - x)$ M

$$K_c = \frac{[Fe^{3+}]}{[Ag^+][Fe^{2+}]} = \frac{(0.300 - x)}{(0.200 + x)(0.100 + x)} = 2.98$$

This equation, which is solved in Appendix A-3, is a quadratic equation for which the acceptable root is $x = 0.11$. To obtain the equilibrium concentrations, we substitute this value of x into the terms shown in the table of data.

$$[Ag^+]_{equil} = 0.200 + 0.11 = 0.31 \text{ M}$$
$$[Fe^{2+}]_{equil} = 0.100 + 0.11 = 0.21 \text{ M}$$
$$[Fe^{3+}]_{equil} = 0.300 - 0.11 = 0.19 \text{ M}$$

Assess

If we have done the calculation correctly, we should obtain a value very close to that given for K_c when we substitute the *calculated* equilibrium concentrations into the reaction quotient, Q_c. We do.

$$Q_c = \frac{[Fe^{3+}]}{[Ag^+][Fe^{2+}]} = \frac{(0.19)}{(0.31)(0.21)} = 2.9 \qquad (K_c = 2.98)$$

PRACTICE EXAMPLE A: Excess Ag(s) is added to 1.20 M $Fe^{3+}(aq)$. Given that

$$Ag^+(aq) + Fe^{2+}(aq) \rightleftharpoons Ag(s) + Fe^{3+}(aq) \qquad K_c = 2.98$$

what are the equilibrium concentrations of the species in solution?

PRACTICE EXAMPLE B: A solution is prepared with $[V^{3+}] = [Cr^{2+}] = 0.0100$ M and $[V^{2+}] = [Cr^{3+}] = 0.150$ M. The following reaction occurs.

$$V^{3+}(aq) + Cr^{2+}(aq) \rightleftharpoons V^{2+}(aq) + Cr^{3+}(aq) \qquad K_c = 7.2 \times 10^2$$

What are the ion concentrations when equilibrium is established? [*Hint*: The algebra can be greatly simplified by extracting the square root of both sides of an equation at the appropriate point.]

MasteringCHEMISTRY **www.masteringchemistry.com**

Reversible reactions play an important role in the conversion of elemental nitrogen, $N_2(g)$, into nitrogen compounds, both in Nature and in the chemical industry. For a discussion of both natural and industrial processes that convert elemental nitrogen to nitrogen compounds, go to the Focus On feature for Chapter 15, The Nitrogen Cycle and the Synthesis of Nitrogen Compounds, on the MasteringChemistry site.

Summary

15-1 Dynamic Equilibrium—**Equilibrium** is the condition in which the forward and reverse reaction rates of reversible processes are equal. Chemical and physical processes in equilibrium are dynamic by nature.

15-2 The Equilibrium Constant Expression—This condition of dynamic equilibrium is described through an **equilibrium constant expression**. The form of the equilibrium constant expression is established from the balanced chemical equation using activities to express the "effective" concentrations (equation 15.7). The numerical value obtained from the equilibrium constant expression is referred to as the **equilibrium constant**, K. Equilibrium constants are unitless.

15-3 Relationships Involving Equilibrium Constants—When the equation for a reversible reaction is written in the reverse order, the equilibrium constant expression and the value of K are both inverted from their original form. When two or more reactions are coupled together, the equilibrium constant for the overall reaction is the product of the K values of the individual reactions. The equilibrium constant of a reaction can have different values depending on the reference state used. For K_c a concentration reference state is used, while for K_p, a pressure reference state is used. The relationship between K_c and K_p is given by equation (15.16).

15-4 The Magnitude of an Equilibrium Constant—The magnitude of the equilibrium constant can be used to determine the outcome of a reaction. For large values of K the reaction goes to completion, with all reactants converted to products. A very small equilibrium constant, for example, a large negative power of ten, indicates that practically none of the reactants have been converted to products. Finally, equilibrium constants of an intermediate value, for example, between 10^{-10} and 10^{10}, indicate that some of the reactants have been converted to products.

15-5 The Reaction Quotient, Q: Predicting the Direction of Net Change—The **reaction quotient**, Q (equation 15.20), has the same form as the equilibrium constant expression; however, its numerical value is determined using the initial reaction activities. A comparison of the reaction quotient with the equilibrium constant makes it possible to predict the direction of net change leading to equilibrium (Fig. 15-5). If $Q < K$, the forward reaction is favored, meaning that when equilibrium is established the amounts of products will have increased and the amounts of reactants will have decreased. If $Q > K$, the reverse reaction is favored until equilibrium is established. If $Q = K$, neither the forward nor reverse reaction is favored. The initial conditions are in fact equilibrium conditions.

15-6 Altering Equilibrium Conditions: Le Châtelier's Principle—**Le Châtelier's principle** is used to make qualitative predictions of the effects of different variables on an equilibrium condition. This principle describes how an equilibrium condition is modified, or "shifts," in response to the addition or removal of reactants or changes in reaction volume, external pressure, or temperature. Catalysts, by speeding up the forward and reverse reactions equally, have no effect on an equilibrium condition.

15-7 Equilibrium Calculations Some Illustrative Examples—For quantitative equilibrium calculations, a few basic principles and algebraic techniques are required. A useful method employs a tabular system, called an **ICE table**, for keeping track of the *initial* concentrations of the reactants and products, *changes* in these concentrations, and the *equilibrium* concentrations.

Integrative Example

In the manufacture of ammonia, the chief source of hydrogen gas is the following reaction for the reforming of methane at high temperatures.

$$CH_4(g) + 2\,H_2O(g) \rightleftharpoons CO_2(g) + 4\,H_2(g) \qquad \textbf{(15.24)}$$

The following data are also given.

(a) $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad \Delta H° = -40\text{ kJ};\ K_c = 1.4 \text{ at } 1000\text{ K}$

(b) $CO(g) + 3\,H_2(g) \rightleftharpoons H_2O(g) + CH_4(g) \qquad \Delta H° = -230\text{ kJ};\ K_c = 190 \text{ at } 1000\text{ K}$

At 1000 K, 1.00 mol each of CH_4 and H_2O are allowed to come to equilibrium in a 10.0 L vessel. Calculate the number of moles of H_2 present at equilibrium. Would the yield of H_2 increase if the temperature were raised above 1000 K?

Analyze

First, we should assemble the data needed to solve this problem. The amounts of substances and a reaction volume are given, so we should be able to work with a K_c expression. However, because the K_c value for the reaction of interest is not given, we will have to derive this value by combining the two equations for which data are given. This will yield values of both K_c and ΔH for the reaction of interest.

To calculate the number of moles of H_2 at equilibrium we can use the ICE method, and to assess the effect of temperature on the equilibrium yield of H_2 we can apply Le Châtelier's principle.

Solve

We combine equations (a) and (b) to obtain the data needed in this problem.

$$\begin{array}{llll}
\textbf{(a)} & CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) & \Delta H = -40\ \text{kJ} & K_c = 1.4 \\
\textbf{(b)} & CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\,H_2(g) & \Delta H = 230\ \text{kJ} & K_c = 1/190 \\
\hline
\textit{Overall:} & CH_4(g) + 2\,H_2O(g) \rightleftharpoons CO_2(g) + 4\,H_2(g) & \Delta H = 190\ \text{kJ} & K_c = 1.4/190 = 7.4 \times 10^{-3}
\end{array}$$

Next we set up an ICE table in which x represents the number of moles of CH_4 consumed in reaching equilibrium.

The reaction:	**$CH_4(g)$**	+	**$2\,H_2O(g)$**	$\rightleftharpoons$	**$CO_2(g)$**	+	**$4\,H_2(g)$**
initial amounts:	1.00 mol		1.00 mol		0.00 mol		0.00 mol
changes:	$-x$ mol		$-2x$ mol		x mol		$4x$ mol
equil amounts:	$(1.00 - x)$ mol		$(1.00 - 2x)$ mol		x mol		$4x$ mol
equil concns, M:	$(1.00 - x)/10.0$		$(1.00 - 2x)/10.0$		$x/10.0$		$4x/10.0$

Now we set up K_c and make substitutions into the expression.

$$K_c = \frac{[CO_2][H_2]^4}{[CH_4][H_2O]^2}$$

$$= \frac{(x/10.0)(4x/10.0)^4}{[(1.00 - x)/10.0][(1.00 - 2x)/10.0]^2}$$

$$= \frac{x(4x)^4}{100(1.00 - x)(1.00 - 2x)^2} = 7.4 \times 10^{-3}$$

The above equation reduces to

$$256x^5 = 0.74[(1.00 - x)(1.00 - 2x)^2]$$

and then to

$$256x^5 - 0.74[(1.00 - x)(1.00 - 2x)^2] = 0 \qquad \textbf{(15.25)}$$

The solution to this equation is $x = 0.23$ mol. The number of moles of H_2 at equilibrium is $4x = 0.92$ mol.

Because the reaction is endothermic ($\Delta H = 190$ kJ), the forward reaction is favored at higher temperatures. The equilibrium yield of H_2 will increase if the temperature is raised above 1000 K.

Assess

Equation (15.25) looks impossibly difficult to solve, but it is not. It can be solved for x rather simply by the method of successive approximations. This is done in Appendix A-3, equation (A.2). An important clue as to the possible range of values for x can be found in the ICE table. Note that the equilibrium amount of $H_2O(g)$ is $1.00 - 2x$, meaning that $x < 0.50$, or else all of the $H_2O(g)$ would be consumed. This marks a good place to start the approximations.

PRACTICE EXAMPLE A: Glycolysis involves ten biochemical reactions. The first two reactions of the glycolysis cycle are

$$C_6H_{12}O_6(aq) + ATP(aq) \rightleftharpoons G6P(aq) + ADP(aq) \qquad \Delta H^\circ = -19.74\ \text{kJ mol}^{-1}$$
$$G6P(aq) \rightleftharpoons F6P(aq) \qquad \Delta H^\circ = 2.84\ \text{kJ mol}^{-1}$$

Calculate the equilibrium concentration of F6P(aq) generated in the glycolysis cycle at normal body temperature, 37 °C, starting with $[C_6H_{12}O_6(aq)] = 1.20 \times 10^{-6}$ M; $[ATP(aq)] = 10^{-4}$ M; and $[ADP(aq)] = 10^{-2}$ M. The equilibrium constant for the first reaction is 4.630×10^{3}; for the second reaction it is 2.76×10^{-1}. During a fever body temperature increases. Will [G6P] increase or decrease with an increase with temperature?

PRACTICE EXAMPLE B: A procedure calls for adding 0.100 mol of $Br_2(g)$ at 25 °C to a reaction. The only source of bromine in the laboratory is a bottle of liquid bromine. **(a)** Given the following data, what size container (in liters) must be used to extract enough $Br_2(g)$ for this reaction? The equilibrium constant at 298 K for the reaction $Br_2(g) \rightleftharpoons 2Br(g)$ is $K = 3.30 \times 10^{-29}$. The vapor pressure of liquid bromine is 0.289 atm. **(b)** At 1000 K the equilibrium constant for the reaction $Br_2(g) \rightleftharpoons 2Br(g)$ is 3.4×10^{-5}. What size vessel (in liters) will be needed if the temperature of the vapor is raised to 1000 K?

Exercises

Writing Equilibrium Constants Expressions

1. Based on these descriptions, write a balanced equation and the corresponding K_c expression for each reversible reaction.
(a) Carbonyl fluoride, $COF_2(g)$, decomposes into gaseous carbon dioxide and gaseous carbon tetrafluoride.
(b) Copper metal displaces silver(I) ion from aqueous solution, producing silver metal and an aqueous solution of copper(II) ion.
(c) Peroxodisulfate ion, $S_2O_8^{2-}$, oxidizes iron(II) ion to iron(III) ion in aqueous solution and is itself reduced to sulfate ion.

2. Based on these descriptions, write a balanced equation and the corresponding K_p expression for each reversible reaction.
(a) Oxygen gas oxidizes gaseous ammonia to gaseous nitrogen and water vapor.
(b) Hydrogen gas reduces gaseous nitrogen dioxide to gaseous ammonia and water vapor.
(c) Nitrogen gas reacts with the solid sodium carbonate and carbon to produce solid sodium cyanide and carbon monoxide gas.

3. Write equilibrium constant expressions, K_c, for the reactions
(a) $2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$
(b) $Zn(s) + 2\,Ag^+(aq) \rightleftharpoons Zn^{2+}(aq) + 2\,Ag(s)$
(c) $Mg(OH)_2(s) + CO_3^{2-}(aq) \rightleftharpoons MgCO_3(s) + 2\,OH^-(aq)$

4. Write equilibrium constant expressions, K_p, for the reactions
(a) $CS_2(g) + 4\,H_2(g) \rightleftharpoons CH_4(g) + 2\,H_2S(g)$
(b) $Ag_2O(s) \rightleftharpoons 2\,Ag(s) + \frac{1}{2}O_2(g)$
(c) $2\,NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + CO_2(g) + H_2O(g)$

5. Write an equilibrium constant, K_c, for the formation from its gaseous elements of **(a)** 1 mol $HF(g)$; **(b)** 2 mol $NH_3(g)$; **(c)** 2 mol $N_2O(g)$; **(d)** 1 mol $ClF_3(l)$.

6. Write an equilibrium constant, K_p, for the formation from its gaseous elements of **(a)** 1 mol $NOCl(g)$; **(b)** 2 mol $ClNO_2(g)$; **(c)** 1 mol $N_2H_4(g)$; **(d)** 1 mol $NH_4Cl(s)$.

7. Determine values of K_c from the K_p values given.
(a) $SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$
$K_p = 2.9 \times 10^{-2}$ at 303 K
(b) $2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$
$K_p = 1.48 \times 10^{4}$ at 184 °C
(c) $Sb_2S_3(s) + 3\,H_2(g) \rightleftharpoons 2\,Sb(s) + 3\,H_2S(g)$
$K_p = 0.429$ at 713 K

8. Determine the values of K_p from the K_c values given.
(a) $N_2O_4(g) \rightleftharpoons 2\,NO_2(g)$
$K_c = 4.61 \times 10^{-3}$ at 25 °C
(b) $2\,CH_4(g) \rightleftharpoons C_2H_2(g) + 3\,H_2(g)$
$K_c = 0.154$ at 2000 K
(c) $2\,H_2S(g) + CH_4(g) \rightleftharpoons 4\,H_2(g) + CS_2(g)$
$K_c = 5.27 \times 10^{-8}$ at 973 K

9. The vapor pressure of water at 25 °C is 23.8 mmHg. Write K_p for the vaporization of water, with pressures in atmospheres. What is the value of K_c for the vaporization process?

10. If $K_c = 5.12 \times 10^{-3}$ for the equilibrium established between liquid benzene and its vapor at 25 °C, what is the vapor pressure of C_6H_6 at 25 °C, expressed in millimeters of mercury?

11. Determine K_c for the reaction

$$\frac{1}{2}N_2(g) + \frac{1}{2}O_2(g) + \frac{1}{2}Br_2(g) \rightleftharpoons NOBr(g)$$

from the following information (at 298 K).

$$2\,NO(g) \rightleftharpoons N_2(g) + O_2(g) \quad K_c = 2.1 \times 10^{30}$$

$$NO(g) + \frac{1}{2}Br_2(g) \rightleftharpoons NOBr(g) \quad K_c = 1.4$$

12. Given the equilibrium constant values

$$N_2(g) + \frac{1}{2}O_2(g) \rightleftharpoons N_2O(g) \quad K_c = 2.7 \times 10^{-18}$$

$$N_2O_4(g) \rightleftharpoons 2\,NO_2(g) \quad K_c = 4.6 \times 10^{-3}$$

$$\frac{1}{2}N_2(g) + O_2(g) \rightleftharpoons NO_2(g) \quad K_c = 4.1 \times 10^{-9}$$

Determine a value of K_c for the reaction

$$2\,N_2O(g) + 3\,O_2(g) \rightleftharpoons 2\,N_2O_4(g)$$

13. Use the following data to estimate a value of K_p at 1200 K for the reaction $2\,H_2(g) + O_2(g) \rightleftharpoons 2\,H_2O(g)$

$$C(graphite) + CO_2(g) \rightleftharpoons 2\,CO(g) \quad K_c = 0.64$$

$$CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g) \quad K_c = 1.4$$

$$C(graphite) + \frac{1}{2}O_2(g) \rightleftharpoons CO(g) \quad K_c = 1 \times 10^{8}$$

14. Determine K_c for the reaction $N_2(g) + O_2(g) + Cl_2(g) \rightleftharpoons 2\,NOCl(g)$, given the following data at 298 K.

$$\frac{1}{2}N_2(g) + O_2(g) \rightleftharpoons NO_2(g) \quad K_p = 1.0 \times 10^{-9}$$

$$\mathrm{NOCl(g)} + \frac{1}{2}\mathrm{O_2(g)} \rightleftharpoons \mathrm{NO_2Cl(g)} \qquad K_p = 1.1 \times 10^2$$

$$\mathrm{NO_2(g)} + \frac{1}{2}\mathrm{Cl_2(g)} \rightleftharpoons \mathrm{NO_2Cl(g)} \qquad K_p = 0.3$$

15. An important environmental and physiological reaction is the formation of carbonic acid, $H_2CO_3(aq)$, from carbon dioxide and water. Write the equilibrium constant expression for this reaction in terms of activities. Convert that expression into an equilibrium constant expression containing concentrations and pressures.

16. Rust, $Fe_2O_3(s)$, is caused by the oxidation of iron by oxygen. Write the equilibrium constant expression first in terms of activities, and then in terms of concentration and pressure.

Experimental Determination of Equilibrium Constants

17. 1.00×10^{-3} mol PCl_5 is introduced into a 250.0 mL flask, and equilibrium is established at 284 °C: $PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$. The quantity of $Cl_2(g)$ present at equilibrium is found to be 9.65×10^{-4} mol. What is the value of K_c for the dissociation reaction at 284 °C?

18. A mixture of 1.00 g H_2 and 1.06 g H_2S in a 0.500 L flask comes to equilibrium at 1670 K: $2\,H_2(g) + S_2(g) \rightleftharpoons 2\,H_2S(g)$. The equilibrium amount of $S_2(g)$ found is 8.00×10^{-6} mol. Determine the value of K_p at 1670 K.

19. The two common chlorides of phosphorus, PCl_3 and PCl_5, both important in the production of other phosphorus compounds, coexist in equilibrium through the reaction

$$\mathrm{PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g)}$$

At 250 °C, an equilibrium mixture in a 2.50 L flask contains 0.105 g PCl_5, 0.220 g PCl_3, and 2.12 g Cl_2. What are the values of **(a)** K_c and **(b)** K_p for this reaction at 250 °C?

20. A 0.682 g sample of ICl(g) is placed in a 625 mL reaction vessel at 682 K. When equilibrium is reached between the ICl(g) and $I_2(g)$ and $Cl_2(g)$ formed by its dissociation, 0.0383 g I_2 is present. What is K_c for this reaction?

21. Write the equilibrium constant expression for the following reaction,

$$\mathrm{Fe(OH)_3 + 3H^+(aq) \rightleftharpoons Fe^{3+}(aq) + 3H_2O(l)} \qquad K = 9.1 \times 10^3$$

and compute the equilibrium concentration for $[Fe^{3+}]$ at pH = 7 (i.e., $[H^+] = 1.0 \times 10^{-7}$).

22. Write the equilibrium constant expression for the dissolution of ammonia in water:

$$\mathrm{NH_3(g) \rightleftharpoons NH_3(aq)} \qquad K = 57.5$$

Use this equilibrium constant expression to estimate the partial pressure of $NH_3(g)$ over a solution containing 5×10^{-9} M $NH_3(aq)$. These are conditions similar to that found for acid rains with a high ammonium ion concentration.

Equilibrium Relationships

23. Equilibrium is established at 1000 K, where $K_c = 281$ for the reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$. The equilibrium amount of $O_2(g)$ in a 0.185 L flask is 0.00247 mol. What is the ratio of $[SO_2]$ to $[SO_3]$ in this equilibrium mixture?

24. For the dissociation of $I_2(g)$ at about 1200 °C, $I_2(g) \rightleftharpoons 2\,I(g)$, $K_c = 1.1 \times 10^{-2}$. What volume flask should we use if we want 0.37 mol I to be present for every 1.00 mol I_2 at equilibrium?

25. In the Ostwald process for oxidizing ammonia, a variety of products is possible—N_2, N_2O, NO, and NO_2—depending on the conditions. One possibility is

$$\mathrm{NH_3(g)} + \frac{5}{4}\mathrm{O_2(g)} \rightleftharpoons \mathrm{NO(g)} + \frac{3}{2}\mathrm{H_2O(g)} \qquad K_p = 2.11 \times 10^{19} \text{ at } 700\text{ K}$$

For the decomposition of NO_2 at 700 K,

$$\mathrm{NO_2(g) \rightleftharpoons NO(g)} + \frac{1}{2}\mathrm{O_2(g)} \qquad K_p = 0.524$$

(a) Write a chemical equation for the oxidation of $NH_3(g)$ to $NO_2(g)$.
(b) Determine K_p for the chemical equation you have written.

26. At 2000 K, $K_c = 0.154$ for the reaction $2\,CH_4(g) \rightleftharpoons C_2H_2(g) + 3\,H_2(g)$. If a 1.00 L equilibrium mixture at 2000 K contains 0.10 mol each of $CH_4(g)$ and $H_2(g)$,
(a) what is the mole fraction of $C_2H_2(g)$ present?
(b) Is the conversion of $CH_4(g)$ to $C_2H_2(g)$ favored at high or low pressures?
(c) If the equilibrium mixture at 2000 K is transferred from a 1.00 L flask to a 2.00 L flask, will the number of moles of $C_2H_2(g)$ increase, decrease, or remain unchanged?

27. An equilibrium mixture at 1000 K contains 0.276 mol H_2, 0.276 mol CO_2, 0.224 mol CO, and 0.224 mol H_2O.

$$\mathrm{CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g)}$$

(a) Show that for this reaction, K_c is independent of the reaction volume, V.
(b) Determine the value of K_c and K_p.

28. For the reaction $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$, $K_p = 23.2$ at 600 K. Explain which of the following situations might be found at equilibrium: **(a)** $P_{CO} = P_{H_2O} = P_{CO_2} = P_{H_2}$; **(b)** $P_{H_2}/P_{H_2O} = P_{CO_2}/P_{CO}$; **(c)** $(P_{CO_2})(P_{H_2}) = (P_{CO})(P_{H_2O})$; **(d)** $P_{CO_2}/P_{H_2O} = P_{H_2}/P_{CO}$.

Direction and Extent of Chemical Change

29. Can a mixture of 2.2 mol O_2, 3.6 mol SO_2, and 1.8 mol SO_3 be maintained indefinitely in a 7.2 L flask at a temperature at which $K_c = 100$ in this reaction? Explain.

$$2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_3(g)$$

30. Is a mixture of 0.0205 mol $NO_2(g)$ and 0.750 mol $N_2O_4(g)$ in a 5.25 L flask at 25 °C, at equilibrium? If not, in which direction will the reaction proceed—toward products or reactants?

$$N_2O_4(g) \rightleftharpoons 2\ NO_2(g) \qquad K_c = 4.61 \times 10^{-3} \text{ at } 25\ °C$$

31. In the reaction $2\ SO_2(g) + O_2(g) \rightleftharpoons 2\ SO_3(g)$, 0.455 mol SO_2, 0.183 mol O_2, and 0.568 mol SO_3 are introduced simultaneously into a 1.90 L vessel at 1000 K.
(a) If $K_c = 2.8 \times 10^2$, is this mixture at equilibrium?
(b) If not, in which direction will a net change occur?

32. In the reaction $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$, $K = 31.4$ at 588 K. Equal masses of each reactant and product are brought together in a reaction vessel at 588 K.
(a) Can this mixture be at equilibrium?
(b) If not, in which direction will a net change occur?

33. A mixture consisting of 0.150 mol H_2 and 0.150 mol I_2 is brought to equilibrium at 445 °C, in a 3.25 L flask. What are the equilibrium amounts of H_2, I_2, and HI?

$$H_2(g) + I_2(g) \rightleftharpoons 2\ HI(g) \qquad K_c = 50.2 \text{ at } 445\ °C$$

34. Starting with 0.280 mol $SbCl_3$ and 0.160 mol Cl_2, how many moles of $SbCl_5$, $SbCl_3$, and Cl_2 are present when equilibrium is established at 248 °C in a 2.50 L flask?

$$SbCl_5(g) \rightleftharpoons SbCl_3(g) + Cl_2(g)$$
$$K_c = 2.5 \times 10^{-2} \text{ at } 248\ °C$$

35. Starting with 0.3500 mol CO(g) and 0.05500 mol $COCl_2(g)$ in a 3.050 L flask at 668 K, how many moles of $Cl_2(g)$ will be present at equilibrium?

$$CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$$
$$K_c = 1.2 \times 10^3 \text{ at } 668\ K$$

36. 1.00 g *each* of CO, H_2O, and H_2 are sealed in a 1.41 L vessel and brought to equilibrium at 600 K. How many grams of CO_2 will be present in the equilibrium mixture?

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad K_c = 23.2$$

37. Equilibrium is established in a 2.50 L flask at 250 °C for the reaction

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g) \qquad K_c = 3.8 \times 10^{-2}$$

How many moles of PCl_5, PCl_3, and Cl_2 are present at equilibrium, if
(a) 0.550 mol each of PCl_5 and PCl_3 are initially introduced into the flask?
(b) 0.610 mol PCl_5 alone is introduced into the flask?

38. For the following reaction, $K_c = 2.00$ at 1000 °C.

$$2\ COF_2(g) \rightleftharpoons CO_2(g) + CF_4(g)$$

If a 5.00 L mixture contains 0.145 mol COF_2, 0.262 mol CO_2, and 0.074 mol CF_4 at a temperature of 1000 °C,
(a) Will the mixture be at equilibrium?
(b) If the gases are not at equilibrium, in what direction will a net change occur?
(c) How many moles of each gas will be present at equilibrium?

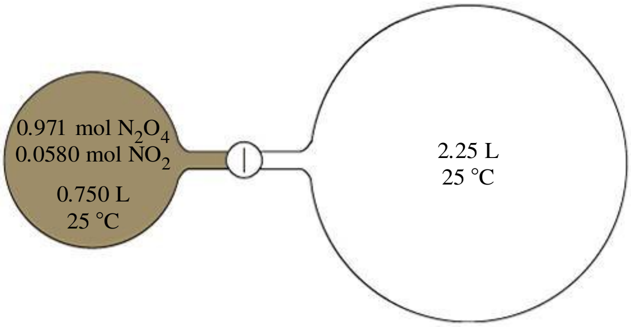
39. In the following reaction, $K_c = 4.0$.

$$C_2H_5OH + CH_3COOH \rightleftharpoons CH_3COOC_2H_5 + H_2O$$

A reaction is allowed to occur in a mixture of 17.2 g C_2H_5OH, 23.8 g CH_3COOH, 48.6 g $CH_3COOC_2H_5$, and 71.2 g H_2O.
(a) In what direction will a net change occur?
(b) How many grams of each substance will be present at equilibrium?

40. The N_2O_4–NO_2 equilibrium mixture in the flask on the left in the figure is allowed to expand into the evacuated flask on the right. What is the composition of the gaseous mixture when equilibrium is re-established in the system consisting of the two flasks?

$$N_2O_4(g) \rightleftharpoons 2\ NO_2(g) \qquad K_c = 4.61 \times 10^{-3} \text{ at } 25\ °C$$



41. Formamide, used in the manufacture of pharmaceuticals, dyes, and agricultural chemicals, decomposes at high temperatures.

$$HCONH_2(g) \rightleftharpoons NH_3(g) + CO(g)$$
$$K_c = 4.84 \text{ at } 400\ K$$

If 0.186 mol $HCONH_2(g)$ dissociates in a 2.16 L flask at 400 K, what will be the *total* pressure at equilibrium?

42. A mixture of 1.00 mol $NaHCO_3(s)$ and 1.00 mol $Na_2CO_3(s)$ is introduced into a 2.50 L flask in which the partial pressure of CO_2 is 2.10 atm and that of $H_2O(g)$ is 715 mmHg. When equilibrium is established at 100 °C, will the partial pressures of $CO_2(g)$ and $H_2O(g)$ be greater or less than their initial partial pressures? Explain.

$$2\ NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + CO_2(g) + H_2O(g)$$
$$K_p = 0.23 \text{ at } 100\ °C$$

43. Cadmium metal is added to 0.350 L of an aqueous solution in which $[Cr^{3+}] = 1.00$ M. What are the concentrations of the different ionic species at equilibrium? What is the minimum mass of cadmium metal required to establish this equilibrium?

$$2\,Cr^{3+}(aq) + Cd(s) \rightleftharpoons 2\,Cr^{2+}(aq) + Cd^{2+}(aq) \qquad K_c = 0.288$$

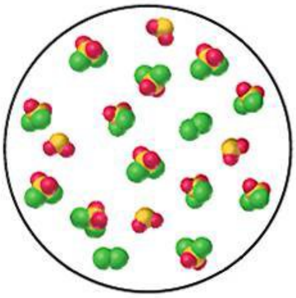
44. Lead metal is added to 0.100 M Cr^{3+}(aq). What are $[Pb^{2+}]$, $[Cr^{2+}]$, and $[Cr^{3+}]$ when equilibrium is established in the reaction?

$$Pb(s) + 2\,Cr^{3+}(aq) \rightleftharpoons Pb^{2+}(aq) + 2\,Cr^{2+}(aq) \qquad K_c = 3.2 \times 10^{-10}$$

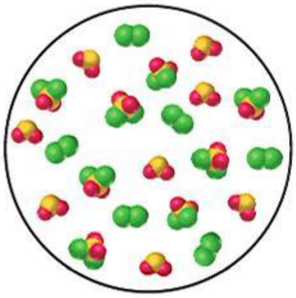
45. One sketch below represents an initial nonequilibrium mixture in the reversible reaction

$$SO_2(g) + Cl_2(g) \rightleftharpoons SO_2Cl_2(g) \qquad K_c = 4.0$$

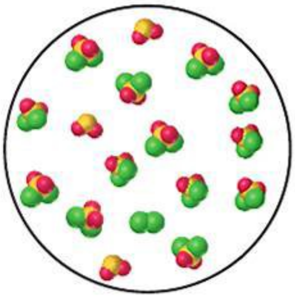
Which of the other three sketches best represents an equilibrium mixture? Explain.



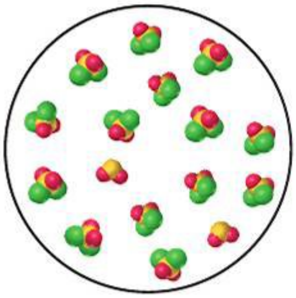
Initial mixture



(a)



(b)

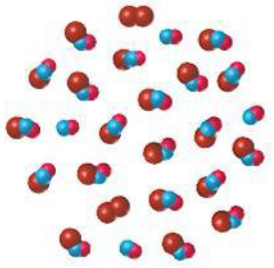


(c)

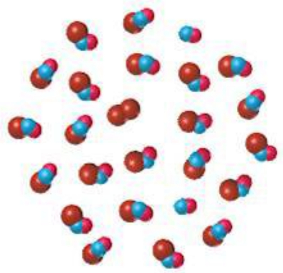
46. One sketch below represents an initial nonequilibrium mixture in the reversible reaction

$$2\,NO(g) + Br_2(g) \rightleftharpoons 2\,NOBr(g) \qquad K_c = 3.0$$

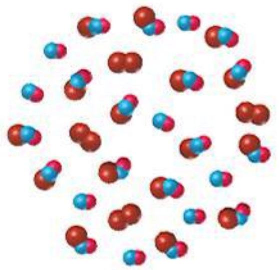
Which of the other three sketches best represents an equilibrium mixture? Explain.



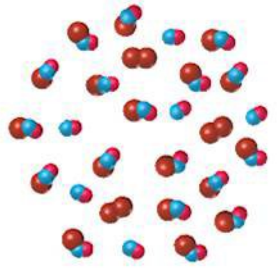
Initial mixture



(a)



(b)



(c)

47. One important reaction in the citric acid cycle is

$$\text{citrate(aq)} \rightleftharpoons \text{aconitate(aq)} + H_2O(l) \qquad K = 0.031$$

Write the equilibrium constant expression for the above reaction. Given that the concentrations of [citrate(aq)] = 0.00128 M, [aconitate(aq)] = 4.0×10^{-5} M, and $[H_2O] = 55.5$ M, calculate the reaction quotient. Is this reaction at equilibrium? If not, in which direction will it proceed?

48. The following reaction is an important reaction in the citric acid cycle:

$$\text{citrate(aq)} + NAD_{ox}(aq) + H_2O(l) \rightleftharpoons$$
$$CO_2(aq) + NAD_{red} + \text{oxoglutarate(aq)} \qquad K = 0.387$$

Write the equilibrium constant expression for the above reaction. Given the following data for this reaction, [citrate] = 0.00128 M, $[NAD_{ox}] = 0.00868$, $[H_2O] = 55.5$ M, $[CO_2] = 0.00868$ M, $[NAD_{red}] = 0.00132$ M, and [oxoglutarate] = 0.00868 M, calculate the reaction quotient. Is this reaction at equilibrium? If not, in which direction will it proceed?

Partial Pressure Equilibrium Constant, K_p

49. Refer to Example 15-4. $H_2S(g)$ at 747.6 mmHg pressure and a 1.85 g sample of $I_2(s)$ are introduced into a 725 mL flask at 60 °C. What will be the total pressure in the flask at equilibrium?

$$H_2S(g) + I_2(s) \rightleftharpoons 2\,HI(g) + S(s) \qquad K_p = 1.34 \times 10^{-5} \text{ at } 60\,°C$$

50. A sample of $NH_4HS(s)$ is placed in a 2.58 L flask containing 0.100 mol $NH_3(g)$. What will be the total gas pressure when equilibrium is established at 25 °C?

$$NH_4HS(s) \rightleftharpoons NH_3(g) + H_2S(g) \qquad K_p = 0.108 \text{ at } 25\,°C$$

51. The following reaction is used in some self-contained breathing devices as a source of $O_2(g)$.

$$4\,KO_2(s) + 2\,CO_2(g) \rightleftharpoons 2\,K_2CO_3(s) + 3\,O_2(g) \qquad K_p = 28.5 \text{ at } 25\,°C$$

Suppose that a sample of $CO_2(g)$ is added to an evacuated flask containing $KO_2(s)$ and equilibrium is established. If the equilibrium partial pressure of $CO_2(g)$ is found to be 0.0721 atm, what are the equilibrium partial pressure of $O_2(g)$ and the total gas pressure?

52. Concerning the reaction in Exercise 51, if $KO_2(s)$ and $K_2CO_3(s)$ are maintained in contact with air at 1.00 atm and 25 °C, in which direction will a net change occur to establish equilibrium? Explain. [*Hint:* Recall equation (6.17). Air is 20.946% O_2 and 0.0379% CO_2 by volume.]

53. 1.00 mol *each* of CO and Cl_2 are introduced into an evacuated 1.75 L flask, and the following equilibrium is established at 668 K.

$$CO(g) + Cl_2(g) \longrightarrow COCl_2(g) \qquad K_p = 22.5$$

For this equilibrium, calculate **(a)** the partial pressure of $COCl_2(g)$; **(b)** the total gas pressure.

54. For the reaction $2\,NO_2(g) \rightleftharpoons 2\,NO(g) + O_2(g)$, $K_c = 1.8 \times 10^{-6}$ at 184 °C. What is the value of K_p for this reaction at 184 °C?

$$NO(g) + \frac{1}{2}O_2(g) \rightleftharpoons NO_2(g)$$

Le Châtelier's Principle

55. Continuous removal of one of the products of a chemical reaction has the effect of causing the reaction to go to completion. Explain this fact in terms of Le Châtelier's principle.

56. We can represent the freezing of $H_2O(l)$ at 0 °C as $H_2O(l, d = 1.00\ g/cm^3) \rightleftharpoons H_2O(s, d = 0.92\ g/cm^3)$. Explain why increasing the pressure on ice causes it to melt. Is this the behavior you expect for solids in general? Explain.

57. Explain how each of the following affects the amount of H_2 present in an equilibrium mixture in the reaction

$$3\,Fe(s) + 4\,H_2O(g) \rightleftharpoons Fe_3O_4(s) + 4\,H_2(g) \qquad \Delta H° = -150\ kJ$$

(a) Raising the temperature of the mixture; **(b)** introducing more $H_2O(g)$; **(c)** doubling the volume of the container holding the mixture; **(d)** adding an appropriate catalyst.

58. In the gas phase, iodine reacts with cyclopentene (C_5H_8) by a free radical mechanism to produce cyclopentadiene (C_5H_6) and hydrogen iodide. Explain how each of the following affects the amount of HI(g) present in the equilibrium mixture in the reaction

$$I_2(g) + C_5H_8(g) \rightleftharpoons C_5H_6(g) + 2\,HI(g) \qquad \Delta H° = 92.5\ kJ$$

(a) Raising the temperature of the mixture; **(b)** introducing more $C_5H_6(g)$; **(c)** doubling the volume of the container holding the mixture; **(d)** adding an appropriate catalyst; **(e)** adding an inert gas such as He to a constant-volume reaction mixture.

59. The reaction $N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g)$, $\Delta H° = +181\ kJ$, occurs in high-temperature combustion processes carried out in air. Oxides of nitrogen produced from the nitrogen and oxygen in air are intimately involved in the production of photochemical smog. What effect does increasing the temperature have on **(a)** the equilibrium production of NO(g); **(b)** the rate of this reaction?

60. Use data from Appendix D to determine whether the forward reaction is favored by high temperatures or low temperatures.

(a) $PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g)$

(b) $SO_2(g) + 2\,H_2S(g) \rightleftharpoons 2\,H_2O(g) + 3\,S(s)$

(c) $2\,N_2(g) + 3\,O_2(g) + 4\,HCl(g) \rightleftharpoons 4\,NOCl(g) + 2\,H_2O(g)$

61. If the volume of an equilibrium mixture of $N_2(g)$, $H_2(g)$, and $NH_3(g)$ is reduced by doubling the pressure, will P_{N_2} have increased, decreased, or remained the same when equilibrium is re established? Explain.

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$$

62. For the reaction

$$A(s) \rightleftharpoons B(s) + 2\,C(g) + \frac{1}{2}D(g) \qquad \Delta H° = 0$$

(a) Will K_p increase, decrease, or remain constant with temperature? Explain.

(b) If a *constant-volume* mixture at equilibrium at 298 K is heated to 400 K and equilibrium re-established, will the number of moles of D(g) increase, decrease, or remain constant? Explain.

63. What effect does increasing the volume of the system have on the equilibrium condition in each of the following reactions?

(a) $C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g)$

(b) $Ca(OH)_2(s) + CO_2(g) \rightleftharpoons CaCO_3(s) + H_2O(g)$

(c) $4\,NH_3(g) + 5\,O_2(g) \rightleftharpoons 4\,NO(g) + 6\,H_2O(g)$

64. For which of the following reactions would you expect the extent of the forward reaction to increase with increasing temperatures? Explain.

(a) $NO(g) \rightleftharpoons \frac{1}{2}N_2(g) + \frac{1}{2}O_2(g) \qquad \Delta H° = -90.2\ kJ$

(b) $SO_3(g) \rightleftharpoons SO_2(g) + \frac{1}{2}O_2(g) \qquad \Delta H° = +98.9\ kJ$

(c) $N_2H_4(g) \rightleftharpoons N_2(g) + 2\,H_2(g) \qquad \Delta H° = -95.4\ kJ$

(d) $COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g) \qquad \Delta H° = +108.3\ kJ$

65. The following reaction represents the binding of oxygen by the protein hemoglobin (Hb):

$$\text{Hb(aq)} + \text{O}_2\text{(aq)} \rightleftharpoons \text{Hb:O}_2\text{(aq)} \qquad \Delta H < 0$$

Explain how each of the following affects the amount of Hb: O_2: **(a)** increasing the temperature; **(b)** decreasing the pressure of O_2; **(c)** increasing the amount of hemoglobin.

66. In the human body, the enzyme carbonic anahydrase catalyzes the interconversion of CO_2 and HCO_3^- by either adding or removing the hydroxide anion. The overall reaction is endothermic. Explain how the following affect the amount of carbon dioxide: **(a)** increasing the amount of bicarbonate anion; **(b)** increasing the pressure of carbon dioxide; **(c)** increasing the amount of carbonic anhydrase; **(d)** decreasing the temperature.

67. A crystal of dinitrogen tetroxide (melting point, −9.3 °C; boiling point, 21.3 °C) is added to an equilibrium mixture of dintrogen tetroxide and nitrogen dioxide that is at 20.0 °C. Will the pressure of nitrogen dioxide increase, decrease, or remain the same? Explain.

68. When hydrogen iodide is heated, the degree of dissociation increases. Is the dissociation reaction exothermic or endothermic? Explain.

69. The standard enthalpy of reaction for the decomposition of calcium carbonate is $\Delta H° = 813.5\ \text{kJ mol}^{-1}$. As temperature increases, does the concentration of calcium carbonate increase, decrease, or remain the same? Explain.

70. Would you expect that the amount of N_2 to increase, decrease, or remain the same in a scuba diver's body as he or she descends below the water surface?

Integrative and Advanced Exercises

71. Explain why the percent of molecules that dissociate into atoms in reactions of the type $I_2(g) \rightleftharpoons 2\ I(g)$ *always* increases with an increase in temperature.

72. A 1.100 L flask at 25 °C and 1.00 atm pressure contains $CO_2(g)$ in contact with 100.0 mL of a saturated aqueous solution in which $[CO_2(aq)] = 3.29 \times 10^{-2}$ M.
(a) What is the value of K_c at 25 °C for the equilibrium $CO_2(g) \rightleftharpoons CO_2(aq)$?
(b) If 0.01000 mol of radioactive $^{14}CO_2$ is added to the flask, how many moles of the $^{14}CO_2$ will be found in the gas phase and in the aqueous solution when equilibrium is re-established? [*Hint:* The radioactive $^{14}CO_2$ distributes itself between the two phases in exactly the same manner as the nonradioactive $^{12}CO_2$.]

73. Refer to Example 15-13. Suppose that 0.100 L of the equilibrium mixture is diluted to 0.250 L with water. What will be the new concentrations when equilibrium is re-established?

74. In the equilibrium described in Example 15-12, the percent dissociation of N_2O_4 can be expressed as

$$\frac{3.00 \times 10^{-3}\ \text{mol N}_2\text{O}_4}{0.0240\ \text{mol N}_2\text{O}_4\ \text{initially}} \times 100\% = 12.5\%$$

What must be the total pressure of the gaseous mixture if $N_2O_4(g)$ is to be 10.0% dissociated at 298 K?

$$\text{N}_2\text{O}_4 \rightleftharpoons 2\ \text{NO}_2\text{(g)} \qquad K_p = 0.113 \text{ at } 298\ \text{K}$$

75. Starting with $SO_3(g)$ at 1.00 atm, what will be the total pressure when equilibrium is reached in the following reaction at 700 K?

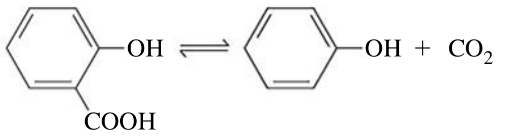
$$2\ \text{SO}_3\text{(g)} \rightleftharpoons 2\ \text{SO}_2\text{(g)} + \text{O}_2\text{(g)} \qquad K_p = 1.6 \times 10^{-5}$$

76. A sample of air with a mole ratio of N_2 to O_2 of 79 : 21 is heated to 2500 K. When equilibrium is established in a closed container with air initially at 1.00 atm, the mole percent of NO is found to be 1.8%. Calculate K_p for the reaction.

$$\text{N}_2\text{(g)} + \text{O}_2\text{(g)} \rightleftharpoons 2\ \text{NO(g)}$$

77. Derive, by calculation, the equilibrium amounts of SO_2, O_2, and SO_3 listed in **(a)** Figure 15-6(c); **(b)** Figure 15-7(b).

78. The decomposition of salicylic acid to phenol and carbon dioxide was carried out at 200.0 °C, a temperature at which the reactant and products are all gaseous. A 0.300 g sample of salicylic acid was introduced into a 50.0 mL reaction vessel, and equilibrium was established. The equilibrium mixture was rapidly cooled to condense salicylic acid and phenol as solids; the $CO_2(g)$ was collected over mercury and its volume was measured at 20.0 °C and 730 mmHg. In two identical experiments, the volumes of $CO_2(g)$ obtained were 48.2 and 48.5 mL, respectively. Calculate K_p for this reaction.



79. One of the key reactions in the gasification of coal is the methanation reaction, in which methane is produced from synthesis gas—a mixture of CO and H_2.

$$\text{CO(g)} + 3\ \text{H}_2\text{(g)} \rightleftharpoons \text{CH}_4\text{(g)} + \text{H}_2\text{O(g)}$$
$$\Delta H = -230\ \text{kJ};\ K_c = 190 \text{ at } 1000\ \text{K}$$

(a) Is the equilibrium conversion of synthesis gas to methane favored at higher or lower temperatures? Higher or lower pressures?
(b) Assume you have 4.00 mol of synthesis gas with a 3:1 mol ratio of $H_2(g)$ to CO(g) in a 15.0 L flask. What will be the mole fraction of $CH_4(g)$ at equilibrium at 1000 K?

80. A sample of pure $PCl_5(g)$ is introduced into an evacuated flask and allowed to dissociate.

$$\text{PCl}_5\text{(g)} \rightleftharpoons \text{PCl}_3\text{(g)} + \text{Cl}_2\text{(g)}$$

If the fraction of PCl_5 molecules that dissociate is denoted by α, and if the total gas pressure is P, show that

$$K_p = \frac{\alpha^2 P}{1 - \alpha^2}$$

81. Nitrogen dioxide obtained as a cylinder gas is always a mixture of $NO_2(g)$ and $N_2O_4(g)$. A 5.00 g sample obtained from such a cylinder is sealed in a 0.500 L flask at 298 K. What is the mole fraction of NO_2 in this mixture?

$$N_2O_4(g) \rightleftharpoons 2\,NO_2(g) \qquad K_c = 4.61 \times 10^{-3}$$

82. What is the apparent molar mass of the gaseous mixture that results when $COCl_2(g)$ is allowed to dissociate at 395 °C and a total pressure of 3.00 atm?

$$COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g)$$
$$K_p = 4.44 \times 10^{-2} \text{ at } 395\ °C$$

Think of the apparent molar mass as the molar mass of a hypothetical single gas that is equivalent to the gaseous mixture.

83. Show that in terms of mole fractions of gases and *total* gas pressure the equilibrium constant expression for

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$$

is

$$K_p = \frac{(x_{NH_3})^2}{(x_{N_2})(x_{H_2})^2} \times \frac{1}{(P_{tot})^2}$$

84. For the synthesis of ammonia at 500 K, $N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$, $K_p = 9.06 \times 10^{-2}$. Assume that N_2 and H_2 are mixed in the mole ratio 1:3 and that the total pressure is maintained at 1.00 atm. What is the mole percent NH_3 at equilibrium? [*Hint*: Use the equation from Exercise 83.]

85. A mixture of $H_2S(g)$ and $CH_4(g)$ in the mole ratio 2:1 was brought to equilibrium at 700 °C and a total pressure of 1 atm. On analysis, the equilibrium mixture was found to contain 9.54×10^{-3} mol H_2S. The CS_2 present at equilibrium was converted successively to H_2SO_4 and then to $BaSO_4$; 1.42×10^{-3} mol $BaSO_4$ was obtained. Use these data to determine K_p at 700 °C for the reaction

$$2\,H_2S(g) + CH_4(g) \rightleftharpoons CS_2(g) + 4\,H_2(g)$$
$$K_p \text{ at } 700\ °C = ?$$

86. A solution is prepared having these initial concentrations: $[Fe^{3+}] = [Hg_2{}^{2+}] = 0.5000$ M; $[Fe^{2+}] = [Hg^{2+}] = 0.03000$ M. The following reaction occurs among the ions at 25 °C.

$$2\,Fe^{3+}(aq) + Hg_2{}^{2+}(aq) \rightleftharpoons 2\,Fe^{2+}(aq) + 2\,Hg^{2+}(aq)$$
$$K_c = 9.14 \times 10^{-6}$$

What will be the ion concentrations at equilibrium?

87. Refer to the Integrative Example. A gaseous mixture is prepared containing 0.100 mol each of $CH_4(g)$, $H_2O(g)$, $CO_2(g)$, and $H_2(g)$ in a 5.00 L flask. Then the mixture is allowed to come to equilibrium at 1000 K in reaction (15.24). What will be the equilibrium amount, in moles, of each gas?

88. Concerning the reaction in Exercise 26 and the situation described in part (c) of that exercise, will the mole fraction of $C_2H_2(g)$ increase, decrease, or remain unchanged when equilibrium is re-established? Explain.

89. The formation of nitrosyl chloride is given by the following equation: $2\,NO(g) + Cl_2(g) \rightleftharpoons 2\,NOCl(g)$; $K_c = 4.6 \times 10^4$ at 298 K. In a 1.50 L flask, there are 4.125 mol of NOCl and 0.1125 mol of Cl_2 present at equilibrium (298 K).
(a) Determine the partial pressure of NO at equilibrium.
(b) What is the total pressure of the system at equilibrium?

90. At 500 K, a 10.0 L equilibrium mixture contains 0.424 mol N_2, 1.272 mol H_2, and 1.152 mol NH_3. The mixture is quickly chilled to a temperature at which the NH_3 liquefies, and the $NH_3(l)$ is completely removed. The 10.0 L gaseous mixture is then returned to 500 K, and equilibrium is re-established. How many moles of $NH_3(g)$ will be present in the new equilibrium mixture?

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3 \qquad K_c = 152 \text{ at } 500\text{ K}$$

91. Recall the formation of methanol from synthesis gas, the reversible reaction at the heart of a process with great potential for the future production of automotive fuels (page 663).

$$CO(g) + 2\,H_2(g) \rightleftharpoons CH_3OH(g)$$
$$K_c = 14.5 \text{ at } 483\text{ K}$$

A particular synthesis gas consisting of 35.0 mole percent CO(*g*) and 65.0 mole percent $H_2(g)$ at a total pressure of 100.0 atm at 483 K is allowed to come to equilibrium. Determine the partial pressure of $CH_3OH(g)$ in the equilibrium mixture.

Feature Problems

92. A classic experiment in equilibrium studies dating from 1862 involved the reaction in solution of ethanol (C_2H_5OH) and acetic acid (CH_3COOH) to produce ethyl acetate and water.

$$C_2H_5OH + CH_3COOH \rightleftharpoons CH_3COOC_2H_5 + H_2O$$

The reaction can be followed by analyzing the equilibrium mixture for its acetic acid content.

$$2\,CH_3COOH(aq) + Ba(OH)_2(aq) \rightleftharpoons Ba(CH_3COO)_2(aq) + 2\,H_2O(l)$$

In one experiment, a mixture of 1.000 mol acetic acid and 0.5000 mol ethanol is brought to equilibrium. A sample containing exactly one-hundredth of the equilibrium mixture requires 28.85 mL 0.1000 M $Ba(OH)_2$ for its titration. Calculate the equilibrium constant, K_c, for the ethanol-acetic acid reaction based on this experiment.

93. The decomposition of HI(g) is represented by the equation

$$2\,HI(g) \rightleftharpoons H_2(g) + I_2(g)$$

HI(g) is introduced into five identical 400 cm^3 glass bulbs, and the five bulbs are maintained at 623 K. Each bulb is opened after a period of time and analyzed for I_2 by titration with 0.0150 M $Na_2S_2O_3$(aq).

$$I_2(aq) + 2\,Na_2S_2O_3(aq) \longrightarrow Na_2S_4O_6(aq) + 2\,NaI(aq)$$

Data for this experiment are provided in the table below. What is the value of K_c at 623 K?

Bulb Number	Initial Mass of HI(g), g	Time Bulb Opened, h	Volume 0.0150 M $Na_2S_2O_3$ Required for Titration, in mL
1	0.300	2	20.96
2	0.320	4	27.90
3	0.315	12	32.31
4	0.406	20	41.50
5	0.280	40	28.68

94. In one of Fritz Haber's experiments to establish the conditions required for the ammonia synthesis reaction, pure NH_3(g) was passed over an iron catalyst at 901 °C and 30.0 atm. The gas leaving the reactor was bubbled through 20.00 mL of a HCl(aq) solution. In this way, the NH_3(g) present was removed by reaction with HCl. The remaining gas occupied a volume of 1.82 L at STP. The 20.00 mL of HCl(aq) through which the gas had been bubbled required 15.42 mL of 0.0523 M KOH for its titration. Another 20.00 mL sample of the same HCl(aq) through which no gas had been bubbled required 18.72 mL of 0.0523 M KOH for its titration. Use these data to obtain a value of K_p at 901 °C for the reaction $N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$.

95. The following is an approach to establishing a relationship between the equilibrium constant and rate constants mentioned in the section on page 660.

- Work with the detailed mechanism for the reaction.
- Use the principle of microscopic reversibility, the idea that every step in a reaction mechanism is reversible. (In the presentation of elementary reactions in Chapter 14, we treated some reaction steps as reversible and others as going to completion. However, as noted in Table 15.3, every reaction has an equilibrium constant even though a reaction is generally considered to go to completion if its equilibrium constant is very large.)
- Use the idea that when equilibrium is attained in an overall reaction, it is also attained in each step of its mechanism. Moreover, we can write an equilibrium constant expression for each step in the mechanism, similar to what we did with the steady-state assumption in describing reaction mechanisms.
- Combine the K_c expressions for the elementary steps into a K_c expression for the overall reaction. The numerical value of the overall K_c can thereby be expressed as a ratio of rate constants, *k*.

Use this approach to establish the equilibrium constant expression for the overall reaction,

$$H_2(g) + I_2(g) \rightleftharpoons 2\,HI(g)$$

The mechanism of the reaction appears to be the following:

Fast: $I_2(g) \rightleftharpoons 2\,I(g)$

Slow: $2\,I(g) + H_2(g) \rightleftharpoons 2\,HI(g)$

96. The following two equilibrium reactions can be written for aqueous carbonic acid, H_2CO_3(aq):

$$H_2CO_3(aq) \rightleftharpoons H^+(aq) + HCO_3^-(aq) \qquad K_1$$
$$HCO_3^-(aq) \rightleftharpoons H^+(aq) + CO_3^{2-}(aq) \qquad K_2$$

For each reaction write the equilibrium constant expression. By using Le Châtelier's principle we may naively predict that by adding H_2CO_3 to the system, the concentration of CO_3^{2-} would increase. What we observe is that after adding H_2CO_3 to the equilibrium mixture, an increase in the concentration of CO_3^{2-} occurs when $[CO_3^{2-}] \ll K_2$; however, the concentration of CO_3^{2-} will decrease when $[CO_3^{2-}] \gg K_2$. Show that this is true by considering the ratio of $[H^+]/[HCO_3^-]$ before and after adding a small amount of H_2CO_3 to the solution, and by using that ratio to calculate the $[CO_3^{2-}]$.

97. In organic synthesis many reactions produce very little yield, that is $K \ll 1$. Consider the following hypothetical reaction: $A(aq) + B(aq) \longrightarrow C(aq)$, $K = 1 \times 10^{-2}$. We can extract product, C, from the aqueous layer by adding an organic layer in which $C(aq) \longrightarrow C(or)$, $K = 15$. Given initial concentrations of $[A] = 0.1$ M, $[B] = 0.1$, and $[C] = 0.1$, calculate how much C will be found in the organic layer. If the organic layer was not present, how much C would be produced?

Self-Assessment Exercises

98. In your own words, define or explain the following terms or symbols: **(a)** K_p; **(b)** Q_c; **(c)** Δn_{gas}.

99. Briefly describe each of the following ideas or phenomena: **(a)** dynamic equilibrium; **(b)** direction of a net chemical change; **(c)** Le Châtelier's principle; **(d)** effect of a catalyst on equilibrium.

100. Explain the important distinctions between each pair of terms: **(a)** reaction that goes to completion and reversible reaction; **(b)** K_c and K_p; **(c)** reaction quotient (Q) and equilibrium constant expression (K); **(d)** homogeneous and heterogeneous reaction.

101. In the reversible reaction $H_2(g) + I_2(g) \rightleftharpoons 2\,HI(g)$, an initial mixture contains 2 mol H_2 and 1 mol I_2. The amount of HI expected at equilibrium is **(a)** 1 mol; **(b)** 2 mol; **(c)** less than 2 mol; **(d)** more than 2 mol but less than 4 mol.

102. Equilibrium is established in the reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$ at a temperature where $K_c = 100$. If the number of moles of $SO_3(g)$ in the equilibrium mixture is the same as the number of moles of $SO_2(g)$, **(a)** the number of moles of $O_2(g)$ is also equal to the number of moles of $SO_2(g)$; **(b)** the number of moles of $O_2(g)$ is half the number of moles of SO_2; **(c)** $[O_2]$ may have any of several values; **(d)** $[O_2] = 0.010$ M.

103. The volume of the reaction vessel containing an equilibrium mixture in the reaction $SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$ is increased. When equilibrium is re-established, **(a)** the amount of Cl_2 will have increased; **(b)** the amount of SO_2 will have decreased; **(c)** the amounts of SO_2 and Cl_2 will have remained the same; **(d)** the amount of SO_2Cl_2 will have increased.

104. For the reaction $2\,NO_2(g) \rightleftharpoons 2\,NO(g) + O_2(g)$, $K_c = 1.8 \times 10^{-6}$ at 184 °C. At 184 °C, the value of K_c for the reaction $NO(g) + \frac{1}{2}O_2(g) \rightleftharpoons NO_2(g)$ is **(a)** 0.9×10^6; **(b)** 7.5×10^2; **(c)** 5.6×10^5; **(d)** 2.8×10^5.

105. For the dissociation reaction $2\,H_2S(g) \rightleftharpoons 2\,H_2(g) + S_2(g)$, $K_p = 1.2 \times 10^{-2}$ at 1065 °C. For this same reaction at 1000 K, **(a)** K_c is less than K_p; **(b)** K_c is greater than K_p; **(c)** $K_c = K_p$; **(d)** whether K_c is less than, equal to, or greater than K_p depends on the total gas pressure.

106. The following data are given at 1000 K: $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$; $\Delta H° = -42$ kJ; $K_c = 0.66$. After an initial equilibrium is established in a 1.00 L container, the equilibrium amount of H_2 can be increased by **(a)** adding a catalyst; **(b)** increasing the temperature; **(c)** transferring the mixture to a 10.0 L container; **(d)** in some way other than (a), (b), or (c).

107. Equilibrium is established in the reversible reaction $2\,A + B \rightleftharpoons 2\,C$. The equilibrium concentrations are $[A] = 0.55$ M, $[B] = 0.33$ M, $[C] = 0.43$ M. What is the value of K_c for this reaction?

108. The Deacon process for producing chlorine gas from hydrogen chloride is used in situations where HCl is available as a by-product from other chemical processes.

$$4\,HCl(g) + O_2(g) \rightleftharpoons 2\,H_2O(g) + 2\,Cl_2(g) \qquad \Delta H° = -114 \text{ kJ}$$

A mixture of HCl, O_2, H_2O, and Cl_2 is brought to equilibrium at 400 °C. What is the effect on the equilibrium amount of $Cl_2(g)$ if

(a) additional $O_2(g)$ is added to the mixture at constant volume?

(b) $HCl(g)$ is removed from the mixture at constant volume?

(c) the mixture is transferred to a vessel of twice the volume?

(d) a catalyst is added to the reaction mixture?

(e) the temperature is raised to 500 °C?

109. For the reaction $SO_2(g) \rightleftharpoons SO_2(aq)$, $K = 1.25$ at 25 °C. Will the amount of $SO_2(g)$ be greater than or less than the amount of $SO_2(aq)$?

110. In the reaction $H_2O_2(g) \rightleftharpoons H_2O_2(aq)$, $K = 1.0 \times 10^5$ at 25 °C. Would you expect a greater amount of product or reactant?

111. An equilibrium mixture of SO_2, SO_3, and O_2 gases is maintained in a 2.05 L flask at a temperature at which $K_c = 35.5$ for the reaction

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$$

(a) If the numbers of moles of SO_2 and SO_3 in the flask are equal, how many moles of O_2 are present?

(b) If the number of moles of SO_3 in the flask is twice the number of moles of SO_2, how many moles of O_2 are present?

112. Using the method in Appendix E, construct a concept map of Section 15-6, illustrating the shift in equilibrium caused by the various types of disturbances discussed in that section.

16

Acids and Bases

Citrus fruit derives its acidic qualities from citric acid, $H_3C_6H_5O_7$, a type of acid (polyprotic) discussed in Section 16-6. Another important constituent of citrus fruit is ascorbic acid, or vitamin C (page 592), a dietary requirement to prevent scurvy.

The general public is familiar with the concepts of acids and bases. The environmental problem of acid rain is a popular topic in newspapers and magazines, and television commercials mention pH in relation to such products as deodorants, shampoos, and antacids.

Chemists have been classifying substances as acids and bases for a long time. Antoine Lavoisier thought that the common element in all acids was oxygen, a fact conveyed by its name. (*Oxygen* means "acid former" in Greek). In 1810, Humphry Davy showed that hydrogen instead is the element that acids have in common. In 1884, Svante Arrhenius developed the theory of acids and bases that we introduced in Chapter 5. There we emphasized the stoichiometry of acid–base reactions.

Some of the topics we will study in this chapter are modern acid–base theories, factors affecting the strengths of acids and bases, the pH scale, and the calculation of ion concentrations in solutions of weak acids and bases. We bring some of these ideas together in a discussion of acid rain in the Focus On discussion for this chapter (see the MasteringChemistry site).

16-7 Ions as Acids and Bases
16-8 Molecular Structure and Acid–Base Behavior
16-9 Lewis Acids and Bases

▶ Descriptions of acids and bases become more general, less restrictive, as we move from the Arrhenius theory, to the Brønsted–Lowry theory, to the Lewis theory.

16-1 Arrhenius Theory: A Brief Review

Some aspects of the behavior of acids and bases can be explained adequately with the theory developed by Arrhenius as part of his studies of electrolytic dissociation (Section 13-9). Arrhenius proposed that in aqueous solutions, strong electrolytes exist only in the form of ions, whereas weak electrolytes exist partly as ions and partly as molecules. When the acid HCl dissolves in water, the HCl molecules ionize completely, yielding hydrogen ions, H^+, as one of the products.

$$\mathrm{HCl} \xrightarrow{\mathrm{H_2O}} \mathrm{HCl(aq)} \rightarrow \mathrm{H^+(aq)} + \mathrm{Cl^-(aq)}$$

When the base NaOH dissolves in water, the Na^+ and OH^- ions in the solid become dissociated from one another through the action of H_2O molecules (see Figure 13-6).

$$\mathrm{NaOH(s)} \xrightarrow{\mathrm{H_2O}} \mathrm{Na^+(aq)} + \mathrm{OH^-(aq)}$$

The neutralization reaction of HCl and NaOH can be represented with the ionic equation

$$\underbrace{\mathrm{H^+(aq)} + \mathrm{Cl^-(aq)}}_{\text{An acid}} + \underbrace{\mathrm{Na^+(aq)} + \mathrm{OH^-(aq)}}_{\text{A base}} \longrightarrow \underbrace{\mathrm{Na^+(aq)} + \mathrm{Cl^-(aq)}}_{\text{A salt}} + \underbrace{\mathrm{H_2O(l)}}_{\text{Water}}$$

or, perhaps better still, with the net ionic equation

$$\underbrace{\mathrm{H^+(aq)}}_{\text{An acid}} + \underbrace{\mathrm{OH^-(aq)}}_{\text{A base}} \longrightarrow \underbrace{\mathrm{H_2O(l)}}_{\text{Water}} \qquad \textbf{(16.1)}$$

BA
Ammonium Hydroxide
AMMONIUM HYDROXIDE NH4OH

▲ A holdover of the Arrhenius theory. Although there is no compelling evidence that NH_4OH molecules exist in $NH_3(aq)$, solutions are commonly labeled as if they do.

Equation (16.1) illustrates an essential idea of the Arrhenius theory: *A neutralization reaction involves the combination of hydrogen ions and hydroxide ions to form water.*

Despite its early successes and continued usefulness, the Arrhenius theory does have limitations. One of the most glaring is in its treatment of the weak base ammonia, NH_3. The Arrhenius theory suggests that all bases contain OH^-. Where is the OH^- in NH_3? To get around this difficulty, chemists began to think of aqueous solutions of NH_3 as containing the compound ammonium hydroxide, NH_4OH, which as a weak base is partially ionized into NH_4^+ and OH^- ions:

$$\mathrm{NH_3(g)} + \mathrm{H_2O(l)} \longrightarrow \mathrm{NH_4OH(aq)}$$
$$\mathrm{NH_4OH(aq)} \rightleftharpoons \mathrm{NH_4^+(aq)} + \mathrm{OH^-(aq)}$$

The problem with this formulation is that there is no compelling evidence that NH_4OH exists in aqueous solutions. We should always question a hypothesis or theory that postulates the existence of hypothetical substances. As we will see in Section 16-2, the essential failure of the Arrhenius theory is in not recognizing the key role of the *solvent* in the ionization of a solute.

KEEP IN MIND

that a "proton donor" is a donor of H^+ ions. That is, a hydrogen atom consists of one proton and one electron, and the hydrogen ion, H^+, is simply a proton.

16-2 Brønsted–Lowry Theory of Acids and Bases

In 1923, J. N. Brønsted in Denmark and T. M. Lowry in Great Britain independently proposed a new acid–base theory. According to their theory, an acid is a **proton donor** and a base is a **proton acceptor**. To describe the behavior of ammonia as a base, which we found difficult to do with the Arrhenius theory, we can write

$$\underbrace{\mathrm{NH_3}}_{\text{Base}} + \underbrace{\mathrm{H_2O}}_{\text{Acid}} \longrightarrow \mathrm{NH_4^+} + \mathrm{OH^-} \qquad \textbf{(16.2)}$$

In reaction (16.2), H_2O acts as an *acid*. It gives up a proton, H^+, which is taken up by NH_3, a *base*. As a result of this transfer, the polyatomic ions NH_4^+ and OH^- are formed—the same ions produced by the ionization of the hypothetical

NH_4OH of the Arrhenius theory. Because NH_3 is a weak base, we need also to consider the reverse of reaction (16.2). In the reverse reaction, NH_4^+ is an acid and OH^- is a base.

◀ Brønsted–Lowry theory is not restricted to the dissociation of acids and bases in water, but is valid for any solvent.

$$\underset{\text{Acid}}{NH_4^+} + \underset{\text{Base}}{OH^-} \longrightarrow NH_3 + H_2O \qquad \textbf{(16.3)}$$

The conventional way to represent a reversible reaction is to use the double arrow notation. In identifying the species in this reversible ionization reaction, we have used the number "1" for the related pair NH_3 and NH_4^+ and the number "2" for the related pair H_2O and OH^-.

$$\underset{\text{Base(1)}}{NH_3} + \underset{\text{Acid(2)}}{H_2O} \rightleftharpoons \underset{\text{Acid(1)}}{NH_4^+} + \underset{\text{Base(2)}}{OH^-} \qquad \textbf{(16.4)}$$

An acid and a base that are related to each other as the pair NH_3/NH_4^+ or the pair H_2O/OH^- in reaction (16.4) are referred to as a *conjugate pair*. Thus, when considering an NH_3 molecule as a base, an NH_4^+ ion is the **conjugate acid** of NH_3. Similarly, in reaction (16.4) H_2O is an acid and OH^- is its **conjugate base**. Figure 16-1 illustrates the proton transfer involved in the forward and reverse reactions of (16.4).

KEEP IN MIND

that in designating conjugate pairs, it does not matter which conjugate pair we call (1) and which we call (2). Nor does it matter in what order the acid and base are written on each side of the equation.

On the basis of what we learned in Chapter 15, we might write as the equilibrium constant expression for reaction (16.4)

$$K = \frac{a_{NH_4^+}a_{OH^-}}{a_{NH_3}\,a_{H_2O}}$$

In an aqueous solution the activities of NH_4^+, OH^-, and NH_3 are approximately equal to $[NH_4^+]$, $[OH^-]$, and $[NH_3]$, respectively. The expression above can be written as

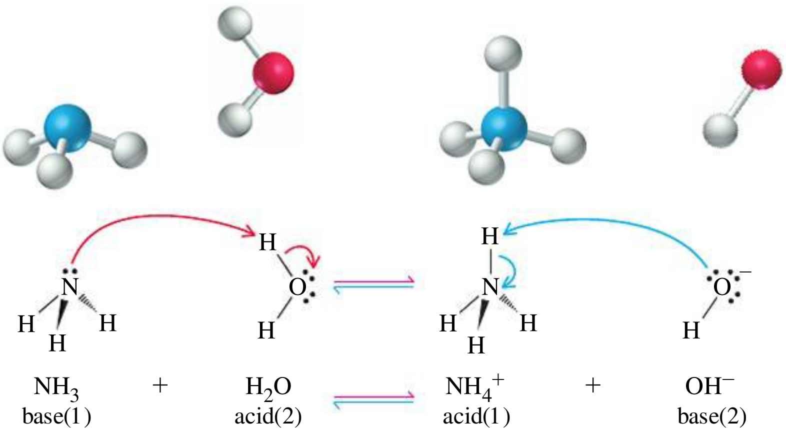
$$K = \frac{[NH_4^+][OH^-]}{[NH_3]} = 1.8 \times 10^{-5} = K_b$$

The equilibrium constant K_b is called the **base ionization constant**.

The ionization of acetic acid can be expressed as

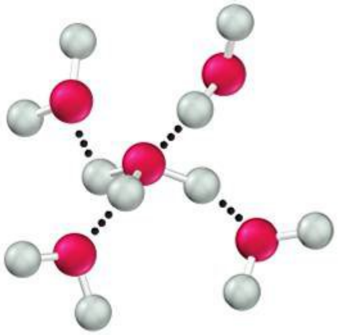
$$\underset{\text{Acid(1)}}{CH_3COOH} + \underset{\text{Base(2)}}{H_2O} \rightleftharpoons \underset{\text{Base(1)}}{CH_3COO^-} + \underset{\text{Acid(2)}}{H_3O^+}$$

Here, acetate ion, CH_3COO^-, is the conjugate base of the acid CH_3COOH. This time, H_2O acts as a base. Its conjugate acid is the **hydronium ion, H_3O^+**. We first



▲ FIGURE 16-1
Brønsted–Lowry acid–base reaction: weak base
The curved arrows summarize our visualization of how electrons flow to form and break bonds. The red arrows represent the forward reaction; the blue arrows, the reverse reaction. Because NH_4^+ is a stronger acid than H_2O and OH^- is a stronger base than NH_3, the reverse reaction proceeds to a greater extent than does the forward reaction. Hence, NH_3 is only slightly ionized.

discussed the formation of the hydronium ion in Chapter 5 (page 154). Because the simple H^+ ion is tiny, the positive charge of this ion is concentrated in a very small region; the ion has a high positive charge density. We should expect H^+ ions (protons) to seek out centers of negative charge with which to bond. When a H^+ ion attaches to a lone pair of electrons in an O atom in H_2O, the resulting hydronium ion forms hydrogen bonds with several water molecules (Fig. 16-2). Figure 16-3 illustrates the proton transfer involved in the forward and reverse reactions of the ionization of acetic acid.



▲ FIGURE 16-2
A hydrated hydronium ion
This species, $H_{11}O_5{}^+$, consists of a central H_3O^+ ion hydrogen-bonded to four H_2O molecules.

Using the same approach as for $NH_3(aq)$, the ionization of acetic acid can be described in the following way.

$$K_a = \frac{[CH_3COO^-][H_3O^+]}{[CH_3COOH]} = 1.8 \times 10^{-5}$$

The equilibrium constant K_a is called the **acid ionization constant**. (The fact that K_a of acetic acid and K_b of ammonia have the same value is just a coincidence.)

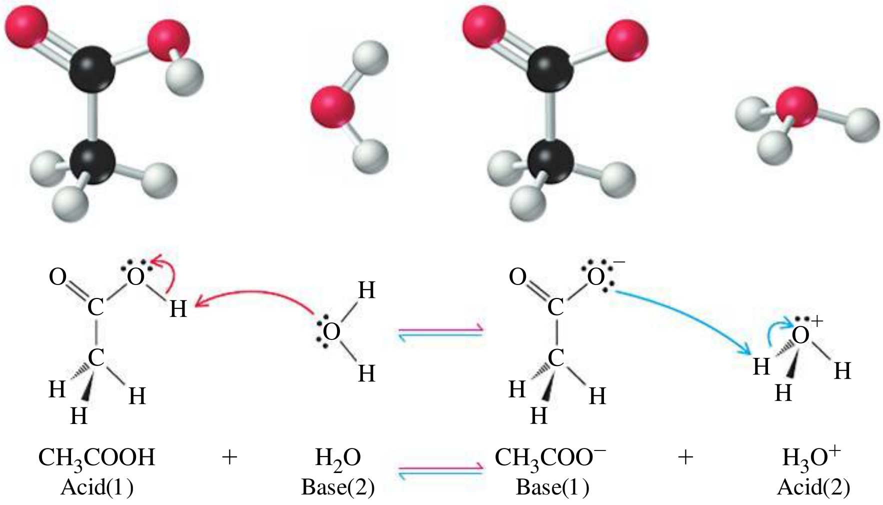
We can represent the ionization of HCl in the same way that we did for acetic acid. In this case, however, because K_a is so large (about 10^6), we can treat the ionization of HCl as a reaction that goes to completion. We denote this by writing the ionization equation with a single arrow.

$$HCl + H_2O \longrightarrow Cl^- + H_3O^+ \tag{16.5}$$

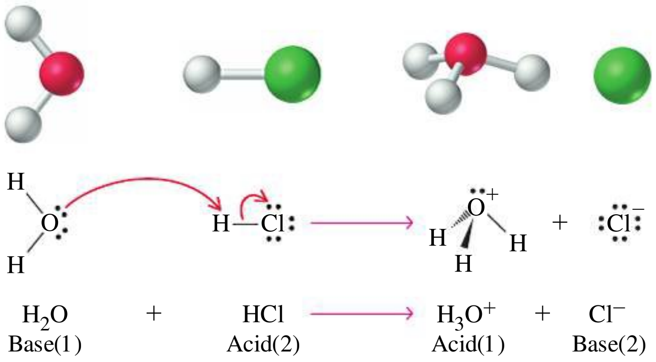
Figure 16-4 illustrates the proton transfer involved in the complete ionization of hydrochloric acid.

In Example 16-1, we identify acids and bases in some typical acid–base reactions. In working through this example, notice the following additional features: (1) Any species that is an acid according to the Arrhenius theory is also an acid according to the Brønsted–Lowry theory; the same is true of bases. (2) Certain species, even though they do not contain the OH group, produce OH^- in aqueous solution—for example, OCl^-. As such, they are Brønsted–Lowry bases. (3) The Brønsted–Lowry theory accounts for substances that can act either as an acid or a base; such substances are said to be **amphiprotic**. The Arrhenius theory does not account for the behavior of amphiprotic substances.

▶ The term *amphiprotic* is similar to the term *amphoteric*, which indicates the ability of a substance to behave as both an acid and a base. Amphiprotic conveys the notion of proton transfer embodied in the Brønsted–Lowry theory of acids and bases.



▲ FIGURE 16-3
Brønsted–Lowry acid–base reaction: weak acid
The arrows represent the proton transfer in the ionization of acetic acid. The red arrows represent the forward reaction; the blue arrows, the reverse reaction. Because H_3O^+ is a stronger acid than CH_3COOH and CH_3COO^- is a stronger base than H_2O, the reverse reaction proceeds to a greater extent than does the forward reaction. Hence, CH_3COOH is only slightly ionized.



◀ FIGURE 16-4
Brønsted–Lowry acid–base reaction: strong acid
The red arrows represent the proton transfer in the ionization of hydrochloric acid. Because H_3O^+ is a weaker acid than HCl and Cl^- is a much weaker base than H_2O, the forward reaction proceeds almost to completion. Hence, HCl is essentially completely ionized.

EXAMPLE 16-1 Identifying Brønsted–Lowry Acids and Bases and Their Conjugates

For each of the following, identify the acids and bases in both the forward and reverse reactions in the manner shown in equation (16.4).

(a) $HClO_2 + H_2O \rightleftharpoons ClO_2^- + H_3O^+$
(b) $OCl^- + H_2O \rightleftharpoons HOCl + OH^-$
(c) $NH_3 + H_2PO_4^- \rightleftharpoons NH_4^+ + HPO_4^{2-}$
(d) $HCl + H_2PO_4^- \rightleftharpoons Cl^- + H_3PO_4$

Analyze

Recall that a Brønsted–Lowry acid is one that gives up a proton and a Brønsted–Lowry base is one that takes a proton. Consider $HClO_2$ in reaction (a). It gives up a proton, H^+, to become ClO_2^-. Therefore, $HClO_2$ is an acid, and ClO_2^- is its conjugate base. Now consider H_2O. It takes the proton from $HClO_2$ and becomes H_3O^+. Thus, H_2O is a base, and H_3O^+ is its conjugate acid. In reaction (b), OCl^- is a base and gains a proton from water. OH^- produced in this reaction is the conjugate base of H_2O.

Solve

(a) $\underset{\text{Acid(1)}}{HClO_2} + \underset{\text{Base(2)}}{H_2O} \rightleftharpoons \underset{\text{Base(1)}}{ClO_2^-} + \underset{\text{Acid(2)}}{H_3O^+}$

(b) $\underset{\text{Base(1)}}{OCl^-} + \underset{\text{Acid(2)}}{H_2O} \rightleftharpoons \underset{\text{Acid(1)}}{HOCl} + \underset{\text{Base(2)}}{OH^-}$

(c) $\underset{\text{Base(1)}}{NH_3} + \underset{\text{Acid(2)}}{H_2PO_4^-} \rightleftharpoons \underset{\text{Acid(1)}}{NH_4^+} + \underset{\text{Base(2)}}{HPO_4^{2-}}$

(d) $\underset{\text{Acid(1)}}{HCl} + \underset{\text{Base(2)}}{H_2PO_4^-} \rightleftharpoons \underset{\text{Base(1)}}{Cl^-} + \underset{\text{Acid(2)}}{H_3PO_4}$

Assess

Notice that in (c), $H_2PO_4^-$ is acting as an acid but in (d), it is acting as a base. The conjugate base of $H_2PO_4^-$ is HPO_4^{2-} (the deprotonated form of $H_2PO_4^-$), and the conjugate acid of $H_2PO_4^-$ is H_3PO_4 (the protonated form of $H_2PO_4^-$). This is an example of the general rule that in a conjugate pair, the acid is the protonated form and the base is the deprotonated form.

PRACTICE EXAMPLE A: For each of the following reactions, identify the acids and bases in both the forward and reverse directions.

(a) $HF + H_2O \rightleftharpoons F^- + H_3O^+$
(b) $HSO_4^- + NH_3 \rightleftharpoons SO_4^{2-} + NH_4^+$
(c) $CH_3COO^- + HCl \rightleftharpoons CH_3COOH + Cl^-$

PRACTICE EXAMPLE B: Of the following species, one is acidic, one is basic, and one is amphiprotic in their reactions with water: HNO_2, PO_4^{3-}, HCO_3^-. Write the *four* equations needed to represent these facts.

16-1 CONCEPT ASSESSMENT

Is it appropriate to describe each of the following as a conjugate acid–base pair? Explain. **(a)** HCO_3^-–CO_3^{2-}; **(b)** HSO_3^-–SO_4^{2-}; **(c)** H_2CO_3–$H_2C_2O_4$; **(d)** $HClO$–ClO^-; **(e)** H_2S–S^{2-}.

The ionization of HCl in aqueous solution (reaction 16.5) goes to completion because HCl is a strong acid; it readily gives up protons to H_2O. At the same time, Cl^- ion, the conjugate base of HCl, has very little tendency to take a proton from H_3O^+; Cl^- is a very weak base. This observation suggests the generalization that follows.

> In an acid–base reaction, the favored direction of the reaction is from the stronger to the weaker member of a conjugate acid–base pair.

With this generalization, we can predict that the neutralization of HCl by OH^- should go to completion.

$$\begin{array}{cccccc} HCl & + & OH^- & \longrightarrow & Cl^- & + & H_2O \\ \text{Acid(1)} & & \text{Base(2)} & & \text{Base(1)} & & \text{Acid(2)} \\ \text{strong} & & \text{strong} & & \text{weak} & & \text{weak} \end{array}$$

And we would predict that the following reaction should occur almost exclusively in the *reverse* direction.

$$\begin{array}{ccccccc} H_2O & + & I^- & \longleftarrow & OH^- & + & HI \\ \text{Acid(1)} & & \text{Base(2)} & & \text{Base(1)} & & \text{Acid(2)} \\ \text{weak} & & \text{weak} & & \text{strong} & & \text{strong} \end{array}$$

To be able to apply the generalization more broadly, though, we need a tabulation of acid and base strengths, such as that in Table 16.1. The strongest acids are at the top of the column on the left, and the strongest bases are at the

▶ The acid–base strengths listed in Table 16.1 are the result of experiments carried out by many chemists.

TABLE 16.1 Relative Strengths of Some Common Brønsted–Lowry Acids and Bases

Increasing acid strength

Increasing base strength

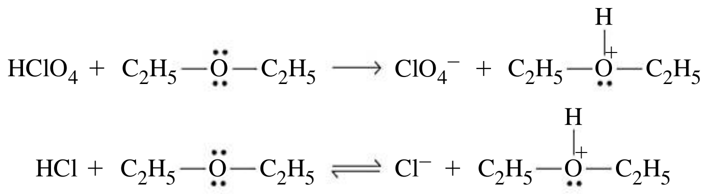
Acid		Conjugate Base	
Perchloric acid	$HClO_4$	Perchlorate ion	ClO_4^-
Hydroiodic acid	HI	Iodide ion	I^-
Hydrobromic acid	HBr	Bromide ion	Br^-
Hydrochloric acid	HCl	Chloride ion	Cl^-
Sulfuric acid	H_2SO_4	Hydrogen sulfate ion	HSO_4^-
Nitric acid	HNO_3	Nitrate ion	NO_3^-
Hydronium ion[a]	H_3O^+	Water[a]	H_2O
Hydrogen sulfate ion	HSO_4^-	Sulfate ion	SO_4^{2-}
Nitrous acid	HNO_2	Nitrite ion	NO_2^-
Acetic acid	CH_3COOH	Acetate ion	CH_3COO^-
Carbonic acid	H_2CO_3	Hydrogen carbonate ion	HCO_3^-
Ammonium ion	NH_4^+	Ammonia	NH_3
Hydrogen carbonate ion	HCO_3^-	Carbonate ion	CO_3^{2-}
Water	H_2O	Hydroxide ion	OH^-
Methanol	CH_3OH	Methoxide ion	CH_3O^-
Ammonia	NH_3	Amide ion	NH_2^-

[a] The hydronium ion–water combination refers to the ease with which a proton is passed from one water molecule to another; that is, $H_3O^+ + H_2O \rightleftharpoons H_2O + H_3O^+$.

bottom of the column on the right. It is important to note that *the stronger an acid, the weaker its conjugate base.*

Both HCl and $HClO_4$ are strong acids because H_2O is a sufficiently strong base to take protons from either acid in a reaction that goes to completion. Because both HCl and $HClO_4$ react to completion with water, yielding H_3O^+ (the strongest acid possible in water), the solvent water is said to have a *leveling effect* on these two acids. How can we ascertain that $HClO_4$ is a stronger acid than HCl as we indicate in Table 16.1?

To determine whether $HClO_4$ or HCl is the stronger acid, we need to use a solvent that is a weaker base than water—a solvent that will take protons from the stronger of the two acids more readily than from the weaker one. In the solvent $(C_2H_5)_2O$, diethyl ether, $HClO_4$ is completely ionized, but HCl is only partially ionized. Thus, $HClO_4$ is a stronger acid than is HCl, and ClO_4^- is a weaker base than Cl^-.

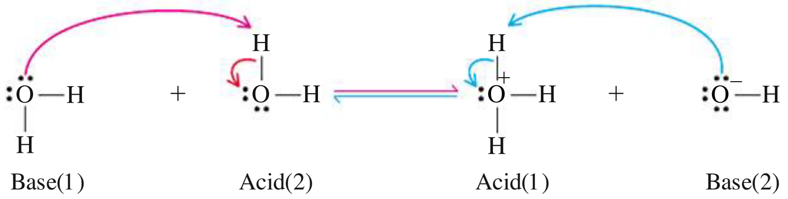


$$HClO_4 + C_2H_5{-}\ddot{\underset{\cdot\cdot}{O}}{-}C_2H_5 \longrightarrow ClO_4^- + C_2H_5{-}\overset{\overset{\displaystyle H}{|}}{\underset{\cdot\cdot}{O^+}}{-}C_2H_5$$

$$HCl + C_2H_5{-}\ddot{\underset{\cdot\cdot}{O}}{-}C_2H_5 \rightleftharpoons Cl^- + C_2H_5{-}\overset{\overset{\displaystyle H}{|}}{\underset{\cdot\cdot}{O^+}}{-}C_2H_5$$

16-3 Self-Ionization of Water and the pH Scale

Even when it is pure, water contains a very low concentration of ions that can be detected in precise electrical conductivity measurements. The ions form as a result of the amphiprotic nature of water; some water molecules donate protons and others accept protons. In the **self-ionization** (or *autoionization*) of water, for each H_2O molecule that acts as an acid, another H_2O molecule acts as a base, and hydronium (H_3O^+) and hydroxide (OH^-) ions are formed. The reaction is reversible, and in the reverse reaction, H_3O^+ releases a proton to OH^-. The reverse reaction is far more significant than the forward reaction. *Equilibrium is displaced far to the left.* In reaction (16.6), acid(1) and base(2) are *much* stronger than are acid(2) and base(1).



(16.6)

Again, we follow the approach we used in writing equilibrium constants for the ionization of NH_3 and CH_3COOH, namely we assume an activity of one for H_2O molecules and replace activities of other species by their molarities. For the self-ionization of water

$$H_2O + H_2O \rightleftharpoons H_3O^+ + OH^-$$

we can write

$$K = [H_3O^+][OH^-]$$

Equation (16.6) indicates that $[H_3O^+]$ and $[OH^-]$ are equal in pure water. There are several experimental methods of determining these concentrations. All lead to this result.

At 25 °C in pure water: $[H_3O^+] = [OH^-] = 1.0 \times 10^{-7}\ M$

◀ A common misconception is that K_w is K_c for the self-ionization reaction. Strictly speaking, it is the ionic product. The equilibrium constant $K_c = [H_3O^+][OH^-]/[H_2O]$ has the value of $10^{-14}/55.55 = 1.8 \times 10^{-16}$ at 25 °C. In Chapter 19, we see that

$$K = (a_{H_3O^+})(a_{OH^-})/(a_{H_2O})^2 = 1.0 \times 10^{-14}$$

The equilibrium condition for the self-ionization of water is called the **ion product of water**. It is symbolized as K_w. At 25 °C,

$$K_w = [H_3O^+][OH^-] = 1.0 \times 10^{-14} \qquad \textbf{(16.7)}$$

Since K_w is an equilibrium constant, the product of the concentrations of the hydronium and hydroxide ions must always equal 10^{-14}. If the concentration of H_3O^+ is increased by the addition of an acid, then the concentration of OH^- must decrease to maintain the value of K_w. If the concentration of OH^- is increased by the addition of a base, then the concentration of H_3O^+ must decrease. Equation (16.7) connects the concentrations of H_3O^+ and OH^- and applies to *all* aqueous solutions, not just to pure water, as we shall see shortly.

pH and pOH

Because their product in an aqueous solution is only 1.0×10^{-14}, we expect $[H_3O^+]$ and $[OH^-]$ also to be small. Typically, they are less than 1 M—often very much less. Exponential notation is useful in these situations; for example, $[H_3O^+] = 2.2 \times 10^{-13}$ M. But we now want to consider an even more convenient way to describe hydronium and hydroxide ion concentrations.

In 1909, the Danish biochemist Søren Sørensen proposed the term **pH** to refer to the "potential of hydrogen ion." He defined pH as the *negative of the logarithm of* $[H^+]$. Restated in terms of $[H_3O^+]$,*

KEEP IN MIND

that this definition of pH is one of the few scientific expressions that uses logarithms to the base 10 (log) rather than natural logarithms (ln).

$$\mathrm{pH} = -\log[H_3O^+] \qquad \textbf{(16.8)}$$

Thus, in a solution that is 0.0025 M HCl,

$$[H_3O^+] = 2.5 \times 10^{-3}\ \mathrm{M} \quad \text{and} \quad \mathrm{pH} = -\log(2.5 \times 10^{-3}) = 2.60$$

▶ The determination of logarithms and inverse logarithms (antilogarithms) is discussed in Appendix A. Significant figure rules for logarithms are also presented there.

To determine the $[H_3O^+]$ that corresponds to a particular pH value, we do an inverse calculation. In a solution with pH = 4.50,

$$\log[H_3O^+] = -4.50 \qquad \text{and} \qquad [H_3O^+] = 10^{-4.50} = 3.2 \times 10^{-5}\ \mathrm{M}$$

The quantity **pOH** can be defined as

$$\mathrm{pOH} = -\log[OH^-] \qquad \textbf{(16.9)}$$

Still another useful expression can be derived by taking the *negative logarithm* of the K_w expression (written for 25 °C) and introducing the symbol pK_w.

$$\begin{aligned} K_w &= [H_3O^+][OH^-] = 1.0 \times 10^{-14} \\ -\log K_w &= -(\log[H_3O^+][OH^-]) = -\log(1.0 \times 10^{-14}) \\ pK_w &= -(\log[H_3O^+] + \log[OH^-]) = -(-14.00) \\ &= -\log[H_3O^+] - \log[OH^-] = 14.00 \end{aligned}$$

$$pK_w = \mathrm{pH} + \mathrm{pOH} = 14.00 \qquad \textbf{(16.10)}$$

---

*Strictly speaking, we should use the *activity* of H_3O^+, $a_{H_3O^+}$, a dimensionless quantity. But we will not use activities here, just as we did not use them in Chapter 15. We will substitute the numerical value of the molarity of H_3O^+ for its activity and recognize that some pH calculations may be only approximations.

▲ FIGURE 16-5

Relating [H_3O^+], pH, [OH^-], and pOH

In aqueous solutions, the sum of the pH and pOH values always gives $pK_w = 14$ because of the self-ionization equilibrium of water.

An aqueous solution with $[H_3O^+] = [OH^-]$ is said to be *neutral*. In pure water at 25 °C, $[H_3O^+] = [OH^-] = 1.0 \times 10^{-7}$ M and pH = 7.00. Thus at 25 °C, all aqueous solutions with pH = 7.00 are neutral. If the pH is less than 7.00, the solution is *acidic*; if the pH is greater than 7.00, the solution is *basic*, or alkaline. Equation 16.10 is a restatement of the interrelationship between $[H_3O^+]$, $[OH^-]$, and K_w in terms of pH, pOH, and pK_w. If we know the value of either $[H_3O^+]$ or $[OH^-]$, we can calculate the value of the other (Fig. 16-5).

16-2 CONCEPT ASSESSMENT

Figure 16-5 indicates that pH and pOH *decrease* as $[H^+]$ and $[OH^-]$ increase. If pH and pOH were defined as $pH = \log[H_3O^+]$ and $pOH = \log[OH^-]$, pH and pOH would *increase* as $[H^+]$ and $[OH^-]$ increase. Why do you suppose that this alternate definition was not adopted? Logarithmic functions appear frequently in chemistry (for example, in chemical kinetics and thermodynamics), but these are based on natural logarithms, ln. Why do you suppose that the definitions $pH = -\ln[H_3O^+]$ and $pOH = -\ln[OH^-]$ were not adopted?

The pH values of a number of materials are depicted in Figure 16-6. These values and the many examples in this chapter and the next should familiarize you with the pH concept. Later, we will consider two methods for measuring pH: by means of acid–base indicators (Section 17-3) and electrical measurements (Section 20-4).

EXAMPLE 16-2 Relating [H_3O^+], [OH^-], pH, and pOH

In a laboratory experiment, students measured the pH of samples of rainwater and household ammonia. Determine **(a)** $[H_3O^+]$ in the rainwater, with pH measured at 4.35; **(b)** $[OH^-]$ in the ammonia, with pH measured at 11.28.

▲ FIGURE 16-6

The pH scale and pH values of some common materials

The scale shown here ranges from pH 0 to pH 14. Slightly negative pH values, perhaps to about −1 (corresponding to $[H_3O^+] \approx 10$ M), are possible. Also possible are pH values up to about 15 (corresponding to $[OH^-] \approx 10$ M). For practical purposes, however, the pH scale is useful only in the range $2 < pH < 12$, because the molarities of H_3O^+ and OH^- in concentrated acids and bases may differ significantly from their true activities.

Analyze

In this example we use the definition $\text{pH} = -\log[\text{H}_3\text{O}^+]$. For pOH we first determine pOH by using $\text{pOH} = 14 - \text{pH}$, and then by using $\text{pOH} = -\log[\text{OH}^-]$. To calculate concentration from a pH, we take the antilogarithm by raising 10 to minus the pH.

Solve

(a) $\log[\text{H}_3\text{O}^+] = -\text{pH} = -4.35$

$$[\text{H}_3\text{O}^+] = 10^{-4.35} = 4.5 \times 10^{-5}\ \text{M}$$

(b) $\text{pOH} = 14.00 - \text{pH} = 14.00 - 11.28 = 2.72$

Now, use the definition $\text{pOH} = -\log[\text{OH}^-]$.

$$\log[\text{OH}^-] = -\text{pOH} = -2.72$$

$$[\text{OH}^-] = 10^{-2.72} = 1.9 \times 10^{-3}\ \text{M}$$

Assess

The process of calculating hydronium ion concentration, $[\text{H}_3\text{O}^+]$, from pH is simply the antilogarithm of minus the pH value. To determine the concentration of $[\text{OH}^-]$ from a pH, we first calculated pOH, which is $14 - \text{pH}$, and then calculated $[\text{OH}^-]$. Be careful when working these types of problems, and keep straight what you have to determine.

PRACTICE EXAMPLE A: Students found that a yogurt sample had a pH of 2.85. What are the $[\text{H}^+]$ and $[\text{OH}^-]$ of the yogurt?

PRACTICE EXAMPLE B: The pH of a solution of HCl in water is found to be 2.50. What volume of water would you add to 1.00 L of this solution to raise the pH to 3.10?

▶ Most people consider strong acids to be more dangerous than strong bases, but strong bases can cause serious burns and should be treated with as much care as acids.

▶ The dilution of strong acids and bases is usually exothermic. Never add water to concentrated strong acids and bases (particularly sulfuric acid) as the heat of dilution will boil the water and spatter concentrated acid.

16-4 Strong Acids and Strong Bases

As equation (16.5) indicated, the ionization of HCl in dilute aqueous solutions

$$\text{HCl} + \text{H}_2\text{O} \longrightarrow \text{Cl}^- + \text{H}_3\text{O}^+$$

goes essentially to completion.* In contrast, equation (16.6) suggested that the self-ionization of water occurs only to a very slight extent. As a result, we conclude that in calculating $[\text{H}_3\text{O}^+]$ in an aqueous solution of a strong acid, the strong acid is the only significant source of H_3O^+. The contribution due to the self-ionization of water can generally be ignored *unless the solution is extremely dilute.*

EXAMPLE 16-3 Calculating Ion Concentrations in an Aqueous Solution of a Strong Acid

Calculate $[\text{H}_3\text{O}^+]$, $[\text{Cl}^-]$, and $[\text{OH}^-]$ in 0.015 M HCl(aq).

Analyze

Because HCl is a strong acid, all the HCl dissociates. The hydronium ion concentration is equal to the molarity of the solution. The hydroxide concentration is determined by using the water equilibrium because the product of the hydronium ion concentration and hydroxide concentration must equal $K_w = 1.0 \times 10^{-14}$.

---

*In very concentrated aqueous solutions, HCl does not exist exclusively as the separated ions H_3O^+ and Cl^-. One indication of this is that we can smell HCl in the vapor above such solutions.

Solve

Therefore,

$$[H_3O^+] = 0.015\ M$$

Because one Cl^- ion is produced for every H_3O^+ ion,

$$[Cl^-] = [H_3O^+] = 0.015\ M$$

To calculate $[OH^-]$, we must use the following facts.

1. All the OH^- is derived from the self-ionization of water, by reaction (16.6).
2. $[OH^-]$ and $[H_3O^+]$ must have values consistent with K_w for water.

$$K_w = [H_3O^+][OH^-] = 1.0 \times 10^{-14}$$

So we have

$$[OH^-] = \frac{1.0 \times 10^{-14}}{1.5 \times 10^{-2}} = 6.7 \times 10^{-13}\ M$$

Assess

The self-ionization of water contributes equal amounts of OH^- and H_3O^+ to the solution. The results of this example show that the self-ionization of water contributes only a small amount (6.7×10^{-13} M) of OH^- and H_3O^+. The self-ionization of water usually, but not always, plays a very minor role in determining the pH of a solution.

PRACTICE EXAMPLE A: A 0.0025 M solution of HI(aq) has $[H_3O^+] = 0.0025$ M. Calculate $[I^-]$, $[OH^-]$, and the pH of the solution.

PRACTICE EXAMPLE B: If 535 mL of *gaseous* HCl, at 26.5 °C and 747 mmHg, is dissolved in enough water to prepare 625 mL of solution, what is the pH of this solution?

The common strong bases are ionic hydroxides. When these bases dissolve in water, H_2O molecules completely dissociate the cations and anions (OH^-) of the base from each other. The self-ionization of water, because it occurs to so very limited an extent, is an inconsequential source of OH^-. This means that in calculating $[OH^-]$ in an aqueous solution of a strong base, the strong base is the only significant source of OH^- *unless the solution is extremely dilute.*

As noted in Chapter 5, the number of common strong acids and strong bases is quite small. Memorize the listing in Table 16.2.

EXAMPLE 16-4 Calculating the pH of an Aqueous Solution of a Strong Base

Calcium hydroxide (slaked lime), $Ca(OH)_2$, is the cheapest strong base available. It is generally used for industrial operations in which a high concentration of OH^- is not required. $Ca(OH)_2(s)$ is soluble in water only to the extent of 0.16 g $Ca(OH)_2$/100.0 mL solution at 25 °C. What is the pH of saturated $Ca(OH)_2(aq)$ at 25 °C?

Analyze

Because the volume of solution is not specified, let's assume it is 100.0 mL = 0.1000 L. The resulting solution will be basic, so we should focus on the hydroxide ion. To solve this problem, we first calculate the molarity of the solution, and then determine the concentration of hydroxide ion in this solution. Finally, we calculate pOH and then pH.

Solve

Express the solubility of $Ca(OH)_2$ on a molar basis.

$$\text{molarity} = \frac{0.16\ g\ Ca(OH)_2 \times \dfrac{1\ mol\ Ca(OH)_2}{74.1\ g\ Ca(OH)_2}}{0.1000\ L} = 0.022\ M\ Ca(OH)_2$$

(continued)

Relate the molarity of OH^- to the molarity of $Ca(OH)_2$.

$$[OH^-] = \frac{0.022 \text{ mol } Ca(OH)_2}{1 \text{ L}} \times \frac{2 \text{ mol } OH^-}{1 \text{ mol } Ca(OH)_2} = 0.044 \text{ M } OH^-$$

Calculate the pOH and, from it, the pH.

$$\text{pOH} = -\log[OH^-] = -\log 0.044 = 1.36$$
$$\text{pH} = 14.00 - \text{pOH} = 14.00 - 1.36 = 12.64$$

Assess

A common error is to neglect the factor 2 mol OH^-/1 mol $Ca(OH)_2$ in determining $[OH^-]$. When solving problems involving basic solutions, we often solve first for pOH. We must remember to finish the problem and convert from pOH to pH. Finally, although $Ca(OH)_2$ is a slightly soluble hydroxide salt, we observe that the pH of the solution is quite high.

PRACTICE EXAMPLE A: Milk of magnesia is a saturated solution of $Mg(OH)_2$. Its solubility is 9.63 mg $Mg(OH)_2$/100.0 mL solution at 20 °C. What is the pH of saturated $Mg(OH)_2$ at 20 °C?

PRACTICE EXAMPLE B: Calculate the pH of an aqueous solution that is 3.00% KOH, by mass, and has a density of 1.0242 g/mL.

TABLE 16.2 The Common Strong Acids and Strong Bases

Acids	Bases
HCl	$LiOH$
HBr	$NaOH$
HI	KOH
$HClO_4$	$RbOH$
HNO_3	$CsOH$
H_2SO_4[a]	$Mg(OH)_2$
	$Ca(OH)_2$
	$Sr(OH)_2$
	$Ba(OH)_2$

[a] H_2SO_4 ionizes in two distinct steps. It is a strong acid only in its first ionization (see page 720).

16-1 ARE YOU WONDERING...

How to calculate $[H_3O^+]$ in an extremely dilute solution of a strong acid?

The method of Example 16-3 won't work for calculating the pH of a solution as dilute as 1.0×10^{-8} M HCl. We would write $[H_3O^+] = 1.0 \times 10^{-8}$ M, and pH = 8.00. But how can a solution of a strong acid, no matter how dilute, have a pH greater than 7? The difficulty is that at this extreme dilution, we must consider two sources of H_3O^+. The sources of H_3O^+ and the ion concentrations from both sources are indicated as follows:

$$\begin{array}{lccccc} & H_2O + H_2O & \rightleftharpoons & H_3O^+ & + & OH^- \\ \textit{Molarity:} & & & x & & x \\ & HCl + H_2O & \longrightarrow & H_3O^+ & + & Cl^- \\ \textit{Molarity:} & & & 1.0 \times 10^{-8} & & 1.0 \times 10^{-8} \end{array}$$

To satisfy the K_w expression for water in this solution, we use equation (16.7) to get

$$[H_3O^+][OH^-] = (x + 1.0 \times 10^{-8})x = 1.0 \times 10^{-14}$$

This expression rearranges to the quadratic form

$$x^2 + (1.0 \times 10^{-8}x) - (1.0 \times 10^{-14}) = 0$$

The solution to this equation is $x = 9.5 \times 10^{-8}$ M. Therefore, we combine $[H_3O^+]$ from both sources to get $[H_3O^+] = (9.5 \times 10^{-8}) + (1.0 \times 10^{-8}) = 1.05 \times 10^{-7}$ M, and pH = 6.98.

From this result, we conclude that the pH is slightly less than 7, as expected for a very dilute acid, and that the self-ionization of water contributes nearly ten times as much hydronium ion to the solution as does the strong acid.

16-5 Weak Acids and Weak Bases

Figure 16-7 illustrates two ways of showing that ionization has occurred in an aqueous solution of an acid: One is by the color of an acid–base indicator; the other, the response of a pH meter. The pink color of the solution in Figure 16-7 tells us the pH of 0.1 M HCl is *less than 1.2*. The pH meter registers a value of 1.20, about what we expect for a strong acid solution with $[H_3O^+]$ approximately equal to 0.1 M. The yellow color of the solution in Figure 16-7 indicates that the pH of 0.1 M CH_3COOH (acetic acid) is *2.8 or greater*. The pH meter registers 2.80.

So we see that two acids can have the same molarity but different pH values. The acid's molarity simply indicates what was put into the solution, but $[H_3O^+]$ and pH depend on what *happens* in the solution. In both solutions, some self-ionization of water occurs, but this reaction is negligible. Ionization of HCl, a strong acid, can be assumed to go to completion, as indicated in equation (16.5). As we previously noted, ionization of CH_3COOH, a weak acid, is a reversible reaction that reaches a condition of equilibrium.*

$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^- \qquad \textbf{(16.11)}$$

The equilibrium constant expression for reaction (16.11) is

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = 1.8 \times 10^{-5} \qquad \textbf{(16.12)}$$

Just as pH is a convenient shorthand designation related to $[H_3O^+]$, pK is related to an equilibrium constant. That is, **p*K*** $= -\log K$. Thus, for acetic acid,

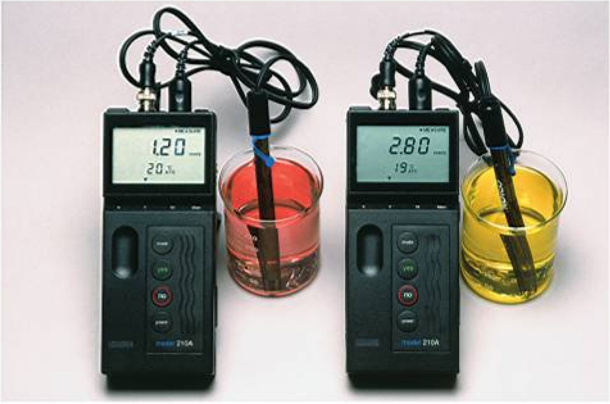
$$pK_a = -\log K_a = -\log(1.8 \times 10^{-5}) = -(-4.74) = 4.74$$

As with other equilibrium constants, the larger the value of K_a (or K_b for a base), the farther the equilibrium condition lies in the direction of the forward reaction. And the more extensive the ionization, the greater are the concentrations of the ions produced. Ionization constants must be determined *by experiment*.

◀ Equilibrium constants (and therefore pK_a and pK_b values) vary with temperature.

◀ The p$K = -\log K$ is introduced so that very large and very small numbers that arise for K can be more easily handled.

◀ Most laboratory pH meters can be read to the nearest 0.01 unit. Some pH meters for research work can be read to 0.001 unit, but unless unusual precautions are taken, the reading of the meter may not correspond to the true pH.



▲ FIGURE 16-7
Strong and weak acids compared
The color of thymol blue indicator, which is present in both solutions, depends on the pH of the solution.

pH < 1.2 <	pH < 2.8 <	pH
Red	Orange	Yellow

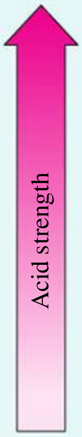
The principle of the pH meter is discussed in Section 20-4. (Left) 0.1 M HCl has pH ≈ 1. The pH meter shows a value of 1.20 rather than 1.00 because the molarity of the HCl solution is, in fact, slightly less than 0.1 M. (Right) 0.1 M CH_3COOH has pH ≈ 2.8.

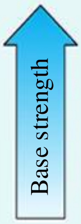
---

*We have been writing ionization equations in the form: acid(1) + base(2) $\rightleftharpoons$ base(1) + acid(2). Here we have written acid(1) + base(2) $\rightleftharpoons$ acid(2) + base(1) to highlight H_3O^+, the species that is usually the subject of a calculation.

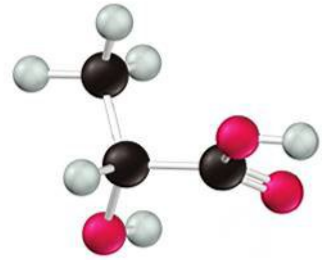
TABLE 16.3 Ionization Constants of Some Weak Acids and Weak Bases in Water at 25 °C

	Ionization Equilibrium	Ionization Constant K	pK
Acid		K_a =	pK_a =
Iodic acid	$HIO_3 + H_2O \rightleftharpoons H_3O^+ + IO_3^-$	1.6×10^{-1}	0.80
Chlorous acid	$HClO_2 + H_2O \rightleftharpoons H_3O^+ + ClO_2^-$	1.1×10^{-2}	1.96
Chloroacetic acid	$ClCH_2COOH + H_2O \rightleftharpoons H_3O^+ + ClCH_2COO^-$	1.4×10^{-3}	2.85
Nitrous acid	$HNO_2 + H_2O \rightleftharpoons H_3O^+ + NO_2^-$	7.2×10^{-4}	3.14
Hydrofluoric acid	$HF + H_2O \rightleftharpoons H_3O^+ + F^-$	6.6×10^{-4}	3.18
Formic acid	$HCOOH + H_2O \rightleftharpoons H_3O^+ + HCOO^-$	1.8×10^{-4}	3.74
Benzoic acid	$C_6H_5COOH + H_2O \rightleftharpoons H_3O^+ + C_6H_5COO^-$	6.3×10^{-5}	4.20
Hydrazoic acid	$HN_3 + H_2O \rightleftharpoons H_3O^+ + N_3^-$	1.9×10^{-5}	4.72
Acetic acid	$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^-$	1.8×10^{-5}	4.74
Hypochlorous acid	$HOCl + H_2O \rightleftharpoons H_3O^+ + OCl^-$	2.9×10^{-8}	7.54
Hydrocyanic acid	$HCN + H_2O \rightleftharpoons H_3O^+ + CN^-$	6.2×10^{-10}	9.21
Phenol	$HOC_6H_5 + H_2O \rightleftharpoons H_3O^+ + C_6H_5O^-$	1.0×10^{-10}	10.00
Hydrogen peroxide	$H_2O_2 + H_2O \rightleftharpoons H_3O^+ + HO_2^-$	1.8×10^{-12}	11.74
Base		K_b =	pK_b =
Diethylamine	$(C_2H_5)_2NH + H_2O \rightleftharpoons (C_2H_5)_2NH_2^+ + OH^-$	6.9×10^{-4}	3.16
Ethylamine	$C_2H_5NH_2 + H_2O \rightleftharpoons C_2H_5NH_3^+ + OH^-$	4.3×10^{-4}	3.37
Ammonia	$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-$	1.8×10^{-5}	4.74
Hydroxylamine	$HONH_2 + H_2O \rightleftharpoons HONH_3^+ + OH^-$	9.1×10^{-9}	8.04
Pyridine	$C_5H_5N + H_2O \rightleftharpoons C_5H_5NH^+ + OH^-$	1.5×10^{-9}	8.82
Aniline	$C_6H_5NH_2 + H_2O \rightleftharpoons C_6H_5NH_3^+ + OH^-$	7.4×10^{-10}	9.13

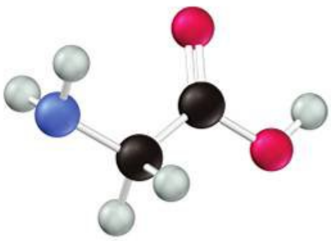




A few ionization constants for weak acids and weak bases are listed in Table 16.3. A more extensive listing is given in Appendix D.



▲ Lactic acid, $CH_3CH(OH)COOH$.



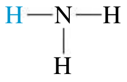
▲ Glycine, NH_2CH_2COOH.

Identifying Weak Acids and Bases

A large number of weak acids have the same structural feature as acetic acid: that is, a —COOH group as part of the molecule. This *carboxyl group* is a common feature of many organic acids, including such biologically important acids as lactic acid and all the amino acids, including glycine. We will use a number of carboxylic acids as examples in this and later chapters.

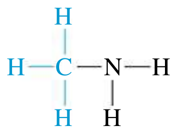
In general, to distinguish a weak acid from a strong acid, you need recall only that the half-dozen strong acids listed in Table 16.2 are the most common strong acids. Unless you are informed to the contrary, assume that any acid not listed in Table 16.2 is a weak acid.

At first glance, weak bases seem more difficult to identify than weak acids: There is no distinctive element, such as H written first in the formula. Yet, if you study the bases in Table 16.3, you will see that all but one of them (pyridine) can be viewed as an ammonia molecule in which some other group ($—C_6H_5$, $—C_2H_5$, —OH, or $—CH_3$) has been substituted for one of the H atoms. The substitution of a methyl group, $—CH_3$, for a H atom is suggested in the following structural formulas.



$$\underset{\displaystyle H}{H—\overset{}{N}—H}$$

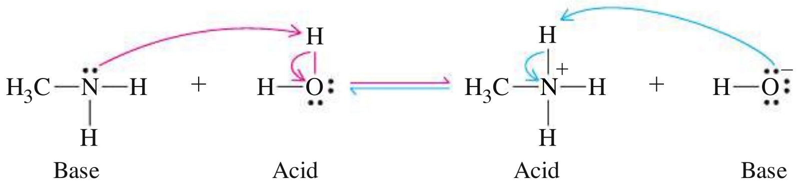
Ammonia

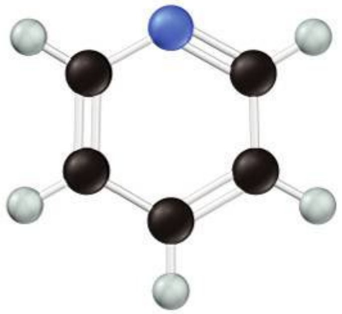


$$H—\underset{\displaystyle H}{\overset{\displaystyle H}{C}}—\underset{\displaystyle H}{N}—H$$

Methylamine

We can represent the ionization of methylamine in this way.





▲ Pyridine, C_5H_5N.

The ionization constant expression is

$$K_b = \frac{[CH_3NH_3^+][OH^-]}{[CH_3NH_2]} = 4.2 \times 10^{-4} \tag{16.13}$$

Not all weak bases contain N. Yet, so many of them do that the similarity to NH_3 outlined here is well worth remembering. These weak bases derived from ammonia are known as *amines*.

16-3 CONCEPT ASSESSMENT

Is it possible for a weak acid solution to have a lower pH than a strong acid solution? If not, why not? If it is possible, under what conditions?

Illustrative Examples

For some students, solution equilibrium calculations are among the most challenging in general chemistry. At times, the difficulty is in sorting out what is relevant to a given problem. The number of types of calculations seems very large, although in fact it is quite limited. The key to solving solution equilibrium problems is to be able to imagine what is going on. Here are some questions to ask yourself.

- Which are the principal species in solution?
- What are the chemical reactions that produce them?
- Can some reactions (for example, the self-ionization of water) be ignored?
- Can you make any assumptions that allow you to simplify the equilibrium calculations?
- What is a reasonable answer to the problem? For instance, should the final solution be acidic ($pH < 7$) or basic ($pH > 7$)?

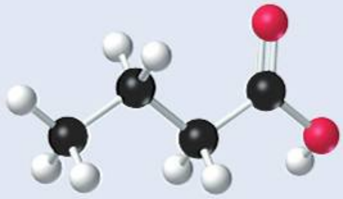
In short, first think through a problem *qualitatively*. At times, you may not even have to do a calculation. Next, organize the relevant data in a clear, logical manner. In this way, many problems that at first appear new to you will take on a familiar pattern. Look for other helpful hints as you proceed through this chapter and the following two chapters.

Example 16-6 presents a common problem involving weak acids and weak bases: calculating the pH of a solution of known molarity. The calculation invariably involves a quadratic equation, but very often we can make a simplifying assumption that leads to a shortcut that saves both time and effort.

EXAMPLE 16-5 Determining a Value of K_a from the pH of a Solution of a Weak Acid

Butyric acid, $CH_3(CH_2)_2COOH$, is used to make compounds employed in artificial flavorings and syrups. A 0.250 M aqueous solution of butyric acid is found to have a pH of 2.72. Determine K_a for butyric acid.

$$CH_3(CH_2)_2COOH + H_2O \rightleftharpoons H_3O^+ + CH_3(CH_2)_2COO^- \qquad K_a = ?$$



▲ Butyric acid, $CH_3CH_2CH_2COOH$.

Analyze

For $CH_3(CH_2)_2COOH$, K_a is likely to be much larger than K_w. Therefore, we can assume that self-ionization of water is unimportant and that ionization of the butyric acid is the only source of H_3O^+. Let's treat the situation as if $CH_3(CH_2)_2COOH$ first dissolves in molecular form, and then the molecules ionize until equilibrium is reached. That is, we write the balanced chemical equation and use it as the basis for an ICE table, as discussed in Chapter 15 (page 681). We will represent the concentrations of H_3O^+ and $CH_3(CH_2)_2COO^-$ at equilibrium as x M.

Solve

	$CH_3(CH_2)_2COOH$ + H_2O ⇌	H_3O^+ +	$CH_3(CH_2)_2COO^-$
initial concns:	0.250 M	—	—
changes:	$-x$ M	$+x$ M	$+x$ M
equil concns:	$(0.250 - x)$ M	x M	x M

But x is known. It is the $[H_3O^+]$ in solution, which we can determine from the pH.

$$\log[H_3O^+] = -pH = -2.72$$
$$[H_3O^+] = 10^{-2.72} = 1.9 \times 10^{-3} = x$$

Now we can solve the following expression for K_a, substituting in the known value for x.

$$K_a = \frac{[H_3O^+][CH_3(CH_2)_2COO^-]}{[CH_3(CH_2)_2COOH]} = \frac{x \cdot x}{0.250 - x}$$
$$= \frac{(1.9 \times 10^{-3})(1.9 \times 10^{-3})}{0.250 - (1.9 \times 10^{-3})} = 1.5 \times 10^{-5}$$

Assess

Notice that our original assumption was correct: K_a is much larger than K_w.

PRACTICE EXAMPLE A: Hypochlorous acid, HOCl, is used in water treatment and as a disinfectant in swimming pools. A 0.150 M solution of HOCl has a pH of 4.18. Determine K_a for hypochlorous acid.

PRACTICE EXAMPLE B: The much-abused drug cocaine is an alkaloid. Alkaloids are noted for their bitter taste, an indication of their basic properties. Cocaine, $C_{17}H_{21}O_4N$, is soluble in water to the extent of 0.17 g/100 mL solution, and a saturated solution has a pH = 10.08. What is the value of K_b for cocaine?

$$C_{17}H_{21}O_4N + H_2O \rightleftharpoons C_{17}H_{21}O_4NH^+ + OH^- \qquad K_b = ?$$

EXAMPLE 16-6 Calculating the pH of a Weak Acid Solution

Show by calculation that the pH of 0.100 M CH_3COOH should be about the value shown on the pH meter in Figure 16-7; that is, pH ≈ 2.8.

Analyze

Here, we know that K_a is much larger than K_w. Let's again treat the situation as if CH_3COOH first dissolves in molecular form and then ionizes until equilibrium is reached. In this case, the quantity x is an unknown that must be obtained by an algebraic solution.

Solve

$$\begin{array}{lcccccc} & \mathbf{CH_3COOH} & \mathbf{+\ H_2O} & \rightleftharpoons & \mathbf{H_3O^+} & \mathbf{+} & \mathbf{CH_3COO^-} \\ \text{initial concns:} & 0.100\ \text{M} & & & — & & — \\ \text{changes:} & -x\ \text{M} & & & +x\ \text{M} & & +x\ \text{M} \\ \text{equil concns:} & (0.100 - x)\ \text{M} & & & x\ \text{M} & & x\ \text{M} \end{array}$$

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{x \cdot x}{0.100 - x} = 1.8 \times 10^{-5}$$

We could solve this equation by using the quadratic formula, but let's instead make a simplifying assumption that is often valid. Assume that x is very small compared with 0.100. That is, assume that $(0.100 - x) \approx 0.100$.

$$x^2 = 0.100 \times 1.8 \times 10^{-5} = 1.8 \times 10^{-6}$$
$$x = [H_3O^+] = \sqrt{1.8 \times 10^{-6}} = 1.3 \times 10^{-3}\ \text{M}$$

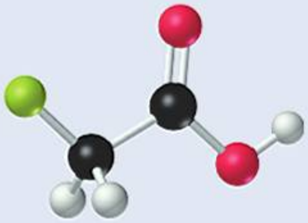
Now, we must check our assumption: $0.100 - 0.0013 = 0.099 \approx 0.100$. Our assumption is good to about 1 part per 100 (1%) and is valid for a calculation involving two or three significant figures.

Finally,

$$\text{pH} = -\log[H_3O^+] = -\log(1.3 \times 10^{-3}) = -(-2.89) = 2.89$$

Assess

We observe that our answer is very close to the number on the pH meter. Therefore, our assumption to simplify the calculation was reasonable. This type of assumption may not always work and so we need to check the final answer until we are comfortable with knowing when and when not to apply the assumption to simplify the calculations.



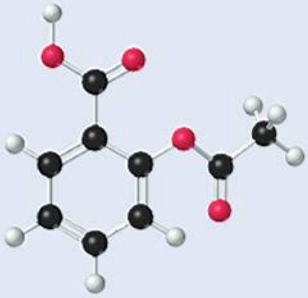
▲ Fluoroacetic acid, CH_2FCOOH.

PRACTICE EXAMPLE A: Substituting halogen atoms for hydrogen atoms bound to carbon increases the strength of carboxylic acids. Show that the pH of 0.100 M CH_2FCOOH, fluoroacetic acid, is lower than that calculated in Example 16-6 for 0.100 M CH_3COOH.

$$CH_2FCOOH + H_2O \rightleftharpoons H_3O^+ + CH_2FCOO^- \qquad K_a = 2.6 \times 10^{-3}$$

PRACTICE EXAMPLE B: Acetylsalicylic acid, $HC_9H_7O_4$, is the active component in aspirin. This acid is the cause of the stomach upset some people get when taking aspirin. Two extra-strength aspirin tablets, each containing 500 mg of acetylsalicylic acid, are dissolved in 325 mL of water. What is the pH of this solution?

$$HC_9H_7O_4 + H_2O \rightleftharpoons H_3O^+ + C_9H_7O_4^- \qquad K_a = 3.3 \times 10^{-4}$$



▲ Acetylsalicylic acid, $C_6H_4(OOCCH_3)COOH$.

EXAMPLE 16-7 Dealing with the Failure of a Simplifying Assumption

What is the pH of a solution that is 0.00250 M $CH_3NH_2(aq)$? For methylamine, $K_b = 4.2 \times 10^{-4}$.

Analyze

In this example we will apply the same techniques as we did in Example 16-6. We will work the problem twice to see that the simplifying assumption breaks down for weak acids and weak bases at very low concentrations.

(continued)

Solve

$$\begin{array}{llcccc}
 & \mathbf{CH_3NH_2} & \mathbf{+\ H_2O} & \rightleftharpoons & \mathbf{CH_3NH_3^+} & \mathbf{+\ OH^-} \\
\text{initial concns:} & 0.00250\ \text{M} & & & \text{—} & \text{—} \\
\text{changes:} & -x\ \text{M} & & & +x\ \text{M} & +x\ \text{M} \\
\text{equil concns:} & (0.00250 - x)\ \text{M} & & & x\ \text{M} & x\ \text{M}
\end{array}$$

$$K_b = \frac{[CH_3NH_3^+][OH^-]}{[CH_3NH_2]} = \frac{x \cdot x}{0.00250 - x} = 4.2 \times 10^{-4}$$

Now let's assume that x is very much less than 0.00250 and that $0.00250 - x \approx 0.00250$.

$$\frac{x^2}{0.00250} = 4.2 \times 10^{-4} \qquad x^2 = 1.1 \times 10^{-6} \qquad [OH^-] = x = 1.0 \times 10^{-3}\ \text{M}$$

The value of x is nearly half as large as 0.00250—too large to ignore. This means using the *quadratic* formula.

$$\frac{x^2}{0.00250 - x} = 4.2 \times 10^{-4}$$

$$x^2 + (4.2 \times 10^{-4}x) - (1.1 \times 10^{-6}) = 0$$

$$x = \frac{(-4.2 \times 10^{-4}) \pm \sqrt{(4.2 \times 10^{-4})^2 + 4 \times 1.1 \times 10^{-6}}}{2}$$

$$x = [OH^-] = \frac{(-4.2 \times 10^{-4}) \pm (2.1 \times 10^{-3})}{2} = 8.4 \times 10^{-4}\ \text{M}$$

$$\text{pOH} = -\log[OH^-] = -\log(8.4 \times 10^{-4}) = 3.08$$

$$\text{pH} = 14.00 - \text{pOH} = 14.00 - 3.08 = 10.92$$

Assess

After applying the simplifying assumption, if the value of x is a significant percentage of the initial concentration (for example, greater than 5%), then we should not use the simplifying assumption to obtain the hydronium concentration.

PRACTICE EXAMPLE A: What is the pH of 0.015 M $CH_2FCOOH(aq)$?

$$CH_2FCOOH + H_2O \rightleftharpoons H_3O^+ + CH_2FCOO^- \qquad K_a = 2.6 \times 10^{-3}$$

PRACTICE EXAMPLE B: Piperidine is a base found in small amounts in black pepper. What is the pH of 315 mL of an aqueous solution containing 114 mg piperidine?

$$C_5H_{11}N + H_2O \rightleftharpoons C_5H_{11}NH^+ + OH^- \qquad K_b = 1.6 \times 10^{-3}$$

▲ Piperidine, $C_5H_{10}NH$.

16-2 ARE YOU WONDERING...

How to calculate the pH of a very dilute solution of a weak acid?

Think of this as a companion question to the one posed in Are You Wondering 16-1, except here the acid in question is weak (represented as HA) rather than strong. The initial approach is similar: Write two equations representing the sources of H_3O^+, and indicate the concentrations of various species in the solution.

$$\begin{array}{lccccc}
 & H_2O + H_2O & \rightleftharpoons & H_3O^+ & + & OH^- \\
\textit{Molarity:} & & & x & & x \\
 & HA + H_2O & \rightleftharpoons & H_3O^+ & + & A^- \\
\textit{Molarity:} & M - y & & y & & y
\end{array}$$

Our ultimate objective is to determine $[H_3O^+]$ in the solution, and this is $x + y$. From $[H_3O^+]$, we can easily get the pH.

Our principal task is to solve a pair of equations simultaneously for x and y. The two equations are

$$K_w = [H_3O^+][OH^-] = (x + y) \times x = 1.0 \times 10^{-14}$$
$$K_a = \frac{[H_3O^+][A^-]}{[HA]} = \frac{(x + y) \times y}{(M - y)}$$

Note the following three points in these equations. (1) There can be only one value of $[H_3O^+]$ in the solution, and it is this value $(x + y)$ that appears in each equation. (2) The stoichiometric concentration of the acid is M (its molarity), and its *equilibrium* concentration is $[HA] = M - y$. The numerical value of M depends on the particular case considered. (3) Similarly, the numerical value of K_a depends on the particular case. When we solve the K_a expression for x, we obtain

$$x = \frac{K_a(M - y)}{y} - y \quad \text{and} \quad x + y = \frac{K_a(M - y)}{y}$$

And when we substitute these values of x and $x + y$ into the K_w equation, we get

$$K_w = \frac{K_a(M - y)}{y} \times \left(\frac{K_a(M - y)}{y} - y\right) = 1.0 \times 10^{-14}$$

The value of y satisfying this equation is not difficult to obtain by the method of successive approximations, illustrated in Appendix A.

The solution of this problem is left for you to do (see Exercise 89), but you will find that for 1.0×10^{-5} M HCN $(K_a = 6.2 \times 10^{-10})$, $y \cong 4.8 \times 10^{-8}$, $(x + y) \cong 1.3 \times 10^{-7}$, and pH $\cong$ 6.90. This certainly seems like a reasonable pH for a very dilute solution of a weak acid in water—just below the neutral pH of 7.00.

Finally, we can use the results of the previous discussion to establish a criterion for ignoring the self-ionization of water in calculations. When we do this, we are assuming that $y \gg x$, so that $y \approx x + y$, and $yx \approx (x + y)x = [H_3O^+][OH^-] = K_w$. Also, if $y \gg x$, then $y^2 \gg K_w$. For what values of y can we say that $y \gg x$? Let's take the maximum value of x consistent with ignoring the self-ionization of water to be 1/100 of y which, as shown below, means that $[H_3O^+]$ must be greater than 10^{-6} M.

$$y^2 > y \times x = y \times \frac{y}{100} = K_w = 1 \times 10^{-14}$$
$$y^2 > 1 \times 10^{-12} \quad \text{and} \quad y > 1 \times 10^{-6}$$

In acid–base calculations, we should first use the simplifying assumptions (ignore K_w and assume that [HA] can be replaced by the molarity of the acid). Then check the answer to see whether $[H_3O^+]$ is greater than 1×10^{-6} M and the 5% criterion presented below is also met.

More on Simplifying Assumptions

The usual simplifying assumption is that of treating a weak acid or weak base as though it remains essentially nonionized (so that $M - x \approx M$). In general, this assumption will work if the molarity of the weak acid, M_A, or that of the weak base, M_B, exceeds the value of K_a or K_b by a factor of at least 100. That is,

$$\frac{M_A\,(\text{or } M_B)}{K_a\,(\text{or } K_b)} > 100$$

◀ Be sure to maintain a clear distinction between the *property* (molarity, M) and the *unit* in which it is expressed, M = mol/L.

In any case, it is important to test the validity of any assumption that you make. If the assumption is good to within a few percent (say, less than 5%), then it is generally valid. In Example 16-6, the simplifying assumption was good to about 1%, but in Example 16-7 it was off by 40%.

Percent Ionization

The extent of ionization of a weak acid or weak base can be described in terms of the degree of ionization or percent ionization. It is convenient to introduce the generic symbol HA for any weak acid, and A^- as the conjugate base of the acid HA.

For the ionization $HA + H_2O \rightleftharpoons H_3O^+ + A^-$, the degree of ionization is the fraction of the acid molecules that ionize. Thus, if in 1.00 M HA, ionization produces $[H_3O^+] = [A^-] = 0.05$ M, the degree of ionization $= 0.05\text{ M}/1.00\text{ M} = 0.05$. **Percent ionization** gives the proportion of ionized molecules on a percentage basis.

$$\text{percent ionization} = \frac{\text{molarity of } H_3O^+ \text{ derived from HA}}{\text{initial molarity of HA}} \times 100\% \qquad \textbf{(16.14)}$$

If, for example, the degree of ionization is 0.05, then the percent of ionization is 5%.

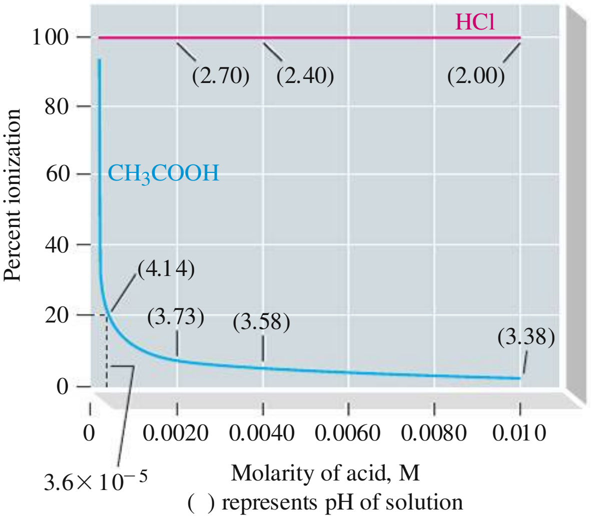
Figure 16-8 compares percent ionization and solution molarity for a weak acid and a strong acid. Example 16-8 shows by calculation that the percent ionization of a weak acid or a weak base *increases* as the solution becomes *more dilute*, a fact that we can also demonstrate by a simple analysis of the ionization reaction

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-$$

At equilibrium, n_{HA} moles of the acid HA, $n_{H_3O^+}$ moles of H_3O^+, and n_{A^-} moles of A^- are present in a volume of V liters. The K_a expression is

$$K_a = \frac{[H_3O^+][A^-]}{[HA]} = \frac{(n_{H_3O^+}/V)(n_{A^-}/V)}{n_{HA}/V} = \frac{(n_{H_3O^+})(n_{A^-})}{n_{HA}} \times \frac{1}{V}$$

When we dilute the solution, V increases, $1/V$ decreases, and the ratio $(n_{H_3O^+})(n_{A^-})/n_{HA}$ must increase to maintain the constant value of K_a. In turn, $n_{H_3O^+}$ and n_{A^-} must increase and n_{HA} must decrease, signifying an increase in the percent ionization.



▶ FIGURE 16-8
Percent ionization of an acid as a function of concentration
Over the concentration range shown, HCl, a strong acid, is essentially 100% ionized. The percent ionization of CH_3COOH, a weak acid, increases from about 4% in 0.010 M to 20% in 3.6×10^{-5} M. For solutions of acetic acid more dilute than 3.6×10^{-5} M, the percent ionization rises sharply with increasing dilution. The pH of 1.0×10^{-7} M CH_3COOH is about 6.79, the same as for 1.0×10^{-7} M HCl.

EXAMPLE 16-8 Determining Percent Ionization as a Function of Weak Acid Concentration

What is the percent ionization of acetic acid in 1.0 M, 0.10 M, and 0.010 M CH_3COOH?

Analyze

The percent ionization is determined by dividing the amount of ionized acid by the initial acid concentration and multiplying by 100%.

Solve

Use the ICE format to describe 1.0 M CH_3COOH:

$$\mathbf{CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^-}$$

	CH_3COOH		H_3O^+	CH_3COO^-
initial concns:	1.0 M		—	—
changes:	$-x$ M		$+x$ M	$+x$ M
equil concns:	$(1.0 - x)$ M		x M	x M

We need to calculate $x = [H_3O^+] = [CH_3COO^-]$. In doing so, let's make the usual assumption: $1.0 - x \approx 1.0$.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{x \cdot x}{1.0 - x} = \frac{x^2}{1.0} = 1.8 \times 10^{-5}$$

$$x = [H_3O^+] = [C_2H_3O_2^-] = \sqrt{1.8 \times 10^{-5}} = 4.2 \times 10^{-3}\,\text{M}$$

The percent ionization of 1.0 M $HC_2H_3O_2$ is

$$\%\ \textit{ionization} = \frac{[H_3O^+]}{[CH_3COOH]} \times 100\% = \frac{4.2 \times 10^{-3}\,\text{M}}{1.0\,\text{M}} \times 100\% = 0.42\%$$

The assumption that x is small compared to 1.0 is clearly valid: x is only 0.42% of 1.0 M. The calculations for 0.10 M CH_3COOH and 0.010 M CH_3COOH are very similar. In 0.10 M CH_3COOH, 1.3% of the acetic acid molecules are ionized and in 0.010 M CH_3COOH, 4.2% are ionized.

Assess

The purpose of calculating the percent ionization for three acetic acid solutions was to confirm the very important point made on page 716: For a weak acid, percent ionization increases with increasing dilution (Fig. 16-8). For very dilute solutions, the calculation of percent ionization is more complicated. (See Are You Wondering 16-2 on page 714.)

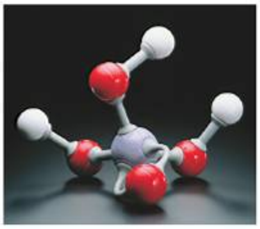
PRACTICE EXAMPLE A: What is the percent ionization of hydrofluoric acid in 0.20 M HF and in 0.020 M HF?

PRACTICE EXAMPLE B: An 0.0284 M aqueous solution of lactic acid, a carboxylic acid that accumulates in the blood and muscles during physical activity, is found to be 6.7% ionized. Determine K_a for lactic acid.

$$CH_3CH(OH)COOH + H_2O \rightleftharpoons H_3O^+ + CH_3CH(OH)COO^- \qquad K_a = ?$$

16-4 CONCEPT ASSESSMENT

You are given two bottles, each of which contains a 0.1 M solution of an unidentified acid. One bottle is labeled $K_a = 7.2 \times 10^{-4}$, and the other is labeled $K_a = 1.9 \times 10^{-5}$. Which bottle contains the more acidic solution? Which bottle has the acid with the larger pK_a?



▲ Phosphoric acid, H_3PO_4.

16-6 Polyprotic Acids

All the acids listed in Table 16.3 are weak *monoprotic acids*, meaning that their molecules have only one ionizable H atom, even though several of these acids contain more than one H atom. But some acids have more than one ionizable H atom per molecule. These are **polyprotic acids**. Table 16.4 lists ionization constants for several polyprotic acids. Additional listings can be found in Appendix D. We will focus on phosphoric acid, H_3PO_4.

◀ Phosphoric acid ranks second only to sulfuric acid among the important commercial acids. It is used in the manufacture of phosphate fertilizers. Various sodium, potassium, and calcium phosphates are used in the food industry.

TABLE 16.4 Ionization Constants of Some Polyprotic Acids

Acid	Ionization Equilibria	Ionization Constants, K	pK
Hydrosulfuric[a]	$H_2S + H_2O \rightleftharpoons H_3O^+ + HS^-$	$K_{a_1} = 1.0 \times 10^{-7}$	$pK_{a_1} = 7.00$
	$HS^- + H_2O \rightleftharpoons H_3O^+ + S^{2-}$	$K_{a_2} = 1 \times 10^{-19}$	$pK_{a_2} = 19.0$
Carbonic[b]	$H_2CO_3 + H_2O \rightleftharpoons H_3O^+ + HCO_3^-$	$K_{a_1} = 4.4 \times 10^{-7}$	$pK_{a_1} = 6.36$
	$HCO_3^- + H_2O \rightleftharpoons H_3O^+ + CO_3^{2-}$	$K_{a_2} = 4.7 \times 10^{-11}$	$pK_{a_2} = 10.33$
Citric	$H_3C_6H_5O_7 + H_2O \rightleftharpoons H_3O^+ + H_2C_6H_5O_7^-$	$K_{a_1} = 7.5 \times 10^{-4}$	$pK_{a_1} = 3.12$
	$H_2C_6H_5O_7^- + H_2O \rightleftharpoons H_3O^+ + HC_6H_5O_7^{2-}$	$K_{a_2} = 1.7 \times 10^{-5}$	$pK_{a_2} = 4.77$
	$HC_6H_5O_7^{2-} + H_2O \rightleftharpoons H_3O^+ + C_6H_5O_7^{3-}$	$K_{a_3} = 4.0 \times 10^{-7}$	$pK_{a_3} = 6.40$
Phosphoric	$H_3PO_4 + H_2O \rightleftharpoons H_3O^+ + H_2PO_4^-$	$K_{a_1} = 7.1 \times 10^{-3}$	$pK_{a_1} = 2.15$
	$H_2PO_4^- + H_2O \rightleftharpoons H_3O^+ + HPO_4^{2-}$	$K_{a_2} = 6.3 \times 10^{-8}$	$pK_{a_2} = 7.20$
	$HPO_4^{2-} + H_2O \rightleftharpoons H_3O^+ + PO_4^{3-}$	$K_{a_3} = 4.2 \times 10^{-13}$	$pK_{a_3} = 12.38$
Oxalic	$H_2C_2O_4 + H_2O \rightleftharpoons H_3O^+ + HC_2O_4^-$	$K_{a_1} = 5.6 \times 10^{-2}$	$pK_{a_1} = 1.25$
	$HC_2O_4^- + H_2O \rightleftharpoons H_3O^+ + C_2O_4^{2-}$	$K_{a_2} = 5.4 \times 10^{-5}$	$pK_{a_2} = 4.27$
Sulfurous[c]	$H_2SO_3 + H_2O \rightleftharpoons H_3O^+ + HSO_3^-$	$K_{a_1} = 1.3 \times 10^{-2}$	$pK_{a_1} = 1.89$
	$HSO_3^- + H_2O \rightleftharpoons H_3O^+ + SO_3^{2-}$	$K_{a_2} = 6.2 \times 10^{-8}$	$pK_{a_2} = 7.21$
Sulfuric[d]	$H_2SO_4 + H_2O \rightleftharpoons H_3O^+ + HSO_4^-$	K_{a_1} = very large	$pK_{a_1} < 0$
	$HSO_4^- + H_2O \rightleftharpoons H_3O^+ + SO_4^{2-}$	$K_{a_2} = 1.1 \times 10^{-2}$	$pK_{a_2} = 1.96$

Acid strength

[a] The value for K_{a_2} of H_2S most commonly found in older literature is about 1×10^{-14}, but current evidence suggests that the value is considerably smaller.

[b] H_2CO_3 cannot be isolated. It is in equilibrium with H_2O and dissolved CO_2. The value given for K_{a_1} is actually for the reaction

$$CO_2(aq) + 2H_2O \rightleftharpoons H_3O^+ + HCO_3^-$$

Generally, aqueous solutions of CO_2 are treated *as if* the $CO_2(aq)$ were first converted to H_2CO_3, followed by ionization of the H_2CO_3.

[c] H_2SO_3 is a hypothetical, nonisolatable species. The value listed for K_{a_1} is actually for the reaction

$$SO_2(aq) + 2H_2O \rightleftharpoons H_3O^+ + HSO_3^-$$

[d] H_2SO_4 is completely ionized in the first step.

The H_3PO_4 molecule has *three* ionizable H atoms; it is a *triprotic acid*. It ionizes in three steps. For each step, we can write an ionization equation and an acid ionization constant expression with a distinctive value of K_a.

$$\textbf{(1)}\quad H_3PO_4 + H_2O \rightleftharpoons H_3O^+ + H_2PO_4^- \qquad K_{a_1} = \frac{[H_3O^+][H_2PO_4^-]}{[H_3PO_4]} = 7.1 \times 10^{-3}$$

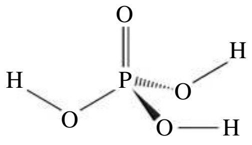
$$\textbf{(2)}\quad H_2PO_4^- + H_2O \rightleftharpoons H_3O^+ + HPO_4^{2-} \qquad K_{a_2} = \frac{[H_3O^+][HPO_4^{2-}]}{[H_2PO_4^-]} = 6.3 \times 10^{-8}$$

$$\textbf{(3)}\quad HPO_4^{2-} + H_2O \rightleftharpoons H_3O^+ + PO_4^{3-} \qquad K_{a_3} = \frac{[H_3O^+][PO_4^{3-}]}{[HPO_4^{2-}]} = 4.2 \times 10^{-13}$$

There is a ready explanation for the relative magnitudes of the ionization constants—that is, for the fact that $K_{a_1} > K_{a_2} > K_{a_3}$. When ionization occurs in step (1), a proton (H^+) moves away from an ion with a 1− charge ($H_2PO_4^-$). In step (2), the proton moves away from an ion with a 2− charge (HPO_4^{2-}), a more difficult separation. As a result, the ionization constant in the second step is smaller than that in the first. Ionization is more difficult still in step (3).

We can make three key statements about the ionization of phosphoric acid, as illustrated in Example 16-9.

▶ A common error is to assume that the $[H_3O^+]$ is the same for all three ionizations. In fact, the pH is dominated by only the first ionization as seen from the different K_a values here. This is only true, of course, for weak acids. The examples here illustrate the points well.



Phosphoric acid

1. K_{a_1} is so much larger than K_{a_2} and K_{a_3} that essentially all the H_3O^+ is produced in the first ionization step.
2. So little of the $H_2PO_4^-$ forming in the first ionization step ionizes any further that we can assume $[H_2PO_4^-] = [H_3O^+]$ in the solution.
3. $[HPO_4^{2-}] \approx K_{a_2}$, regardless of the molarity of the acid.*

Although statement (1) seems essential if statements (2) and (3) are to be valid, it is not as crucial as might first appear. Even for polyprotic acids whose K_a values do not differ greatly between successive ionizations, H_3O^+ is often still determined almost exclusively by the K_{a_1} expression, and statements (2) and (3) remain valid. As long as the polyprotic acid is weak in its first ionization step, the concentration of the anion produced in this step will be so much less than the molarity of the acid that additional $[H_3O^+]$ produced in the second ionization remains negligible.

EXAMPLE 16-9 Calculating Ion Concentrations in a Polyprotic Acid Solution

For a 3.0 M H_3PO_4 solution, calculate **(a)** $[H_3O^+]$; **(b)** $[H_2PO_4^-]$; **(c)** $[HPO_4^{2-}]$; and **(d)** $[PO_4^{3-}]$.

Analyze

For a solution of a *weak* polyprotic acid, the first ionization step produces essentially all the H_3O^+ in solution, so we begin as we would for a weak monoprotic acid solution. The concentrations of the other species are obtained by using the expressions for K_{a2} and K_{a3}.

Solve

(a) For the reasons discussed above, let's assume that all the H_3O^+ forms in the *first* ionization step. This is equivalent to thinking of H_3PO_4 as though it were a monoprotic acid, ionizing only in the first step.

	H_3PO_4 + H_2O $\rightleftharpoons$	H_3O^+ +	$H_2PO_4^-$
initial concns:	3.0 M	—	—
changes:	$-x$ M	$+x$ M	$+x$ M
after first ionization:	$(3.0 - x)$ M	x M	x M

Following the usual assumption that x is much smaller than 3.0 and that $3.0 - x \approx 3.0$, we obtain

$$K_{a_1} = \frac{[H_3O^+][H_2PO_4^-]}{[H_3PO_4]} = \frac{x \cdot x}{(3.0 - x)} = \frac{x^2}{3.0} = 7.1 \times 10^{-3}$$

$$x^2 = 0.021 \qquad x = [H_3O^+] = 0.14\ \text{M}$$

In the assumption $3.0 - x \approx 3.0$, $x = 0.14$, which is 4.7% of 3.0. This is about the maximum error that can be tolerated for an acceptable assumption.

(b) From part (a), $x = [H_2PO_4^-] = [H_3O^+] = 0.14$ M.

(c) To determine $[H_3O^+]$ and $[H_2PO_4^-]$, we assumed that the second ionization is insignificant. Here we must consider the second ionization, no matter how slight; otherwise we would have no source of the ion HPO_4^{2-}. We can represent the second ionization, as shown in the following table. *Note especially how the results of the first ionization enter in.* We start with a solution in which $[H_2PO_4^-] = [H_3O^+] = 0.14$ M.

	$H_2PO_4^-$ + H_2O $\rightleftharpoons$	H_3O^+ +	HPO_4^{2-}
from first ionization:	0.14 M	0.14 M	—
changes:	$-y$ M	$+y$ M	$+y$ M
after second ionization:	$(0.14 - y)$ M	$(0.14 + y)$ M	y M

If we assume that y is much smaller than 0.14, then $(0.14 + y) \approx (0.14 - y) \approx 0.14$.

(continued)

---

*If we assume that $[H_2PO_4^-] = [H_3O^+]$, the second ionization expression reduces to

$$\frac{\cancel{[H_3O^+]}[HPO_4^{2-}]}{\cancel{[H_2PO_4^-]}} = K_{a_2}$$

We then get

$$K_{a_2} = \frac{[H_3O^+][HPO_4^{2-}]}{[H_2PO_4^-]} = \frac{(0.14 + y)(y)}{(0.14 - y)} = \frac{\cancel{(0.14)}(y)}{\cancel{(0.14)}} = 6.3 \times 10^{-8}$$

$$y = [HPO_4^{2-}] = 6.3 \times 10^{-8}\text{ M}$$

Note that the assumption is valid.

(d) The PO_4^{3-} ion forms only in the third ionization step. When we write this acid ionization constant expression, we see that we have already calculated the ion concentrations other than $[PO_4^{3-}]$. We can simply solve the K_{a_3} expression for $[PO_4^{3-}]$.

$$K_{a_3} = \frac{[H_3O^+][PO_4^{3-}]}{[HPO_4^{2-}]} = \frac{0.14 \times [PO_4^{3-}]}{6.3 \times 10^{-8}} = 4.2 \times 10^{-13}$$

$$[PO_4^{3-}] = \frac{4.2 \times 10^{-13} \times 6.3 \times 10^{-8}}{0.14} = 1.9 \times 10^{-19}\text{ M}$$

Assess

In this example the major source of hydronium ions is from the first ionization step. In the second step the amount of hydronium ions is around 10^{-8} M, which is negligible compared with 0.14 M.

PRACTICE EXAMPLE A: Malonic acid, $HOOCCH_2COOH$, is a diprotic acid used in the manufacture of barbiturates.

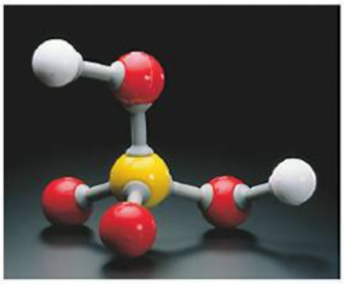
$$HOOCCH_2COOH + H_2O \rightleftharpoons H_3O^+ + HOOCCH_2COO^- \qquad K_{a_1} = 1.4 \times 10^{-3}$$
$$HOOCCH_2COO^- + H_2O \rightleftharpoons H_3O^+ + {}^-OOCCH_2COO^- \qquad K_{a_2} = 2.0 \times 10^{-6}$$

Calculate $[H_3O^+]$, $[HOOCCH_2COO^-]$, and $[{}^-OOCCH_2COO^-]$ in a 1.00 M solution of malonic acid.

PRACTICE EXAMPLE B: Oxalic acid, found in the leaves of rhubarb and other plants, is a diprotic acid.

$$H_2C_2O_4 + H_2O \rightleftharpoons H_3O^+ + HC_2O_4^- \qquad K_{a_1} = ?$$
$$HC_2O_4^- + H_2O \rightleftharpoons H_3O^+ + C_2O_4^{2-} \qquad K_{a_2} = ?$$

An aqueous solution that is 1.05 M $H_2C_2O_4$ has pH $= 0.67$. The free oxalate ion concentration in this solution is $[C_2O_4^{2-}] = 5.3 \times 10^{-5}$ M. Determine K_{a_1} and K_{a_2} for oxalic acid.



▲ Sulfuric acid, H_2SO_4.

A Somewhat Different Case: H_2SO_4

Sulfuric acid differs from most polyprotic acids in this important respect: It is a *strong* acid in its first ionization and a *weak* acid in its second. Ionization is complete in the first step, which means that in most $H_2SO_4(aq)$ solutions, $[H_2SO_4] \approx 0$ M. Thus, if a solution is 0.50 M H_2SO_4, we can treat it as though it were 0.50 M H_3O^+ and 0.50 M HSO_4^- initially. Then we can determine the extent to which ionization of HSO_4^- produces additional H_3O^+ and SO_4^{2-}, as illustrated in Example 16-10.

EXAMPLE 16-10 Calculating Ion Concentrations in Sulfuric Acid Solutions: Strong Acid Ionization Followed by Weak Acid Ionization

Calculate $[H_3O^+]$, $[HSO_4^-]$, and $[SO_4^{2-}]$ in 0.50 M H_2SO_4.

Analyze

We will modify the approach we used in Example 16-9 to incorporate the fact that for H_2SO_4 the first ionization step goes to completion.

Solve

	H_2SO_4 + H_2O ⟶	H_3O^+ +	HSO_4^-
initial concn:	0.50 M	—	—
changes:	−0.50 M	+0.50 M	+0.50 M
after first ionization:	≈ 0	0.50 M	0.50 M

	HSO_4^- + H_2O ⇌	H_3O^+ +	SO_4^{2-}
from first ionization:	0.50 M	0.50 M	—
changes:	$-x$ M	$+x$ M	$+x$ M
after second ionization:	$(0.50 - x)$ M	$(0.50 + x)$ M	x M

We need to deal only with the ionization constant expression for K_{a_2}. If we assume that x is much smaller than 0.50, then $(0.50 + x) \approx (0.50 - x) \approx 0.50$ and

$$K_{a_2} = \frac{[H_3O^+][SO_4^{2-}]}{[HSO_4^-]} = \frac{(0.50 + x) \cdot x}{(0.50 - x)} = \frac{\cancel{0.50} \cdot x}{\cancel{0.50}} = 1.1 \times 10^{-2}$$

Our results, then, are

$$[H_3O^+] = 0.50 + x = 0.51\text{ M}; \qquad [HSO_4^-] = 0.50 - x = 0.49\text{ M}$$

$$[SO_4^{2-}] = x = K_{a_2} = 0.011\text{ M}$$

Assess

In obtaining these results, we assumed that x was much smaller than 0.50. This assumption is appropriate because $x = 0.011$ is only 2.2% of 0.50. Had x been greater than 5% of 0.50, then the assumption would not have been appropriate. Such a situation arises when dealing with more dilute solutions of H_2SO_4.

PRACTICE EXAMPLE A: Calculate $[H_3O^+]$, $[HSO_4^-]$, and $[SO_4^{2-}]$ in 0.20 M H_2SO_4.

PRACTICE EXAMPLE B: Calculate $[H_3O^+]$, $[HSO_4^-]$, and $[SO_4^{2-}]$ in 0.020 M H_2SO_4.
[*Hint:* Is the assumption that $[HSO_4^-] = [H_3O^+]$ valid?]

A General Approach to Solution Equilibrium Calculations

Suppose we were required to determine the stoichiometric molarity of the H_2SO_4(aq) that is required to produce a solution with pH = 2.15. We could start by determining the hydronium ion concentration in the solution: $[H_3O^+] = 10^{-pH} = 10^{-2.15} = 7.1 \times 10^{-3}$ M. What next? We cannot follow the approach used in Example 16-6 because H_2SO_4 is not a monoprotic acid. Instead, we have to use a method like that outlined in Are You Wondering 16-1 and 16-2. An alternative approach worth considering has the appeal of getting us on the right track for all kinds of solution equilibrium calculations. That method has the following format.

1. Identify the species present in any significant amount in the solution (excluding H_2O molecules). Consider the concentrations of these species as unknowns.
2. Write equations that include these species. The number of equations involving these species should match the number of unknowns. The equations are of three types.
   (a) equilibrium constant expressions
   (b) material balance equations
   (c) an electroneutrality condition
3. Solve the system of equations for the unknowns.

Let's apply this approach to the H_2SO_4(aq) solution mentioned in the first sentence of this section.

Possible Species:

$$\cancel{H_2SO_4},\ H_3O^+,\ HSO_4^-,\ SO_4^{2-},\ \cancel{OH^-}$$

We can eliminate H_2SO_4 because its ionization goes to completion in the first step. We can also eliminate OH^- because $[OH^-]$ is exceedingly small in an *acidic* solution that has a pH = 2.15.

Unknowns:

$$\cancel{[H_3O^+]},\ [HSO_4^-],\ [SO_4^{2-}],\ \text{and } M\,[\text{the molarity of the } H_2SO_4(aq)]$$

▶ Calculations like this are not as complicated when performed for other polyprotic acids (phosphoric acid, carbonic acid, etc.) because essentially all the hydronium ions are produced in the first ionization step.

We can eliminate $[H_3O^+]$ because we essentially know its value from the outset. A pH = 2.15 corresponds to $[H_3O^+] = 0.0071$ M. Thus, we are left with three unknowns, and we need three equations.

Equations:

(a) The K_a expression for the ionization $HSO_4^- + H_2O \rightleftharpoons H_3O^+ + SO_4^{2-}$ is

$$K_{a_2} = \frac{[H_3O^+][SO_4^{2-}]}{[HSO_4^-]} = 1.1 \times 10^{-2}$$

(b) The following material balance equation accounts for the fact that the sum of the concentrations of the sulfur-containing species must equal the stoichiometric molarity of the $H_2SO_4(aq)$.

$$[HSO_4^-] + [SO_4^{2-}] = M$$

(c) The electroneutrality condition simply verifies that the solution carries no net charge. The sum of the positive charges must equal the sum of the negative charges. We can sum these charges on a mol/liter basis. For example, because there is one positive charge for every H_3O^+ ion, the number of moles per liter of positive charge is the same as the number of moles per liter of H_3O^+, 0.0071 M. We multiply $[SO_4^{2-}]$ by *two* because each SO_4^{2-} ion carries two units of negative charge.

$$[H_3O^+] = [HSO_4^-] + (2 \times [SO_4^{2-}]) = 0.0071$$

Solving the Equations:

Solve equation (c) for $[HSO_4^-]$: $[HSO_4^-] = 0.0071 - 2[SO_4^{2-}]$. Substitute this result, together with $[H_3O^+] = 0.0071$, into equation (a) and obtain the expression

$$\frac{0.0071 \times [SO_4^{2-}]}{0.0071 - 2[SO_4^{2-}]} = 1.1 \times 10^{-2}$$

Solve this equation to find that $[SO_4^{2-}] = 0.0027$ M. Then substitute this result into equation (c) to obtain $[HSO_4^-] = 0.0017$ M. Finally, according to equation (b), $[HSO_4^-] + [SO_4^{2-}] = 0.0044$ M. The required molarity is 0.0044 M H_2SO_4.

Check:

There are usually ways to check the reasonableness of an answer obtained by this method. In this case, we can easily determine the possible pH range for 0.0044 M H_2SO_4. If the acid ionized only in the first step, $[H_3O^+] = 0.0044$ M (pH = 2.36); if the second ionization step also went to completion, $[H_3O^+] = 0.0088$ M (pH = 2.06). The observed pH, 2.15, falls squarely in this range.

The alternative method outlined here is ideal for computerized calculation. Moreover, because the additional manipulations required to convert stoichiometric concentrations to activities can be incorporated into the calculations, the solutions obtained are generally both more accurate and more readily obtained than are those derived by traditional methods.

KEEP IN MIND

that although this method gives you a quick way to set up a solution equilibrium calculation, more information may be needed for you to arrive at an answer without undue effort. For example, answers to the general questions posed on page 711 may point the way to simplifying the algebraic solution.

16-7 Ions as Acids and Bases

In our discussion to this point, we have emphasized the behavior of electrically neutral molecules as acids (for example, HCl, CH_3COOH, H_3PO_4) or as bases (for example, NH_3, CH_3NH_2). We have also seen, however, that ions can act as acids or bases. For instance, in the second ionization step of H_3PO_4 (part c of Example 16-9), the $H_2PO_4^-$ ion acts as an acid.

Let's think about how each of the following can be described as an acid–base reaction.

$$\underset{\text{Acid}(1)}{NH_4^+} + \underset{\text{Base}(2)}{H_2O} \rightleftharpoons \underset{\text{Base}(1)}{NH_3} + \underset{\text{Acid}(2)}{H_3O^+} \qquad \textbf{(16.15)}$$

$$\underset{\text{Base}(1)}{CH_3COO^-} + \underset{\text{Acid}(2)}{H_2O} \rightleftharpoons \underset{\text{Acid}(1)}{CH_3COOH} + \underset{\text{Base}(2)}{OH^-} \qquad \textbf{(16.16)}$$

In reaction (16.15), NH_4^+ is an *acid*, giving up a proton to water, a *base*. Equilibrium in this reaction is described by means of the *acid ionization constant* of the ammonium ion, NH_4^+.

$$K_a = \frac{[NH_3][H_3O^+]}{[NH_4^+]} = ? \qquad \textbf{(16.17)}$$

Two of the concentrations in equation (16.17)—$[NH_3]$ and $[NH_4^+]$—are the same as in the K_b expression for NH_3, the conjugate base of NH_4^+. It seems that K_a for NH_4^+ and K_b for NH_3 should bear some relationship to each other, and they do. The easiest way to see this is to multiply both the numerator and the denominator of (16.17) by $[OH^-]$. The product $[H_3O^+] \times [OH^-]$ is the ion product of water, K_w, shown in red. The other concentrations, shown in blue, represent the *inverse* of K_b for NH_3. The value obtained, 5.6×10^{-10}, is the missing value of K_a in expression (16.17).

$$K_a = \frac{[NH_3][H_3O^+][OH^-]}{[NH_4^+][OH^-]} = \frac{K_w}{K_b} = \frac{1.0 \times 10^{-14}}{1.8 \times 10^{-5}} = 5.6 \times 10^{-10}$$

This result is an important consequence of the Brønsted–Lowry theory.

The product of the ionization constants of an acid and its conjugate base equals the ion product of water.

$$\begin{aligned} K_a(\text{acid}) \times K_b(\text{its conjugate base}) &= K_w \\ K_b(\text{base}) \times K_a(\text{its conjugate acid}) &= K_w \end{aligned} \qquad \textbf{(16.18)}$$

◀ In many tabulations of ionization constants, only K_a values are listed, whether for neutral molecules or for ions. Equation (16.18) can be used to obtain the values of their conjugates.

In reaction (16.16), CH_3COO^- acts as a *base* by taking a proton from water, an *acid*. Here, equilibrium is described by means of the *base ionization constant* of the acetate ion, CH_3COO^-. With expression (16.18) we can evaluate K_b.

$$K_b = \frac{[CH_3COOH][OH^-]}{[CH_3COO^-]} = \frac{K_w}{K_a(CH_3COOH)} = \frac{1.0 \times 10^{-14}}{1.8 \times 10^{-5}} = 5.6 \times 10^{-10}$$

From equation (16.18), we deduce that (1) the stronger the acid, the weaker its conjugate base; and (2) the weaker the acid, the stronger its conjugate base. It is easy to misinterpret the second statement. It does *not* mean that the conjugate base of a weak acid is a strong base. When we compare the values of the ionization constants for CH_3COOH and CH_3COO^-, it is clear that *the conjugate base of a weak acid is a weak base*. It is also true that the conjugate acid of a weak base is a weak acid. The following statement summarizes these relationships.

The conjugate of *weak* is *weak*.

16-5 CONCEPT ASSESSMENT

A handbook that lists only pK_a values for weak electrolytes has the following entry for 1,2-ethanediamine, $NH_2CH_2CH_2NH_2$: $pK_1 = 6.85(+2)$; $pK_2 = 9.92(+1)$, and 2-aminopropanoic acid, $NH_2CH(CH_3)COOH$: $pK_1 = 2.34(+1)$; $pK_2 = 9.87(0)$. Interpret these handbook entries by writing equations for the ionization reactions to which these pK values apply. What are the corresponding values of the base ionization constants K_{b_1} and K_{b_2}?

Hydrolysis

In pure water at 25 °C, $[H_3O^+] = [OH^-] = 1.0 \times 10^{-7}$ M and pH $= 7.00$. *Pure water is pH neutral.* When NaCl dissolves in water at 25 °C, complete dissociation into Na^+ and Cl^- ions occurs, and the pH of the solution remains 7.00. We can represent this fact with the equation

$$Na^+ + Cl^- + H_2O \longrightarrow \text{no reaction}$$

As shown in Figure 16-9, when NH_4Cl is added to water, the pH falls below 7. This means that $[H_3O^+] > [OH^-]$ in the solution. A reaction producing H_3O^+ must occur.

$$Cl^- + H_2O \longrightarrow \text{no reaction}$$
$$NH_4^+ + H_2O \rightleftharpoons NH_3 + H_3O^+$$

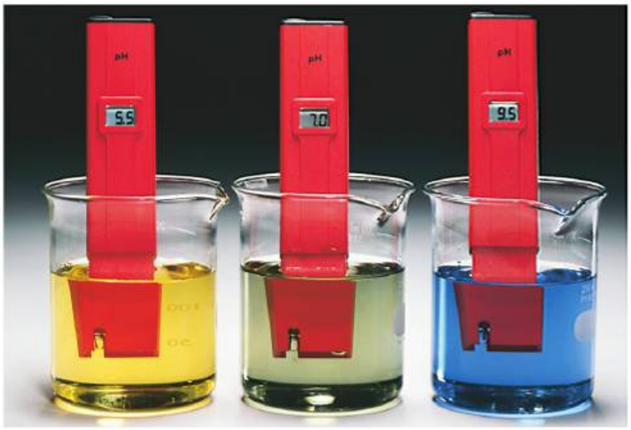
KEEP IN MIND

that many students find hydrolysis problems challenging. The equilibrium calculations are actually quite straightforward. The challenging aspect of these problems is recognizing *when* a hydrolysis reaction is the one on which to base the calculations.

The reaction between NH_4^+ and H_2O is fundamentally no different from other acid–base reactions. A reaction between an ion and water, however, is often called a **hydrolysis** reaction. We say that ammonium ion *hydrolyzes* (and chloride ion does not).

When sodium acetate is dissolved in water, the pH rises above 7 (see Figure 16-9). This means that $[OH^-] > [H_3O^+]$ in the solution. Here, acetate ion hydrolyzes.

$$Na^+ + H_2O \longrightarrow \text{no reaction}$$
$$CH_3COO^- + H_2O \rightleftharpoons CH_3COOH + OH^-$$



▲ FIGURE 16-9
Ions as acids and bases
Each of these 1 M solutions contains bromthymol blue indicator, which has the following colors:

pH< 7	pH = 7	pH> 7
Yellow	Green	Blue

(Left) $NH_4Cl(aq)$ is acidic. (Center) $NaCl(aq)$ is neutral. (Right) $NaCH_3COO(aq)$ is basic.

The pH of Salt Solutions

We are now in a position to make both qualitative predictions and quantitative calculations concerning the pH values of aqueous solutions of salts. Whichever of these tasks is called for, note that hydrolysis takes place only if there is a chemical reaction producing a weak acid or weak base. The following generalizations are useful.

- Salts of strong bases and strong acids (for example, NaCl) *do not hydrolyze*: for the solution, pH = 7.
- Salts of strong bases and *weak* acids (for example, $NaCH_3COO$) *hydrolyze*: pH > 7. (The *anion* acts as a *base*.)
- Salts of *weak* bases and strong acids (for example, NH_4Cl) *hydrolyze*: pH < 7. (The *cation* acts as an *acid*.)
- Salts of *weak* bases and *weak* acids (for example, NH_4CH_3COO) *hydrolyze*. (The cations are acids, and the anions are bases. Whether the solution is acidic or basic, however, depends on the relative values of K_a and K_b for the ions.)

EXAMPLE 16-11 Making Qualitative Predictions About Hydrolysis Reactions

Predict whether each of the following solutions is acidic, basic, or pH neutral: **(a)** NaOCl(aq); **(b)** KCl(aq); **(c)** NH_4NO_3(aq).

Analyze

We need to recognize that all three salts are strong electrolytes and completely dissociate in water. Then, we can consider the ions separately and ask which will react (either as an acid or as a base) with water. Recall that the anions from strong acids (e.g., Cl^-) and the cations from strong bases (e.g., Na^+) do not participate in hydrolysis.

Solve

(a) The ions present are Na^+, which does not hydrolyze, and OCl^-, which does. OCl^- is the conjugate base of HOCl and forms a basic solution.

$$OCl^- + H_2O \rightleftharpoons HOCl + OH^-$$

(b) Neither K^+ nor Cl^- hydrolyzes. KCl(aq) is neutral—that is, pH = 7.

(c) NH_4^+ hydrolyzes, but NO_3^- does not (HNO_3 is a strong acid).

$$NH_4^+ + H_2O \rightleftharpoons NH_3 + H_3O^+$$

In this case, $[H_3O^+] > [OH^-]$, and the solution is acidic.

Assess

Recognizing that certain ions in solution can undergo hydrolysis in water will be an important concept in the next chapter. It is important to learn and understand here how this concept works.

PRACTICE EXAMPLE A: Predict whether each of the following 1.0 M solutions is acidic, basic, or pH neutral: **(a)** $CH_3NH_3^+NO_3^-$(aq); **(b)** NaI(aq); **(c)** $NaNO_2$(aq).

PRACTICE EXAMPLE B: An aqueous solution containing $H_2PO_4^-$ has a pH of about 4.7. Write equations for *two* reactions of $H_2PO_4^-$ with water, and explain which reaction occurs to the greater extent.

16-6 CONCEPT ASSESSMENT

Write a chemical equation showing how an HPO_4^{2-} ion can act as both an acid and a base in aqueous solution. Without doing any pH calculations, determine whether 0.10 M Na_2HPO_4 is acidic, basic, or pH neutral. What about 0.10 M NaH_2PO_4?

EXAMPLE 16-12 Evaluating Ionization Constants for Hydrolysis Reactions

Both sodium nitrite, $NaNO_2$, and sodium benzoate, NaC_6H_5COO, are used as food preservatives. If separate solutions of these two salts have the same molarity, which solution will have the *higher* pH?

Analyze

Each of these substances is the salt of a strong base (NaOH) and a *weak acid*. The anions should ionize as *bases*, making their solutions somewhat basic. The hydrolysis will lead to a weak acid species, for which we know the K_a value; however, the expression we write will be for K_b.

$$NO_2^- + H_2O \rightleftharpoons HNO_2 + OH^- \qquad K_b(NO_2^-) = ?$$
$$C_6H_5COO^- + H_2O \rightleftharpoons C_6H_5COOH + OH^- \qquad K_b(C_6H_5COO^-) = ?$$

Therefore, we will need to recall the relationship between K_a and K_b.

Solve

Our task is to determine the K_b values, neither of which is listed in a table in this chapter. Table 16.3 does list K_a for the conjugate acids, however. Equation (16.18) can be used to write

$$K_b \text{ of } NO_2^- = \frac{K_w}{K_a(HNO_2)} = \frac{1.0 \times 10^{-14}}{7.2 \times 10^{-4}} = 1.4 \times 10^{-11}$$
$$K_b \text{ of } C_6H_5COO^- = \frac{K_w}{K_a(C_6H_5COOH)} = \frac{1.0 \times 10^{-14}}{6.3 \times 10^{-5}} = 1.6 \times 10^{-10}$$

Because the K_b of $C_6H_5COO^-$ is larger than that of NO_2^-, the benzoate ion will hydrolyze to a greater extent than the nitrite ion and will give a solution with a higher $[OH^-]$. A sodium benzoate solution is more basic and has a higher pH than a sodium nitrite solution of the same concentration.

Assess

We could have reasoned out the answer without performing any calculations by focusing instead on the conjugate acids. Because HNO_2 is a stronger acid than C_6H_5COOH, the NO_2^- ion must be a weaker base than the $C_6H_5COO^-$ ion. This is all the information we need to decide which of the two solutions is more basic.

PRACTICE EXAMPLE A: The organic bases cocaine ($pK_b = 8.41$) and codeine ($pK_b = 7.95$) react with hydrochloric acid to form salts (similar to the formation of NH_4Cl by the reaction of NH_3 and HCl). If solutions of the following salts have the same molarity, which solution would have the higher pH: cocaine hydrochloride, $C_{17}H_{21}O_4NH^+Cl^-$, or codeine hydrochloride, $C_{18}H_{21}ClO_3NH^+Cl^-$?

PRACTICE EXAMPLE B: Predict whether the solution $NH_4CN(aq)$ is acidic, basic, or neutral; and explain the basis of your prediction.

EXAMPLE 16-13 Calculating the pH of a Solution in Which Hydrolysis Occurs

Sodium cyanide, NaCN, is extremely poisonous, but it has very useful applications in gold and silver metallurgy and in the electroplating of metals. Aqueous solutions of cyanides are especially hazardous if they become acidified, because toxic hydrogen cyanide gas, HCN(g), is released. Are NaCN(aq) solutions normally acidic, basic, or pH neutral? What is the pH of 0.50 M NaCN(aq)? Note that solutions containing cyanide ion must be handled with extreme caution. They should be handled only in a fume hood by an operator wearing protective clothing.

Analyze

Na^+ does not hydrolyze, but as represented below, CN^- does hydrolyze, producing a basic solution. The question now becomes a hydrolysis equilibrium problem.

Solve

In the tabulation of the concentrations of the species involved in the hydrolysis reaction, let $[OH^-] = x$.

	$CN^- + H_2O \rightleftharpoons$	$HCN +$	OH^-
initial concns:	0.50 M	—	—
changes:	$-x$ M	$+x$ M	$+x$ M
equil concns:	$(0.50 - x)$ M	x M	x M

Use equation (16.18) to obtain a value of K_b.

$$K_b = \frac{K_w}{K_a(\text{HCN})} = \frac{1.0 \times 10^{-14}}{6.2 \times 10^{-10}} = 1.6 \times 10^{-5}$$

Now return to the tabulated data.

$$K_b = \frac{[\text{HCN}][\text{OH}^-]}{[\text{CN}^-]} = \frac{x \cdot x}{0.50 - x} = \frac{x^2}{0.50 - x} = 1.6 \times 10^{-5}$$

Assume: $x \ll 0.50$ and $0.50 - x \approx 0.50$.

$$x^2 = 0.50 \times 1.6 \times 10^{-5} = 0.80 \times 10^{-5} = 8.0 \times 10^{-6}$$

$$x = [\text{OH}^-] = (8.0 \times 10^{-6})^{1/2} = 2.8 \times 10^{-3}$$

$$\text{pOH} = -\log[\text{OH}^-] = -\log(2.8 \times 10^{-3}) = 2.55$$

$$\text{pH} = 14.00 - \text{pOH} = 14.00 - 2.55 = 11.45$$

Assess

We see that in this example, the simplifying assumption works. We also note that the solution is fairly basic for a relatively dilute solution of a salt of a weak acid and a strong base.

PRACTICE EXAMPLE A: Sodium fluoride, NaF, is found in some toothpaste formulations as an anticavity agent. What is the pH of 0.10 M NaF(aq)?

PRACTICE EXAMPLE B: The pH of an aqueous solution of NaCN is 10.38. What is $[\text{CN}^-]$ in this solution?

16-8 Molecular Structure and Acid–Base Behavior

We have now dealt with a number of aspects of acid–base chemistry, both qualitatively and quantitatively. Yet some very fundamental questions still remain to be answered, such as these: Why is HCl a strong acid, whereas HF is a weak acid? Why is acetic acid (CH_3COOH) a stronger acid than ethanol (CH_3CH_2OH) but a weaker acid than chloroacetic acid ($ClCH_2COOH$)?

These questions involve relative acid strengths. In this section, we will examine the relationship between molecular structure and the strengths of acids and bases.

Strengths of Binary Acids

Because the behavior of acids requires the loss of a proton through bond breakage, acid strength and bond strength appear to be related. In general, the stronger the H—X bond, the *weaker* the acid is. Stronger bonds are characterized by short bond lengths and high bond dissociation energies. The appropriate bond dissociation energy to use is the ionization of the H—X bond in the gas phase in equation (16.19):

$$\text{HX(g)} \longrightarrow \text{H}^+\text{(g)} + \text{X}^-\text{(g)} \qquad \textbf{(16.19)}$$

The bond dissociation energy for the gas phase ionization reaction (equation 16.19) can be obtained by using the following thermodynamic cycle:

$$\begin{tikzcd}
\text{HX(g)} \arrow[r, "D(\text{H—X})"] \arrow[dr, "D(\text{H}^+\text{X}^-)"'] & \text{H(g)} \arrow[d, "IE(\text{H})"', "-e^-"] & + & \text{X(g)} \arrow[d, "\Delta H_{ea}"', "+e^-"] \\
 & \text{H}^+\text{(g)} & + & \text{X}^-\text{(g)}
\end{tikzcd}$$

We can write $D(\text{H}^+\text{X}^-) = D(\text{H—X}) + IE(\text{H}) + \Delta H_{ea}$, where $D(\text{H—X})$ is the bond dissociation energy for $\text{HX(g)} \rightarrow \text{H(g)} + \text{X(g)}$, $IE(\text{H})$ is the ionization energy of the hydrogen atom, and ΔH_{ea} is the electron affinity of X, as defined on page 378. $D(\text{H}^+\text{X}^-)$ is called the *heterolytic bond dissociation energy.*

▶ The dissociation of a gas-phase molecule, AB, into A^+ and B^- is called *heterolysis* and the energy change for this process is called the *heterolytic bond dissociation energy*. The dissociation of a gas-phase molecule, AB, into A and B is called *homolysis*. Thus, the bond dissociation energy (D), introduced in Chapter 10, is more precisely called the *homolytic bond dissociation energy*.

Figure 16-10 shows $D(H^+X^-)$ values of binary acids formed by several elements. For binary acids, acid strength increases as the heterolytic bond dissociation energy decreases. Intuitively, this makes a lot of sense. The lower the energy requirement for converting an H—X molecule into H^+ and X^- ions, the greater the acid strength. Can we explain the trend in acid strengths in terms of (homolytic) bond dissociation energies, $D(H—X)$? Not really. For example, $D(H—X)$ values tend to increase from left to right in Figure 16-10, suggesting that the acid strength should decrease across the row. But they don't. The energy requirements for converting an H—X molecule into H and X atoms are not reliable for predicting trends in acid strengths.

Trends in the strengths of binary acids are often explained by considering variations in bond length and bond polarity. Such rationalizations are possible but a little tricky. Intuitively, we expect the acid strength of H—X to increase as the length and polarity of the bond increase. Longer bonds are weaker and easier to break. Polar H—X bonds more readily produce H^+ and X^- ions because such bonds already have partial ionic charges on the H and X atoms. As we move from left to right across a row in Figure 16-10, the H—X bond length decreases whereas the polarity of the bond increases. Because the acid strength (K_a value) increases across the row, we arrive at the following conclusion.

KEEP IN MIND

that electronegativity increases as we move from left to right across a period and decreases from top to bottom in a given group. Thus, the polarity of the H—X bond increases from left to right across a row in Figure 16-10 and decreases as we move from top to bottom down a column. Atomic radii show the opposite trend (decrease from left to right and increase from top to bottom) and so H—X bond lengths decrease from left to right and increase from top to bottom in Figure 16-10.

> When comparing binary acids of elements *in the same row* of the periodic table, acid strength increases as the polarity of the bond increases.

We arrive at a different conclusion if we compare binary acids from the same column in Figure 16-10. As we move from top to bottom in a column, both the bond length and acid strength of H—X increase whereas the polarity of the H—X bond decreases. The following statement summarizes the situation.

> When comparing binary acids of elements *in the same group* of the periodic table, acid strength increases as the length of the bond increases.

That HF is a weaker acid than the other hydrogen halides is expected, but that it should be so much weaker has always seemed an anomaly. Explanations

increasing acid strength →

	H—CH_3	**H—NH_2**	**H—OH**	**H—F**
K_a	1×10^{-60}	1×10^{-34}	1.8×10^{-16}	6.6×10^{-4}

▶ FIGURE 16-10
Bond dissociation energies (kJ mol^{-1}) and K_a values for some binary acids
Homolytic bond dissociation energies, $D(X—H)$, tend to increase from left to right and decrease from top to bottom in this table. Heterolytic bond dissociation energies, $D(H^+X^-)$, decrease from left to right and from top to bottom in this table. The arrows indicate that acid strengths (K_a values) increase from left to right and from top to bottom. The K_a values for NH_3 and CH_4 are very small. These molecules do not behave as acids in water.

of this behavior center on the tendency for hydrogen bonding in HF (recall Figure 12-6). For example, in HF(aq), ion pairs are held together by strong hydrogen bonds, which keeps the concentration of free H_3O^+ from being as large as otherwise expected.

$$HF + H_2O \longrightarrow \underset{\text{Ion pair}}{({}^-F \cdots H_3O^+)} \rightleftharpoons H_3O^+ + F^-$$

CH_4 and NH_3 do not have acidic properties in water, but HF is an acid of moderate strength ($K_a = 6.6 \times 10^{-4}$).

Strengths of Oxoacids

To describe the relative strengths of oxoacids, we must focus on the attraction of electrons from the O—H bond toward the central atom. The following factors promote this electron withdrawal from O—H bonds: (1) a high electronegativity (EN) of the central atom and (2) a large number of terminal O atoms in the acid molecule.

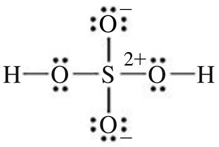
◀ The term *oxoacid* was defined in Chapter 3.

Neither HOCl nor HOBr has a terminal O atom. The major difference between the two acids is one of electronegativity—Cl is slightly more electronegative than Br. As expected, HOCl is more acidic than HOBr.

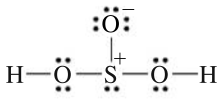
$EN_{Cl} = 3.0$
$K_a = 2.9 \times 10^{-8}$

$EN_{Br} = 2.8$
$K_a = 2.1 \times 10^{-9}$

To compare the acid strengths of H_2SO_4 and H_2SO_3, we must look beyond the central atom, which is S in each acid.



$K_{a_1} \approx 10^3$

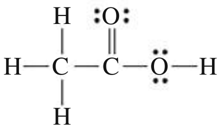


$K_{a_1} = 1.3 \times 10^{-2}$

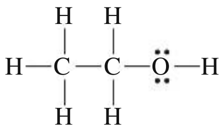
A highly electronegative terminal O atom tends to withdraw electrons from the O—H bonds, weakening the bonds and increasing the acidity of the molecule. Because H_2SO_4 has *two* terminal O atoms to only one in H_2SO_3, the electron-withdrawing effect is greater in H_2SO_4. As a result, H_2SO_4 is a stronger acid than H_2SO_3.

Strengths of Organic Acids

This discussion of the relationship between molecular structure and acid strength concludes with a brief consideration of some organic compounds. Consider first the case of acetic acid and ethanol. Both have an O—H group bonded to a carbon atom, but acetic acid is a much stronger acid than ethanol.



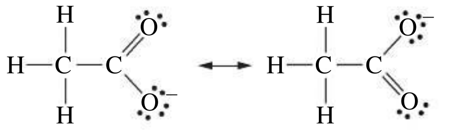
Acetic acid
$K_a = 1.8 \times 10^{-5}$



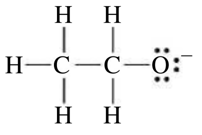
Ethanol
$K_a = 1.3 \times 10^{-16}$

◀ Review the concept of resonance. Compounds or ions with more resonance structures are more stable.

One possible explanation for the large difference in acidity of these two compounds is that the highly electronegative terminal O atom in acetic acid withdraws electrons from the O—H bond. The bond is weakened, and a proton (H^+) is more readily taken from a molecule of the acid by a base. A more satisfactory explanation focuses on the anions formed in the ionization.



Acetate ion



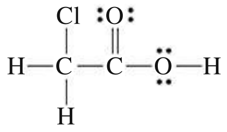
Ethoxide ion

There are two plausible structures for the acetate ion. These structures suggest that each carbon-to-oxygen bond is a "$\frac{3}{2}$" bond and that each O atom carries "$\frac{1}{2}$" unit of negative charge. In short, the excess unit of negative charge in CH_3COO^- is spread out. This arrangement reduces the ability of either O atom to attach a proton and makes acetate ion only a weak Brønsted–Lowry base. In ethoxide ion, conversely, the unit of negative charge is localized on the single O atom. Ethoxide ion is a much stronger base than is acetate ion. The stronger the conjugate base, the weaker the corresponding acid.

The length of the carbon chain in a carboxylic acid has little effect on the acid strength, as in a comparison of acetic acid and octanoic acid.

CH_3COOH	$CH_3(CH_2)_6COOH$
Acetic acid	Octanoic acid
$K_a = 1.8 \times 10^{-5}$	$K_a = 1.3 \times 10^{-5}$

Yet, other atoms or groups of atoms substituted onto the carbon chain may strongly affect acid strength. If a Cl atom is substituted for one of the H atoms that is bonded to carbon in acetic acid, the result is chloroacetic acid.



Chloroacetic acid

$K_a = 1.4 \times 10^{-3}$

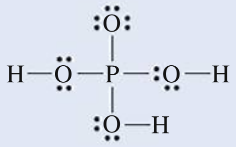
The highly electronegative Cl atom helps draw electrons away from the O—H bond. The O—H bond is weakened, the proton is lost more readily, and the acid is a stronger acid than acetic acid. This effect falls off rapidly as the distance increases between the substituted atom or group and the O—H bond in an organic acid.

Example 16-14 illustrates some of the factors affecting acid strength that are discussed in this section.

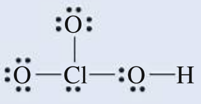
EXAMPLE 16-14 Identifying Factors That Affect the Strengths of Acids

Explain which member of each of the following pairs is the stronger acid.

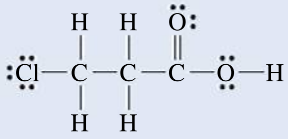
(a) (I)



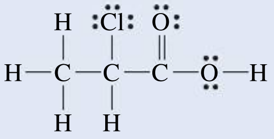
or (II)



(b) (I)



or (II)



Analyze

In these types of questions we first identify the acidic proton(s), and then look for electronegative atoms or groups that pull electron density away from the acidic proton(s). The more electron density that is pulled away from the proton, the more acidic it is.

(a) Phosphoric acid, H_3PO_4, has four O atoms to the three in $HClO_3$, but it is the number of *terminal* O atoms that we must consider, not just the total number of O atoms in the molecule. $HClO_3$ has *two* terminal O atoms and H_3PO_4 has *one*. Also, the Cl atom $(EN = 3.0)$ is considerably more electronegative than the P atom $(EN = 2.1)$. These facts point to chloric acid (II) as being the stronger of the two acids. $(K_a \approx 5 \times 10^2$ for $HClO_3$ and $K_{a_1} = 7.1 \times 10^{-3}$ for H_3PO_4.)

(b) The Cl atom withdraws electrons more strongly when it is directly adjacent to the carboxyl group. Compound (II), 2-chloropropanoic acid $(K_a = 1.4 \times 10^{-3})$, is a stronger acid than compound (I), 3-chloropropanoic acid $(K_a = 1.0 \times 10^{-4})$.

Assess

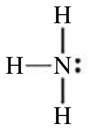
This type of analysis is important in organic chemistry. To successfully solve these types of problems, we must know how to draw Lewis structures and we must understand the concept of electronegativity.

PRACTICE EXAMPLE A: Explain which is the stronger acid, HNO_3 or $HClO_4$; CH_2FCOOH or $CH_2BrCOOH$. [*Hint:* Draw plausible Lewis structures.]

PRACTICE EXAMPLE B: Explain which is the stronger acid, H_3PO_4 or H_2SO_3; CCl_3CH_2COOH or CCl_2FCH_2COOH. [*Hint:* Draw plausible Lewis structures.]

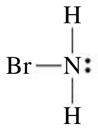
Strengths of Amines as Bases

The fundamental factor affecting the strength of an amine as a base concerns the ability of the lone pair of electrons on the N atom to bind a proton taken from an acid. When an atom or group of atoms more electronegative than H replaces one of the H atoms of NH_3, the electronegative group withdraws electron density from the N atom. The lone-pair electrons cannot bind a proton as strongly, and the base is weaker. Thus, bromamine, in which the electronegative Br atom is attached to the amine group (NH_2), is a *weaker* base than ammonia.



$\mathrm{H{-}\overset{\displaystyle H}{\underset{\displaystyle H}{N}}\!:}$

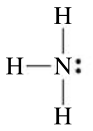
Ammonia
$pK_b = 4.74$



$\mathrm{Br{-}\overset{\displaystyle H}{\underset{\displaystyle H}{N}}\!:}$

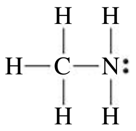
Bromamine
NH_2Br, $pK_b = 7.61$

Hydrocarbon chains have no electron-withdrawing ability. When they are attached to the amine group, the pK_b values are lower than for ammonia due to the electron-donating ability of CH_3 and CH_2CH_3.



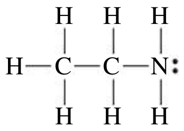
$\mathrm{H{-}\overset{\displaystyle H}{\underset{\displaystyle H}{N}}\!:}$

Ammonia
$pK_b = 4.74$



$\mathrm{H{-}\overset{\displaystyle H}{\underset{\displaystyle H}{C}}{-}\overset{\displaystyle H}{\underset{\displaystyle H}{N}}\!:}$

Methylamine
CH_3NH_2, $pK_b = 3.38$

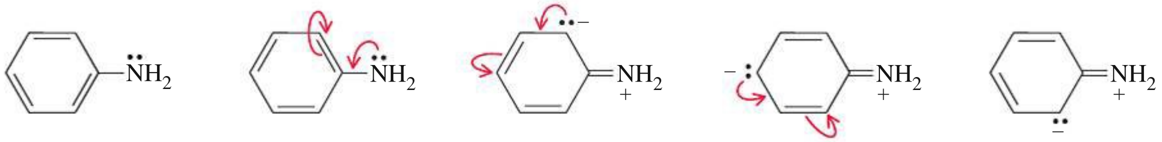


$\mathrm{H{-}\overset{\displaystyle H}{\underset{\displaystyle H}{C}}{-}\overset{\displaystyle H}{\underset{\displaystyle H}{C}}{-}\overset{\displaystyle H}{\underset{\displaystyle H}{N}}\!:}$

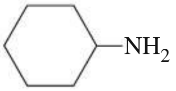
Ethylamine
$CH_3CH_2NH_2$, $pK_b = 3.37$

An additional electron-withdrawing effect is seen in amines that are based on the benzene ring or related structures. Such amines are called *aromatic* amines. Aniline, $C_6H_5NH_2$, is based on benzene, C_6H_6, which, as we learned in Section 11-7 and depicted in several different ways in Figures 11-28, 11-29 and 11-30, is a six-carbon ring molecule with unsaturation in the carbon-to-carbon bonds. The electrons associated with this unsaturation are said to be *delocalized*. As suggested by the following structures, to some extent even the lone-pair electrons of the NH_2 group participate in the "spreading out" of delocalized electrons. (The curved arrows suggest the progressive movement of electrons around the ring.)

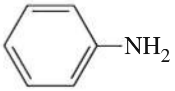
◀ Note that these are actually resonance Lewis structures.



The withdrawal of electron charge density from the NH_2 group causes aniline to be a much weaker base than is cyclohexylamine. (H atoms bonded to ring carbon atoms are not shown in the following structures.)



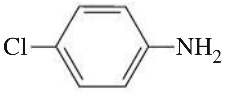
Cyclohexylamine, pK_b = 3.36



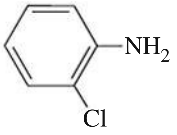
Aniline, pK_b = 9.13

▶ The pK_b for *meta*-chloroaniline is 10.66.

Replacement of a ring-bound H atom in aniline with an atom or group that has a high electronegativity causes even more electron density to be drawn away from the NH_2 group, further reducing the base strength. Also, the closer this ring substituent is to the NH_2 group, the greater is the effect.



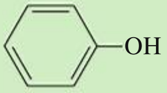
para-Chloroaniline, pK_b = 10.01



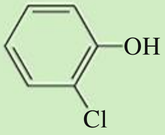
ortho-Chloroaniline, pK_b = 11.36

16-7 CONCEPT ASSESSMENT

Would you expect pK_a of *ortho*-chlorophenol to be greater than, less than, or nearly the same as that of phenol? Explain.



Phenol, pK_a = 10.00



ortho-Chlorophenol, pK_a = ?

16-9 Lewis Acids and Bases

In the previous section, we presented ideas about the molecular structures of acids and bases. In 1923, G. N. Lewis proposed an acid–base theory closely related to bonding and structure. The Lewis acid–base theory is not limited to reactions involving H^+ and OH^-: It extends acid–base concepts to reactions in gases and in solids. It is especially important in describing certain reactions between organic molecules.

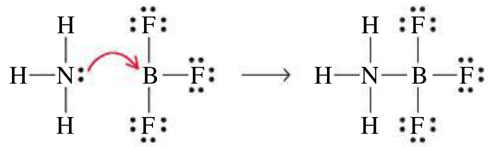
A **Lewis acid** is a species (an atom, ion, or molecule) that is an *electron-pair acceptor*, and a **Lewis base** is a species that is an *electron-pair donor*. A reaction between a Lewis acid (A) and a Lewis base ($B\!:$) results in the formation of a covalent bond between them. The product of a Lewis acid–base reaction is called an **adduct** (or *addition compound*). The reaction can be represented as

$$B\!: + A \longrightarrow B - A$$

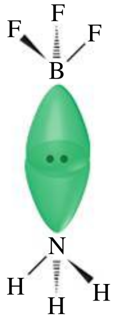
where $B\!:$ A is the adduct. The formation of a covalent chemical bond by one species donating a pair of electrons to another is called *coordination*, and the bond joining the Lewis acid and Lewis base is called a *coordinate covalent bond* (see page 399). *Lewis acids* are species with vacant orbitals that can accommodate electron pairs; *Lewis bases* are species that have lone-pair electrons available for sharing.

By these definitions, OH^-, a Brønsted–Lowry base, is also a Lewis base because lone-pair electrons are present on the O atom. So too is NH_3 a Lewis base. HCl, conversely, is not a Lewis acid: It is not an electron-pair acceptor. We can think of HCl as producing H^+, however, and H^+ is a Lewis acid. H^+ forms a coordinate covalent bond with an available electron pair.

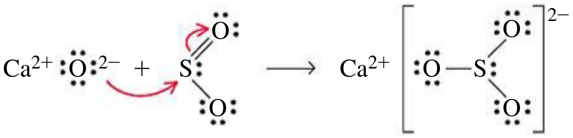
Species with an incomplete valence shell are Lewis acids. When the Lewis acid forms a coordinate covalent bond with a Lewis base, the octet is completed. A good example of octet completion is the reaction of BF_3 and NH_3.



◀ Bonding in the $H_3N—BF_3$ adduct can be described by the overlap of sp^3 orbitals on the N and B atoms, with the two electrons donated by the N atom.



The reaction of lime (CaO) with sulfur dioxide is an important reaction for reducing SO_2 emissions from coal-fired power plants. This reaction between a solid and a gas underscores that Lewis acid–base reactions can occur in all states of matter. The smaller curved red arrow in reaction (16.20) suggests that an electron pair in the Lewis structure is rearranged.



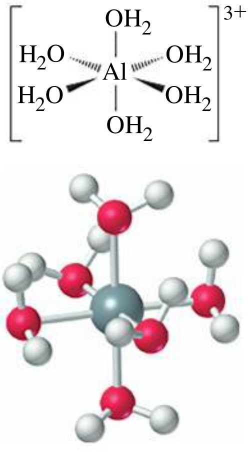
(16.20)

An important application of the Lewis acid–base theory involves the formation of *complex ions*. Complex ions are polyatomic ions that contain a central metal ion to which other ions or small molecules are attached. *Hydrated metal ions* form in aqueous solution because the water acts as a Lewis base and the metal ion as a Lewis acid. The water molecules attach themselves to the metal ion by means of coordinate covalent bonds. Thus, for example, when anhydrous $AlCl_3$ is added to water, the resultant solution becomes hot because of the heat evolved in the formation of the hydrated metal ion $[Al(H_2O)_6]^{3+}(aq)$ (Fig. 16-11).

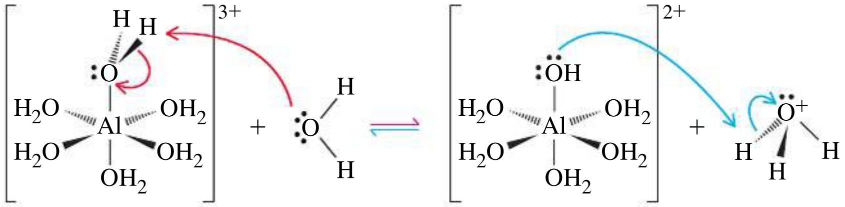
The interaction between the metal ion and the water molecules is so strong that when the salt is crystallized from the solution, the water molecules crystallize along with the metal ion, forming the hydrated metal salt $AlCl_3 \cdot 6\,H_2O$. In aqueous solution, the hydrated metal ions can act as Brønsted acids. For instance, the hydrolysis of hydrated Al^{3+} is given by

$$[Al(H_2O)_6]^{3+} + H_2O \rightleftharpoons [Al(OH)(H_2O)_5]^{2+} + H_3O^+$$

In the hydrated metal ion, the OH bond in a water molecule becomes weakened. This happens because, in forming the coordinate covalent bond with the O atom of the water, the metal ion causes electron density to be drawn toward it; hence, electron density is drawn away from the OH bond. As a consequence, the coordinated H_2O molecule can donate a H^+ to a solvent H_2O molecule (Fig. 16-12). The H_2O molecule that has ionized is converted to OH^-, which remains attached to the Al^{3+}; the charge on the complex ion is reduced from 3+ to 2+. The extent of ionization of $[Al(H_2O)_6]^{3+}$, measured by its K_a value and as pictured in Figure 16-13, is essentially the same as that of acetic acid ($K_a = 1.8 \times 10^{-5}$). Many other metal ions hydrolyze, especially the transition metal ions. These and other hydrated metal ions acting as acids are discussed in later chapters.



▲ FIGURE 16-11
The Lewis structure of $[Al(H_2O)_6]^{3+}$ and a ball-and-stick representation



◀ FIGURE 16-12
Hydrolysis of $[Al(H_2O)_6]^{3+}$ to produce H_3O^+
An uncoordinated water molecule removes a proton from a coordinated water molecule.

▲ FIGURE 16-13
Acidic properties of hydrated metal ions
The yellow color of bromthymol blue indicator in $Al_2(SO_4)_3(aq)$ denotes that the solution is acidic. The pH meter gives a more precise indication of the pH.

Complex ions can also form between transition metal ions and other Lewis bases, such as NH_3. For instance, Zn^{2+} combines with NH_3 to form the complex ion $[Zn(NH_3)_4]^{2+}$. The central Zn^{2+} ion accepts electrons from the Lewis base NH_3. to form coordinate covalent bonds; it is a Lewis acid. We will discuss the application of Lewis acid–base theory to complex ions in Chapter 24.

16-3 ARE YOU WONDERING...

Why Na^+(aq) does not act as an acid in aqueous solution?

Whether an aqueous solution of a metal ion is acidic depends on two principal factors. The first is the amount of charge on the cation; the second is the size of the ion. The greater the charge on the cation, the greater is the ability of the metal ion to draw electron density away from the O—H bond in a H_2O molecule in its hydration sphere, favoring the release of a H^+ ion. The smaller the cation, the more highly concentrated is the positive charge. Hence, for a given positive charge, the smaller the cation, the more acidic the solution.

The ratio of the charge on the cation to the volume of the cation is called the *charge density*.

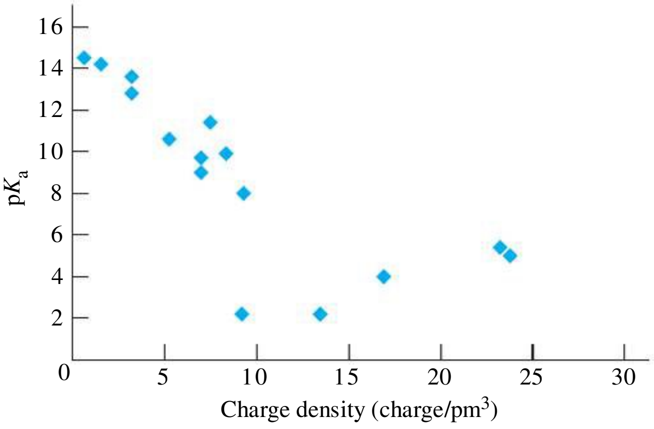
$$\rho = \text{charge density} = \frac{\text{ionic charge}}{\text{ionic volume}}$$

The greater its charge density, the more effective a metal ion is at pulling electron density from the O—H bond and the more acidic is the hydrated cation (see the table and plot below). A highly concentrated positive charge on a small cation is better able to pull electron density from the O—H bond than is a less concentrated positive charge on a larger cation.

Thus the small, highly charged Al^{3+} ion produces acidic solutions, but the larger Na^+ cation, with a charge of just 1+, does not increase the concentration of H_3O^+. In fact, none of the group 1 cations produces appreciably acidic solutions, and only Be^{2+} of the group 2 elements is small enough to do so ($pK_a = 5.4$).

Metal Cation	Ionic Radius, pm	$\rho \times 10^7$, Charge pm^{-3}	pK_a
Li^+	76	3.27	13.6
Na^+	102	1.53	14.2
K^+	138	0.680	14.5
Be^{2+}	45	23.2	5.4
Cu^{2+}	66	9.33	8.0
Ni^{2+}	69	8.35	9.9
Mg^{2+}	72	7.51	11.4
Zn^{2+}	74	7.00	9.0
Co^{2+}	74	7.00	9.7
Mn^{2+}	83	5.23	10.6
Ca^{2+}	100	3.22	12.8
Al^{3+}	53	23.8	5.0
Cr^{3+}	61	17.0	4.0
Ti^{3+}	67	13.5	2.2
Fe^{3+}	78	9.19	2.2

The pK_a of H_3O^+ is −1.7, and the pK_a of water is 15.7.



EXAMPLE 16-15 Identifying Lewis Acids and Bases

According to the Lewis theory, each of the following is an acid–base reaction. Which species is the acid and which is the base?

(a) $BF_3 + F^- \longrightarrow BF_4^-$

(b) $OH^-(aq) + CO_2(aq) \longrightarrow HCO_3^-(aq)$

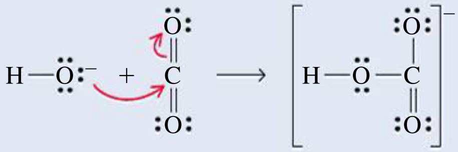
Analyze

Recall that in Lewis theory an acid–base reaction involves the movement of electrons. The Lewis acid accepts electrons and the Lewis base donates electrons. In this example, we need to identify the species that is accepting the electrons and the one that is donating electrons.

Solve

(a) In BF_3, the B atom has a vacant orbital and an incomplete octet. The fluoride ion has an outer-shell octet of electrons. BF_3 is the electron-pair acceptor—the acid. F^- is the electron-pair donor—the base.

(b) We have already identified OH^- as a Lewis base, so we might suspect that it is the base and that $CO_2(aq)$ is the Lewis acid. The following Lewis structures show this to be so. As in reaction (16.20), a rearrangement of an electron pair at one of the double bonds is also required, as indicated by the smaller red arrow.



Assess

Typically, those species that have filled orbitals are Lewis bases, and those with vacant orbitals are Lewis acids. The transfer of electron density from a Lewis base to a vacant orbital on a Lewis acid is a recurring concept in chemistry. We will make use of this concept in the later chapters, as well as in organic chemistry. To describe the reaction in (b) in this way requires us to consider the electronic structure of CO_2 in terms of molecular orbital theory. Some of the $2p$ orbitals on the carbon and oxygen atoms in CO_2 combine to give bonding and antibonding π-type molecular orbitals. We describe a similar situation in Chapter 11 (see Figure 11-33). The vacant orbital in CO_2 that accepts the lone pair from OH^- is an antibonding π-type orbital.

PRACTICE EXAMPLE A: Identify the Lewis acids and bases in these reactions.

(a) $BF_3 + NH_3 \longrightarrow F_3BNH_3$

(b) $Cr^{3+} + 6\,H_2O \longrightarrow [Cr(H_2O)_6]^{3+}$

PRACTICE EXAMPLE B: Identify the Lewis acids and bases in these reactions.

(a) $Al(OH)_3 + OH^- \longrightarrow [Al(OH)_4]^-$

(b) $SnCl_4 + 2\,Cl^- \longrightarrow [SnCl_6]^{2-}$

16-8 CONCEPT ASSESSMENT

Liquid bromine in the presence of iron(III) tribromide forms a bromonium:iron(III) tribromide adduct. Propose a plausible mechanism for adduct formation and identify the Lewis acid and Lewis base. [*Hint*: What is the iron(III) electron configuration?]

Mastering CHEMISTRY www.masteringchemistry.com

Pure water has a pH of 7, but not rainwater. What causes rainwater to be acidic? Rainwater is acidic, in part, because carbon dioxide from the atmosphere reacts with water to form carbonic acid, H_2CO_3, a diprotic acid. For a discussion of the natural sources of acidity in rainwater, and how human activities also contribute, go to the Focus On feature for Chapter 16, Acid Rain, on the MasteringChemistry site.

Summary

16-1 Arrhenius Theory—The central concept in Arrhenius theory describes a neutralization reaction as the combination of hydrogen ions and hydroxide ions to form water (expression 16.1). A major failing of this theory is that it does not account for the key role of the solvent in the ionization of a solute.

16-2 Brønsted–Lowry Theory of Acids and Bases—The Brønsted–Lowry theory describes an acid as a **proton donor** and a base as a **proton acceptor**. In an acid–base reaction, a base takes a proton (H^+) from an acid. In general, acid–base reactions are reversible, but equilibrium is displaced in the direction from the *stronger* acids and bases to their *weaker* conjugates. The **conjugate base** (A^-) is derived from the acid HA while the **conjugate acid** (HB^+) is derived from the base (B). The combinations of HA/A^- and B/HB^+ are known as conjugate acid–base pairs. The conjugate acid of the base H_2O is the **hydronium ion**, H_3O^+. The equilibrium constants representing the ionization of an acid or a base in water are commonly referred to as the **acid ionization constant** and **base ionization constant**, respectively. Certain substances, for example water, are said to be **amphiprotic**. They can act as an acid or base.

16-3 Self-Ionization of Water and the pH Scale—In pure water and in aqueous solutions, **self-ionization** of the water occurs to a very slight extent, producing H_3O^+ and OH^-, as described by the equilibrium constant K_w, known as the **ion product of water** (expression 16.7). The designations **pH** (expression 16.8) and **pOH** (expression 16.9) are often used to describe the concentrations of H_3O^+ and OH in aqueous solutions.

16-4 Strong Acids and Strong Bases—In aqueous solutions, strong acids ionize completely to produce H_3O^+, and strong bases dissociate completely to produce OH^-. Common strong acids and bases are given in Table 16.2 and can be easily memorized.

16-5 Weak Acids and Weak Bases—The ionizations of weak acids and weak bases are reversible reactions, and the extent of their ionization can be related to the ionization constants K_a and K_b or their logarithmic equivalents $pK_a = -\log K_a$ and $pK_b = -\log K_b$ (Table 16.3). Another method used to indicate the degree of ionization is **percent ionization** (expression 16.14). The acidity of many weak acids is associated with the carboxylic acid group, —COOH (page 97). Weak bases typically contain one or more nitrogen atoms. Calculations involving ionization equilibria are in many ways similar to those introduced in Chapter 15, although some additional considerations are necessary for polyprotic acids.

16-6 Polyprotic Acids—**Polyprotic acids** are acids with more than one ionizable H atom that undergo a stepwise ionization and have a different ionization constant, $K_{a_1}, K_{a_2}, \dots$, for each ionization step.

16-7 Ions as Acids and Bases—In reactions between ions and water—**hydrolysis** reactions—the ions react as weak acids or weak bases. The pH of salt solutions depends on the anions and/or cations present. Anions from weak acids lead to solutions with $pH > 7$ while cations from weak bases lead to $pH < 7$.

16-8 Molecular Structure and Acid–Base Behavior—Molecular composition and structure are the keys to determining whether a substance is acidic, basic, or amphiprotic. In addition, molecular structure affects whether an acid or base is strong or weak. In assessing acid strength, for example, factors that affect the strength of the bond that must be broken to release H^+ must be considered. In assessing base strength, factors that affect the ability of lone-pair electrons to bind a proton are of primary concern.

16-9 Lewis Acids and Bases—The Lewis acid–base theory views an electron-pair acceptor as a **Lewis acid** and an electron-pair donor as a **Lewis base**. The addition compound of a Lewis acid–base reaction is referred to as an **adduct**. The theory is most useful in situations that cannot be described by means of proton transfers, for example, in reactions involving gases and solids and in reactions between organic compounds (considered in Chapter 26).

Integrative Example

Bromoacetic acid, $BrCH_2COOH$, has $pK_a = 2.902$. Calculate the expected values of **(a)** the freezing point of 0.0500 M $BrCH_2COOH(aq)$ and **(b)** the osmotic pressure at 25 °C of 0.00500 M $BrCH_2COOH(aq)$.

Analyze

Freezing point and osmotic pressure are both colligative properties. As we saw in Chapter 13, the values of these properties depend on the total concentrations of particles (molecules and ions) in a solution, but not on the identity of those particles. We can use the ICE method for equilibrium calculations (Chapter 15) to determine the total concentrations of particles (molecules and ions) in a weak electrolyte solution, as we learned to do in this chapter. Once we have those results we can turn to equations (13.5) and (13.4) to do the calculations required in parts (a) and (b).

Solve

A good place to begin is to convert the pK_a for bromoacetic acid to K_a.

$$pK_a = 2.902 = -\log K_a$$

$$K_a = 10^{-2.902} = 1.25 \times 10^{-3}$$

Next, write the equation for the reversible ionization reaction and the equilibrium constant expression.

$$\mathrm{BrCH_2COOH + H_2O \rightleftharpoons H_3O^+ + BrCH_2COO^-}$$

$$K_a = \frac{[\mathrm{H_3O^+}][\mathrm{BrCH_2COO^-}]}{[\mathrm{BrCH_2COOH}]} = 1.25 \times 10^{-3}$$

(a) Enter the relevant data into the ICE format under the equation for the ionization reaction.

	$\mathbf{BrCH_2COOH + H_2O \rightleftharpoons}$	$\mathbf{H_3O^+ \; +}$	$\mathbf{BrCH_2COO^-}$
initial concns:	0.0500 M	—	—
changes:	$-x$ M	$+x$ M	$+x$ M
equil concns:	$(0.0500 - x)$ M	x M	x M

The equilibrium constant expression based on these data is

$$K_a = \frac{[\mathrm{H_3O^+}][\mathrm{BrCH_2COO^-}]}{[\mathrm{BrCH_2COOH}]} = \frac{x \cdot x}{0.0500 - x} = 1.25 \times 10^{-3}$$

Solve for x.

$$x^2 + 1.25 \times 10^{-3}x - 6.25 \times 10^{-5} = 0$$

$$x = \frac{-1.25 \times 10^{-3} \pm \sqrt{(1.25 \times 10^{-3})^2 + 4 \times 6.25 \times 10^{-5}}}{2}$$

$$x = \frac{-1.25 \times 10^{-3} \pm 1.59 \times 10^{-2}}{2} = 7.3 \times 10^{-3}\,\mathrm{M}$$

The total concentration of molecules and ions at equilibrium is

$$(0.0500 - x)\,\mathrm{M} + x\,\mathrm{M} + x\,\mathrm{M} = (0.0500 + x)\,\mathrm{M} = 0.0573\,\mathrm{M}$$

Assuming that $0.0573\,\mathrm{M} = 0.0573\,m$, the freezing point depression of water caused by 0.0573 mol/L of particles is

$$\Delta T_f = -K_f \times m = -1.86\,°\mathrm{C}\,m^{-1} \times 0.0573\,m = -0.107\,°\mathrm{C}$$

The freezing point of 0.0500 M $\mathrm{BrCH_2COOH(aq)}$ is 0.107 °C below the freezing point of water (0.000 °C), that is, −0.107 °C.

(b) Enter the relevant data into the ICE format under the equation for the ionization reaction.

	$\mathbf{BrCH_2COOH + H_2O \rightleftharpoons}$	$\mathbf{H_3O^+ \; +}$	$\mathbf{BrCH_2COO^-}$
initial concns:	0.00500 M	—	—
changes:	$-x$ M	$+x$ M	$+x$ M
equil concns:	$(0.00500 - x)$ M	x M	x M

The equilibrium constant expression based on these data is

$$K_a = \frac{[\mathrm{H_3O^+}][\mathrm{BrCH_2COO^-}]}{[\mathrm{BrCH_2COOH}]} = \frac{x \cdot x}{0.00500 - x} = 1.25 \times 10^{-3}$$

Solve for x.

$$x^2 + 1.25 \times 10^{-3}x - 6.25 \times 10^{-6} = 0$$

$$x = \frac{-1.25 \times 10^{-3} \pm \sqrt{(1.25 \times 10^{-3})^2 + 4 \times 6.25 \times 10^{-6}}}{2}$$

$$x = \frac{-1.25 \times 10^{-3} \pm 5.15 \times 10^{-3}}{2} = 1.95 \times 10^{-3}\,\mathrm{M}$$

The total concentration of molecules and ions at equilibrium is

$$(0.00500 - x)\,\mathrm{M} + x\,\mathrm{M} + x\,\mathrm{M} = (0.00500 + x)\,\mathrm{M} = 0.00695\,\mathrm{M}$$

At 25.00 °C, the osmotic pressure of an aqueous solution with 0.00695 mol/L of particles (molecules and ions) is

$$\pi = \mathrm{M} \times RT = 0.00695\,\mathrm{mol\,L^{-1}} \times 0.08206\,\mathrm{L\,atm\,mol^{-1}\,K^{-1}} \times 298.15\,\mathrm{K} = 0.170\,\mathrm{atm}$$

Assess

The pK_a is stated more precisely than in most previous equilibrium calculations, and this permitted us to carry three significant figures rather than the usual two in most of the calculations. The assumption in part (a) that $0.0573\ M = 0.0573\ m$ is reasonable for a dilute aqueous solution with a density of essentially 1.00 g/mL. The mass of solvent (water) in one liter of solution is very close to one kilogram, so that molarity (mol solute/L solution) and molality (mol solute/kg solvent) are essentially the same. The calculation in part (b) could have been done more easily by assuming that the concentration of solute particles would be just 10% of that in part (a), that is, 0.00573 M compared to 0.0573 M. However, this would have been a false assumption. Because the percent ionization of the acid is a function of its concentration, the total particle concentration in part (b) was about 12% of that found in part (a), not 10%.

PRACTICE EXAMPLE A: The solubility of $CO_2(g)$ in H_2O at 25 °C and under a $CO_2(g)$ pressure of 1 atm is 1.45 g CO_2/L. Air contains 0.037% CO_2 by volume. Use this information, together with data from Table 16.4, to show that rainwater saturated with CO_2 has a $pH \approx 5.6$ (the normal pH for rainwater). [*Hint:* Recall Henry's law. What is the partial pressure of $CO_2(g)$ in air?]

PRACTICE EXAMPLE B: Often the following generalization applies to oxoacids with the formula $EO_m(OH)_n$ (where E is the central atom): If $m = 0$, $K_a \approx 10^{-7}$; if $m = 1$, $K_a \approx 10^{-2}$; if $m = 2$, K_a is large; and if $m = 3$, K_a is very large.

(a) Show that this generalization works well for the oxoacids of chlorine: HOCl, $pK_a = 7.52$; HOClO, $pK_a = 1.92$; $HOClO_2$, $pK_a = -3$; $HOClO_3$, $pK_a = -8$.

(b) Estimate the value of K_{a_1} for H_3AsO_4.

(c) Write a Lewis structure for hypophosphorous acid, H_3PO_2, for which $pK_a = 1.1$.

Exercises

Brønsted–Lowry Theory of Acids and Bases

1. According to the Brønsted–Lowry theory, label each of the following as an acid or a base. **(a)** HNO_2; **(b)** OCl^-; **(c)** NH_2^-; **(d)** NH_4^+; **(e)** $CH_3NH_3^+$
2. Write the formula of the conjugate base in the reaction of each acid with water. **(a)** HIO_3; **(b)** C_6H_5COOH; **(c)** HPO_4^{2-}; **(d)** $C_2H_5NH_3^+$
3. For each of the following, identify the acids and bases involved in both the forward and reverse directions.
   (a) $HOBr + H_2O \rightleftharpoons OBr^- + H_3O^+$
   (b) $HSO_4^- + H_2O \rightleftharpoons SO_4^{2-} + H_3O^+$
   (c) $HS^- + H_2O \rightleftharpoons H_2S + OH^-$
   (d) $C_6H_5NH_3^+ + OH^- \rightleftharpoons C_6H_5NH_2 + H_2O$
4. Which of the following species are *amphiprotic* in aqueous solution? For such a species, write one equation showing it acting as an acid, and another equation showing it acting as a base. OH^-, NH_4^+, H_2O, HS^-, NO_2^-, HCO_3^-, HBr.
5. With which of the following bases will the ionization of acetic acid, CH_3COOH, proceed furthest toward completion (to the right): **(a)** H_2O; **(b)** NH_3; **(c)** Cl^-; **(d)** NO_3^-? Explain your answer.
6. In a manner similar to equation (16.6), represent the self-ionization of the following liquid solvents: **(a)** NH_3; **(b)** HF; **(c)** CH_3OH; **(d)** CH_3COOH; **(e)** H_2SO_4.
7. With the aid of Table 16.1, predict the direction (forward or reverse) favored in each of the following acid–base reactions.
   (a) $NH_4^+ + OH^- \rightleftharpoons H_2O + NH_3$
   (b) $HSO_4^- + NO_3^- \rightleftharpoons HNO_3 + SO_4^{2-}$
   (c) $CH_3OH + CH_3COO \rightleftharpoons CH_3COOH + CH_3O^-$
8. With the aid of Table 16.1, predict the direction (forward or reverse) favored in each of the following acid–base reactions.
   (a) $CH_3COOH + CO_3^{2-} \rightleftharpoons HCO_3^- + CH_3COO$
   (b) $HNO_2 + ClO_4^- \rightleftharpoons HClO_4 + NO_2^-$
   (c) $H_2CO_3 + CO_3^{2-} \rightleftharpoons HCO_3^- + HCO_3^-$

Strong Acids, Strong Bases, and pH

9. Calculate $[H_3O^+]$ and $[OH^-]$ for each solution: **(a)** 0.00165 M HNO_3; **(b)** 0.0087 M KOH; **(c)** 0.00213 M $Sr(OH)_2$; **(d)** 5.8×10^{-4} M HI.
10. What is the pH of each of the following solutions? **(a)** 0.0045 M HCl; **(b)** 6.14×10^{-4} M HNO_3; **(c)** 0.00683 M NaOH; **(d)** 4.8×10^{-3} M $Ba(OH)_2$.

11. Calculate $[H_3O^+]$ and pH in saturated $Ba(OH)_2(aq)$, which contains 3.9 g $Ba(OH)_2 \cdot 8\,H_2O$ per 100 mL of solution.

12. A saturated aqueous solution of $Ca(OH)_2$ has a pH of 12.35. What is the solubility of $Ca(OH)_2$, expressed in milligrams per 100 mL of solution?

13. What is $[H_3O^+]$ in a solution obtained by dissolving 205 mL HCl(g), measured at 23 °C and 751 mmHg, in 4.25 L of aqueous solution?

14. What is the pH of the solution obtained when 125 mL of 0.606 M NaOH is diluted to 15.0 L with water?

15. How many milliliters of concentrated HCl(aq) (36.0% HCl by mass, $d = 1.18$ g/mL) are required to produce 12.5 L of a solution with pH = 2.10?

16. How many milliliters of a 15.0%, by mass solution of KOH(aq) ($d = 1.14$ g/mL) are required to produce 25.0 L of a solution with pH = 11.55?

17. What volume of 6.15 M HCl(aq) is required to exactly neutralize 1.25 L of 0.265 M $NH_3(aq)$?

$$NH_3(aq) + H_3O^+(aq) \longrightarrow NH_4^+(aq) + H_2O$$

18. A 28.2 L volume of HCl(g), measured at 742 mmHg and 25.0 °C, is dissolved in water. What volume of $NH_3(g)$, measured at 762 mmHg and 21.0 °C, must be absorbed by the same solution to neutralize the HCl?

19. 50.00 mL of 0.0155 M HI(aq) is mixed with 75.00 mL of 0.0106 M KOH(aq). What is the pH of the final solution?

20. 25.00 mL of a $HNO_3(aq)$ solution with a pH of 2.12 is mixed with 25.00 mL of a KOH(aq) solution with a pH of 12.65. What is the pH of the final solution?

Weak Acids, Weak Bases, and pH

(Use data from Table 16.3 as necessary.)

21. What are the $[H_3O^+]$ and pH of 0.143 M HNO_2?

22. What are the $[H_3O^+]$ and pH of 0.085 M $C_2H_5NH_2$?

23. For the ionization of phenylacetic acid,

$$C_6H_5CH_2CO_2H + H_2O \rightleftharpoons H_3O^+ + C_6H_5CH_2CO_2 \qquad K_a = 4.9 \times 10^{-5}$$

(a) What is $[C_6H_5CH_2CO_2^-]$ in 0.186 M $C_6H_5CH_2CO_2H$?

(b) What is the pH of 0.121 M $C_6H_5CH_2CO_2H$?

24. A 625 mL sample of an aqueous solution containing 0.275 mol propionic acid, $CH_3CH_2CO_2H$, has $[H_3O^+] = 0.00239$ M. What is the value of K_a for propionic acid?

$$CH_3CH_2CO_2H + H_2O \rightleftharpoons H_3O^+ + CH_3CH_2CO_2^- \qquad K_a = ?$$

25. Fluoroacetic acid occurs in gifblaar, one of the most poisonous of all plants. A 0.318 M solution of the acid is found to have a pH = 1.56. Calculate K_a of fluoroacetic acid.

$$CH_2FCOOH(aq) + H_2O \rightleftharpoons H_3O^+(aq) + CH_2FCOO^-(aq) \qquad K_a = ?$$

26. Caproic acid, $HC_6H_{11}O_2$, found in small amounts in coconut and palm oils, is used in making artificial flavors. A saturated aqueous solution of the acid contains 11 g/L and has pH = 2.94. Calculate K_a for the acid.

$$HC_6H_{11}O_2 + H_2O \rightleftharpoons H_3O^+ + C_6H_{11}O_2^- \qquad K_a = ?$$

27. What mass of benzoic acid, C_6H_5COOH, would you dissolve in 350.0 mL of water to produce a solution with a pH = 2.85?

$$C_6H_5COOH + H_2O \rightleftharpoons H_3O^+ + C_6H_5COO^- \qquad K_a = 6.3 \times 10^{-5}$$

28. What must be the molarity of an aqueous solution of trimethylamine, $(CH_3)_3N$, if it has a pH = 11.12?

$$(CH_3)_3N + H_2O \rightleftharpoons (CH_3)_3NH^+ + OH^- \qquad K_b = 6.3 \times 10^{-5}$$

29. What are $[H_3O^+]$, $[OH^-]$, pH, and pOH of 0.55 M M $HClO_2$?

30. What are $[H_3O^+]$, $[OH^-]$, pH, and pOH of 0.386 M CH_3NH_2?

31. The solubility of 1-naphthylamine, $C_{10}H_7NH_2$, a substance used in the manufacture of dyes, is given in a handbook as 1 g per 590 g H_2O. What is the approximate pH of a saturated aqueous solution of 1-naphthylamine?

$$C_{10}H_7NH_2 + H_2O \rightleftharpoons C_{10}H_7NH_3^+ + OH^- \qquad pK_b = 3.92$$

32. A saturated aqueous solution of *o*-nitrophenol, $HOC_6H_4NO_2$, has pH = 4.53. What is the solubility of *o*-nitrophenol in water, in grams per liter?

$$HOC_6H_4NO_2 + H_2O \rightleftharpoons H_3O^+ + {}^-OC_6H_4NO_2 \qquad pK_a = 7.23$$

33. A particular vinegar is found to contain 5.7% acetic acid, CH_3COOH, by mass. What mass of this vinegar should be diluted with water to produce 0.750 L of a solution with pH = 4.52?

34. A particular household ammonia solution ($d = 0.97$ g/mL) is 6.8% NH_3 by mass. How many milliliters of this solution should be diluted with water to produce 625 mL of a solution with pH = 11.55?

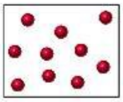
35. A 275 mL sample of vapor in equilibrium with 1-propylamine at 25.0 °C is removed and dissolved in 0.500 L H_2O. For 1-propylamine, $pK_b = 3.43$ and v.p. = 316 Torr.

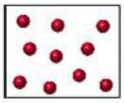
(a) What should be the pH of the aqueous solution?

(b) How many mg of NaOH dissolved in 0.500 L of water give the same pH?

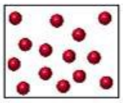
36. One handbook lists a value of 9.5 for pK_b of quinoline, C_9H_7N, a weak base used as a preservative for anatomical specimens and to make dyes. Another handbook lists the solubility of quinoline in water at 25 °C as 0.6 g/100 mL. Use this information to calculate the pH of a saturated solution of quinoline in water.

37. The sketch on the far left represents the $[H_3O^+]$ present in an acetic acid solution of molarity M. If the molarity of the solution is doubled, which of the sketches below best represents the resulting solution?

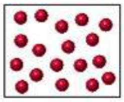




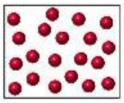
(a)



(b)

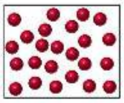


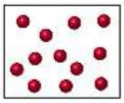
(c)



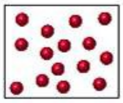
(d)

38. The sketch on the far left represents the $[OH^-]$ present in an ammonia solution of molarity M. If the solution is diluted to half its original molarity, which of the sketches below best represents the resulting solution?

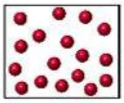




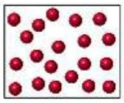
(a)



(b)



(c)



(d)

Percent Ionization

39. What is the **(a)** degree of ionization and **(b)** percent ionization of propionic acid in a solution that is 0.45 M $CH_3CH_2CO_2H$?

$$CH_3CH_2CO_2H + H_2O \rightleftharpoons H_3O^+ + CH_3CH_2CO_2^- \qquad pK_a = 4.89$$

40. What is the **(a)** degree of ionization and **(b)** percent ionization of ethylamine, $C_2H_5NH_2$, in an 0.85 M aqueous solution?

41. What must be the molarity of an aqueous solution of NH_3 if it is 4.2% ionized?

42. What must be the molarity of an acetic acid solution if it has the same percent ionization as 0.100 M $CH_3CH_2CO_2H$ (propionic acid, $K_a = 1.3 \times 10^{-5}$)?

43. Continuing the dilutions described in Example 16-8, should we expect the percent ionization to be 13% in 0.0010 M CH_3COOH and 42% in 0.00010 M CH_3COOH? Explain.

44. What is the **(a)** degree of ionization and **(b)** percent ionization of trichloroacetic acid in a 0.035 M CCl_3COOH solution?

$$CCl_3COOH + H_2O \rightleftharpoons H_3O^+ + CCl_3COO^- \qquad pK_a = 0.52$$

Polyprotic Acids

(Use data from Table 16.4 as necessary.)

45. Explain why $[PO_4^{3-}]$ in 1.00 M H_3PO_4 is *not* simply $\frac{1}{3}[H_3O^+]$, but much, much less than $\frac{1}{3}[H_3O^+]$.

46. Cola drinks have a phosphoric acid content that is described as "from 0.057 to 0.084% of 75% phosphoric acid, by mass." Estimate the pH range of cola drinks corresponding to this range of H_3PO_4 content.

47. Determine $[H_3O^+]$, $[HS^-]$, and $[S^{2-}]$ for the following $H_2S(aq)$ solutions: **(a)** 0.075 M H_2S; **(b)** 0.0050 M H_2S; **(c)** 1.0×10^{-5} M H_2S.

48. For 0.045 M H_2CO_3, a weak diprotic acid, calculate **(a)** $[H_3O^+]$, **(b)** $[HCO_3^-]$, and **(c)** $[CO_3^{2-}]$. Use data from Table 16.4 as necessary.

49. Calculate $[H_3O^+]$, $[HSO_4^-]$, and $[SO_4^{2-}]$ in **(a)** 0.75 M H_2SO_4; **(b)** 0.075 M H_2SO_4; **(c)** 7.5×10^{-4} M H_2SO_4. [*Hint:* Check any assumptions that you make.]

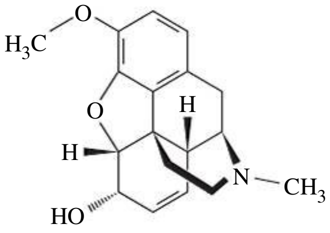
50. Adipic acid, $HOOC(CH_2)_4COOH$, is among the top 50 manufactured chemicals in the United States (nearly 1 million metric tons annually). Its chief use is in the manufacture of nylon. It is a *diprotic* acid having $K_{a_1} = 3.9 \times 10^{-5}$ and $K_{a_2} = 3.9 \times 10^{-6}$. A saturated solution of adipic acid is about 0.10 M $HOOC(CH_2)_4COOH$. Calculate the concentration of each ionic species in this solution.

51. The antimalarial drug quinine, $C_{20}H_{24}O_2N_2$, is a *diprotic base* with a water solubility of 1.00 g/1900 mL of solution.
(a) Write equations for the ionization equilibria corresponding to $pK_{b_1} = 6.0$ and $pK_{b_2} = 9.8$.
(b) What is the pH of saturated aqueous quinine?

52. For hydrazine, N_2H_4, $pK_{b_1} = 6.07$ and $pK_{b_2} = 15.05$. Draw a structural formula for hydrazine, and write equations to show the ionization of hydrazine in two distinctive steps. Calculate the pH of 0.245 M $N_2H_4(aq)$.

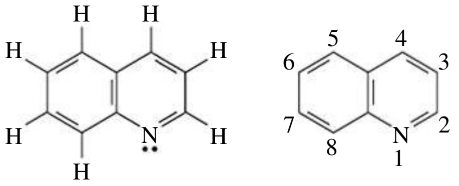
Ions as Acids and Bases (Hydrolysis)

53. Codeine, $C_{18}H_{21}O_3N$, is an opiate, has analgesic and antidiarrheal properties, and is widely used. In water, codeine is a weak base. A handbook gives $pK_a = 6.05$ for protonated codeine, $C_{18}H_{21}O_3NH^+$. Write the reaction for $C_{18}H_{21}O_3NH^+$ and calculate pK_b for codeine.



Codeine

54. Approximately 4 metric tons of quinoline, C_9H_7N, is produced annually. The principal source of quinoline is coal tar. Quinoline is a weak base in water. A handbook gives $K_a = 6.3 \times 10^{-10}$ for protonated quinoline, $C_9H_7NH^+$. Write the ionization reaction for $C_9H_7NH^+$ and calculate pK_b for quinoline.



Quinoline

55. Complete the following equations in those instances in which a reaction (hydrolysis) will occur. If no reaction occurs, so state.

(a) $NH_4^+(aq) + NO_3^-(aq) + H_2O \longrightarrow$

(b) $Na^+(aq) + NO_2^-(aq) + H_2O \longrightarrow$

(c) $K^+(aq) + C_6H_5COO^-(aq) + H_2O \longrightarrow$

(d) $K^+(aq) + Cl^-(aq) + Na^+(aq) + I^-(aq) + H_2O \longrightarrow$

(e) $C_6H_5NH_3^+(aq) + Cl^-(aq) + H_2O \longrightarrow$

56. From data in Table 16.3, determine **(a)** K_a for $C_5H_5NH^+$; **(b)** K_b for $HCOO^-$; **(c)** K_b for $C_6H_5O^-$.

57. Predict whether a solution of each of the following salts is acidic, basic, or pH neutral: **(a)** KCl; **(b)** KF; **(c)** $NaNO_3$; **(d)** $Ca(OCl)_2$; **(e)** NH_4NO_2.

58. Arrange the following 0.010 M solutions in order of *increasing* pH: $NH_3(aq)$, $HNO_3(aq)$, $NaNO_2(aq)$, $CH_3COOH(aq)$, $NaOH(aq)$, $NH_4CH_3COO(aq)$, $NH_4ClO_4(aq)$.

59. What is the pH of an aqueous solution that is 0.089 M NaOCl?

60. What is the pH of an aqueous solution that is 0.123 M NH_4Cl?

61. Sorbic acid, $CH_2CH{=}CH{=}CHCH_2CO_2H$ (pK_a = 4.77), is widely used in the food industry as a preservative. For example, its potassium salt (potassium sorbate) is added to cheese to inhibit the formation of mold. What is the pH of 0.37 M potassium sorbate solution?

62. Pyridine, C_5H_5N (pK_b = 8.82), forms a salt, pyridinium chloride, as a result of a reaction with HCl. Write an ionic equation to represent the hydrolysis of the pyridinium ion, and calculate the pH of 0.0482 M $C_5H_5NH^+Cl^-(aq)$.

63. For each of the following ions, write two equations—one showing its ionization as an acid and the other as a base: **(a)** HSO_3^-; **(b)** HS^-; **(c)** HPO_4^-. Then use data from Table 16.4 to predict whether each ion makes the solution acidic or basic.

64. Suppose you wanted to produce an aqueous solution of pH = 8.65 by dissolving one of the following salts in water. Which salt would you use, and at what molarity? **(a)** NH_4Cl; **(b)** $KHSO_4$; **(c)** KNO_2; **(d)** $NaNO_3$.

Molecular Structure and Acid–Base Behavior

65. Predict which is the stronger acid: **(a)** $HClO_2$ or $HClO_3$; **(b)** H_2CO_3 or HNO_2; **(c)** H_2SiO_3 or H_3PO_4. Explain.

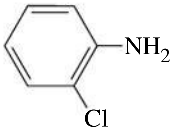
66. Explain why trichloroacetic acid, CCl_3COOH, is a stronger acid than acetic acid, CH_3COOH.

67. Which is the stronger acid of each of the following pairs of acids? Explain your reasoning. **(a)** HBr or HI; **(b)** HOClO or HOBr; **(c)** $I_3CCH_2CH_2COOH$ or $CH_3CH_2CCl_2COOH$.

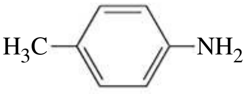
68. Indicate which of the following is the *weakest* acid, and give reasons for your choice: HBr; $CH_2ClCOOH$; CH_3CH_2COOH; CH_2FCH_2COOH; CI_3COOH.

69. From the following bases, select the one with the *smallest* K_b and the one with the *largest* K_b, and give reasons for your choices.

(a)

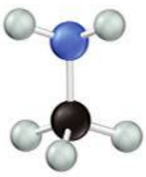


(b)

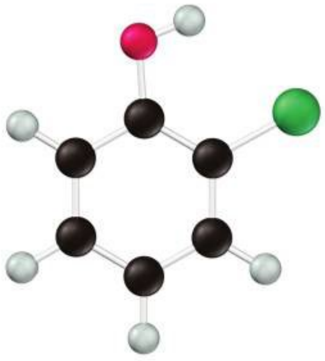


(c) $CH_3CH_2CH_2NH_2$ **(d)** $N{\equiv}CCH_2NH_2$

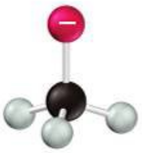
70. For the molecular models shown, write the formula of the species that is the most acidic and the one that is most basic, and give reasons for your choices.



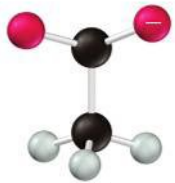
(a)



(b)



(c)



(d)

Lewis Theory of Acids and Bases

71. For each reaction draw a Lewis structure for each species and indicate which is the acid and which is the base:
(a) $CO_2 + H_2O \longrightarrow H_2CO_3$
(b) $H_2O + BF_3 \longrightarrow H_2OBF_3$
(c) $O^{2-} + H_2O \longrightarrow 2\,OH^-$
(d) $S^{2-} + SO_3 \longrightarrow S_2O_3{}^{2-}$

72. In the following reactions indicate which is the Lewis acid and which is the Lewis base:
(a) $SOI_2 + BaSO_3 \longrightarrow Ba^{2+} + 2\,I^- + 2\,SO_2$
(b) $HgCl_3{}^- + Cl^- \longrightarrow HgCl_4{}^{2-}$

73. Indicate whether each of the following is a Lewis acid or base. **(a)** OH^-; **(b)** $(C_2H_5)_3B$; **(c)** CH_3NH_2.

74. Each of the following is a Lewis acid–base reaction. Which reactant is the acid, and which is the base? Explain.
(a) $SO_3 + H_2O \longrightarrow H_2SO_4$
(b) $Zn(OH)_2(s) + 2\,OH^-(aq) \longrightarrow [Zn(OH)_4]^{2-}(aq)$

75. The three following reactions are acid–base reactions according to the Lewis theory. Draw Lewis structures, and identify the Lewis acid and Lewis base in each reaction.
(a) $B(OH)_3 + OH^- \longrightarrow [B(OH)_4]^-$
(b) $N_2H_4 + H_3O^+ \longrightarrow N_2H_5{}^+ + H_2O$
(c) $(C_2H_5)_2O + BF_3 \longrightarrow (C_2H_5)_2OBF_3$

76. $CO_2(g)$ can be removed from confined quarters (such as a spacecraft) by allowing it to react with an alkali metal hydroxide. Show that this is a Lewis acid–base reaction. For example,

$$CO_2(g) + LiOH(s) \longrightarrow LiHCO_3(s)$$

77. The molecular solid $I_2(s)$ is only slightly soluble in water but will dissolve to a much greater extent in an aqueous solution of KI, because the $I_3{}^-$ anion forms. Write an equation for the formation of the $I_3{}^-$ anion, and indicate the Lewis acid and Lewis base.

78. The following very strong acids are formed by the reactions indicated:

$$HF + SbF_5 \longrightarrow HSbF_6$$

(called "super acid," hexafluoroantimonic acid)

$$HF + BF_3 \longrightarrow HBF_4$$

(tetrafluoroboric acid)

(a) Identify the Lewis acids and bases.
(b) To which atom is the H atom bonded in each acid?

79. Use Lewis structures to diagram the following reaction in the manner of reaction (16.20).

$$H_2O + SO_2 \longrightarrow H_2SO_3$$

Identify the Lewis acid and Lewis base.

80. Use Lewis structures to diagram the following reaction in the manner of reaction (16.19).

$$2\,NH_3 + Ag^+ \longrightarrow [Ag(NH_3)_2]^+$$

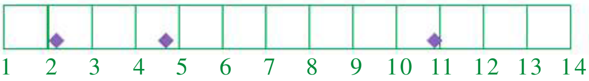
Identify the Lewis acid and Lewis base.

Integrative and Advanced Exercises

81. The Brønsted–Lowry theory can be applied to acid–base reactions in nonaqueous solvents, where the relative strengths of acids and bases can differ from what they are in aqueous solutions. Indicate whether each of the following would be an acid, a base, or amphiprotic in pure liquid acetic acid, CH_3COOH, as a solvent. **(a)** CH_3COO^-; **(b)** H_2O; **(c)** CH_3COOH; **(d)** $HClO_4$. [*Hint:* Refer to Table 16.1.]

82. The pH of saturated $Sr(OH)_2(aq)$ is found to be 13.12. A 10.0 mL sample of saturated $Sr(OH)_2(aq)$ is diluted to 250.0 mL in a volumetric flask. A 10.0 mL sample of the diluted $Sr(OH)_2(aq)$ is transferred to a beaker, and some water is added. The resulting solution requires 25.1 mL of a HCl solution for its titration. What is the molarity of this HCl solution?

83. Several approximate pH values are marked on the following pH scale.



Some of the following solutions can be matched to one of the approximate pH values marked on the scale; others cannot. For solutions that can be matched to a pH value, identify each solution and its pH value. Identify the solutions that cannot be matched, and give reasons why matches are not possible. **(a)** 0.010 M H_2SO_4; **(b)** 1.0 M NH_4Cl; **(c)** 0.050 M KI; **(d)** 0.0020 M CH_3NH_2; **(e)** 1.0 M NaOCl; **(f)** 0.10 M C_6H_5OH; **(g)** 0.10 M HOCl; **(h)** 0.050 M $ClCH_2COOH$; **(i)** 0.050 M HCOOH.

84. Show that when $[H_3O^+]$ is reduced to half its original value, the pH of a solution increases by 0.30 unit, *regardless of the initial pH.* Is it also true that when any solution is diluted to half its original concentration, the pH increases by 0.30 unit? Explain.

85. Explain why $[H_3O^+]$ in a strong acid solution *doubles* as the total acid concentration doubles, whereas in a weak acid solution, $[H_3O^+]$ increases only by about a factor of $\sqrt{2}$.

86. Use data from Appendix D to determine whether the ion product of water, K_w, increases, decreases, or remains unchanged with increasing temperature.

87. From the observation that 0.0500 M vinylacetic acid has a freezing point of −0.096 °C, determine K_a for this acid.

$$CH_2{=}CHCH_2CO_2H + H_2O \rightleftharpoons H_3O^+ + CH_2{=}CHCH_2CO_2{}^-$$

88. You are asked to prepare a 100.0 mL sample of a solution with a pH of 5.50 by dissolving the appropriate amount of a solute in water with pH = 7.00. Which of these solutes would you use, and in what quantity? Explain your choice. **(a)** 15 M $NH_3(aq)$; **(b)** 12 M $HCl(aq)$; **(c)** $NH_4Cl(s)$; **(d)** glacial (pure) acetic acid, CH_3COOH.

89. Determine the pH of **(a)** 1.0×10^{-5} M HCN and **(b)** 1.0×10^{-5} M $C_6H_5NH_2$ (aniline).

90. It is possible to write simple equations to relate pH, pK, and molarities (M) of various solutions. Three such equations are shown here.

Weak acid: $$\mathrm{pH} = \frac{1}{2}\mathrm{p}K_a - \frac{1}{2}\log \mathrm{M}$$

Weak base: $$\mathrm{pH} = 14.00 - \frac{1}{2}\mathrm{p}K_b + \frac{1}{2}\log \mathrm{M}$$

Salt of weak acid (pK_a) *and strong base:* $$\mathrm{pH} = 14.00 - \frac{1}{2}\mathrm{p}K_w + \frac{1}{2}\mathrm{p}K_a + \frac{1}{2}\log \mathrm{M}$$

(a) Derive these three equations, and point out the assumptions involved in the derivations.
(b) Use these equations to determine the pH of 0.10 M $CH_3COOH(aq)$, 0.10 M $NH_3(aq)$, and 0.10 M $NaCH_3COO$. Verify that the equations give correct results by determining these pH values in the usual way.

91. A handbook lists the following formula for the percent ionization of a weak acid.

$$\%\ \text{ionized} = \frac{100}{1 + 10^{(\mathrm{p}K - \mathrm{pH})}}$$

(a) Derive this equation. What assumptions must you make in this derivation?
(b) Use the equation to determine the percent ionization of a formic acid solution, HCOOH(aq), with a pH of 2.50.
(c) A 0.150 M solution of propionic acid, CH_3CH_2COOH, has a pH of 2.85. What is K_a for propionic acid?

$$CH_3CH_2CO_2H + H_2O \rightleftharpoons H_3O^+ + CH_3CH_2CO_2^-$$

92. Oxalic acid, HOOCCOOH, a weak diprotic acid, has p$K_{a_1} = 1.25$ and p$K_{a_2} = 3.81$. A related diprotic acid, suberic acid, $HOOC(CH_2)_8COOH$ has p$K_{a_1} = 4.21$ and p$K_{a_2} = 5.40$. Offer a plausible reason as to why the *difference* between pK_{a_1} and pK_{a_2} is so much greater for oxalic acid than for suberic acid.

93. Here is a way to test the validity of the statement made on page 719 in conjunction with the three key ideas governing the ionization of polyprotic acids. Determine the pH of 0.100 M succinic acid in two ways: first by assuming that H_3O^+ is produced only in the first ionization step, and then by allowing for the possibility that some H_3O^+ is also produced in the second ionization step. Compare the results, and discuss the significance of your finding.

$$H_2C_4H_4O_4 + H_2O \rightleftharpoons H_3O^+ + HC_4H_4O_4^- \qquad K_{a_1} = 6.2 \times 10^{-5}$$

$$HC_4H_4O_4^- + H_2O \rightleftharpoons H_3O^+ + C_4H_4O_4^{2-} \qquad K_{a_2} = 2.3 \times 10^{-6}$$

94. What mass of acetic acid, CH_3COOH, must be dissolved per liter of aqueous solution if the solution is to have the same freezing point as 0.150 M $ClCH_2COOH$ (chloroacetic acid)?

95. What is the pH of a solution that is 0.68 M H_2SO_4 and 1.5 M HCOOH (formic acid)?

96. An aqueous solution of two weak acids has a stoichiometric molarity, M, in each acid. If one acid has a K_a value twice as large as the other, show that the pH of the solution is given by the equation $\mathrm{pH} = -\frac{1}{2}\log 3\,\mathrm{M}\,K_a$. Assume that the criteria for the simplifying assumption on page 715 are met.

97. Use the concept of hybrid orbitals to describe the bonding in the strong acids given in Exercise 78.

98. Phosphorous acid is listed in Appendix D as a *di*protic acid. Propose a Lewis structure for phosphorous acid that is consistent with this fact.

99. The following four equilibria lie to the right: $N_2H_5^+ + CH_3NH_2 \longrightarrow N_2H_4 + CH_3NH_3^+$; $H_2SO_3 + F^- \longrightarrow HSO_3^- + HF$; $CH_3NH_3^+ + OH^- \longrightarrow CH_3NH_2 + H_2O$; and $HF + N_2H_4 \longrightarrow F^- + N_2H_5^+$.
(a) Rank all the acids involved in order of decreasing acid strength.
(b) Rank all the bases involved in order of decreasing base strength.
(c) State whether each of the following two equilibria lie primarily to the right or to the left: **(i)** $HF + OH^- \longrightarrow F^- + H_2O$; **(ii)** $CH_3NH_3^+ + HSO_3^- \longrightarrow CH_3NH_2 + H_2SO_3$.

Feature Problems

100. Maleic acid is a carbon–hydrogen–oxygen compound used in dyeing and finishing fabrics and as a preservative of oils and fats. In a combustion analysis, a 1.054 g sample of maleic acid yields 1.599 g CO_2 and 0.327 g H_2O. In a freezing-point depression experiment, a 0.615 g sample of maleic acid dissolved in 25.10 g of glacial acetic acid, $CH_3COOH(l)$ (which has the freezing-point depression constant $K_f = 3.90\ °C\ m^{-1}$ and in which maleic acid does not ionize), lowers the freezing point by 0.82°C. In a titration experiment, a 0.4250 g sample of maleic acid is dissolved in water and requires 34.03 mL of 0.2152 M KOH for its complete neutralization. The pH of a 0.215 g sample of maleic acid dissolved in 50.00 mL of aqueous solution is found to be 1.80.
(a) Determine the empirical and molecular formulas of maleic acid. [*Hint:* Which experiment(s) provide the necessary data?]
(b) Use the results of part (a) and the titration data to rewrite the molecular formula to reflect the number of ionizable H atoms in the molecule.
(c) Given that the ionizable H atom(s) is(are) associated with the carboxyl group(s), write the plausible condensed structural formula of maleic acid.
(d) Determine the ionization constant(s) of maleic acid. If the data supplied are insufficient, indicate what additional data would be needed.

(e) Calculate the expected pH of a 0.0500 M aqueous solution of maleic acid. Indicate any assumptions required in this calculation.

101. In Example 16-7, rather than use the quadratic formula to solve the quadratic equation, we could have proceeded in the following way. Substitute the value yielded by our failed assumption—$x = 0.0010$—into the *denominator* of the quadratic equation; that is, use $(0.00250 - 0.0010)$ as the value of $[CH_3NH_2]$ and solve for a new value of x. Use this second value of x to re-evaluate $[CH_3NH_2]$: $[CH_3NH_2] = (0.00250 - \text{second value of } x)$. Solve the simple quadratic equation for a third value of x, and so on. After three or four trials, you will find that the value of x no longer changes. This is the answer you are seeking. **(a)** Complete the calculation of the pH of 0.00250 M CH_3NH_2 by this method, and show that the result is the same as that obtained by using the quadratic formula. **(b)** Use this method to determine the pH of 0.500 M $HClO_2$.

102. Apply the general method for solution equilibrium calculations outlined on page 720 to determine the pH values of the following solutions. In applying the method, look for valid assumptions that may simplify the numerical calculations.
(a) a solution that is 0.315 M CH_3COOH and 0.250 M HCOOH
(b) a solution that contains 1.55 g CH_3NH_2 and 12.5 g NH_3 in 375 mL
(c) 1.0 M $NH_4CN(aq)$

Self-Assessment Exercises

103. In your own words, define or explain the following terms or symbols: **(a)** K_w; **(b)** pH; **(c)** pK_a; **(d)** hydrolysis; **(e)** Lewis acid.

104. Briefly describe each of the following ideas or phenomena: **(a)** conjugate base; **(b)** percent ionization of an acid or base; **(c)** self-ionization; **(d)** amphiprotic behavior.

105. Explain the important distinctions between each pair of terms: **(a)** Brønsted–Lowry acid and base; **(b)** $[H_3O^+]$ and pH; **(c)** K_a for NH_4^+ and K_b for NH_3; **(d)** leveling effect and electron-withdrawing effect.

106. Of the following, the amphiprotic ion is **(a)** HCO_3^-; **(b)** CO_3^{2-}; **(c)** NH_4^+; **(d)** $CH_3NH_3^+$; **(e)** ClO_4^-.

107. The pH in 0.10 M $CH_3CH_2COOH(aq)$ must be **(a)** equal to $[H_3O^+]$ in 0.10 M $HNO_2(aq)$; **(b)** less than the pH in 0.10 M HI(aq); **(c)** greater than the pH in 0.10 M HBr(aq); **(d)** equal to 1.0.

108. In 0.10 M $CH_3NH_2(aq)$, **(a)** $[H_3O^+] = 0.10$ M; **(b)** $[OH^-] = 0.10$ M; **(c)** pH < 7; **(d)** pH < 13.

109. The reaction of $CH_3COOH(aq)$ proceeds furthest toward completion with a base when that base is **(a)** H_2O; **(b)** $CH_3NH_3^+$; **(c)** NH_4^+; **(d)** Cl^-; **(e)** CO_3^{2-}.

110. In 0.10 M $H_2SO_4(aq)$, $[H_3O^+]$ is equal to **(a)** 0.050 M; **(b)** 0.10 M; **(c)** 0.11 M; **(d)** 0.20 M.

111. For $H_2SO_3(aq)$, $K_{a_1} = 1.3 \times 10^{-2}$ and $K_{a_2} = 6.3 \times 10^{-8}$. In 0.10 M $H_2SO_3(aq)$, **(a)** $[HSO_3^-] = 0.013$ M; **(b)** $[SO_3^{2-}] = 6.3 \times 10^{-8}$ M; **(c)** $[H_3O^+] = 0.10$ M; **(d)** $[H_3O^+] = 0.013$ M; **(e)** $[SO_3^{2-}] = 0.036$ M.

112. What is the pH of the solution obtained by mixing 24.80 mL of 0.248 M HNO_3 and 15.40 mL of 0.394 M KOH?

113. How many milliliters of a concentrated acetic acid solution (35.0% CH_3COOH by mass; $d = 1.044$ g/mL) must be diluted with water to produce 12.5 L of solution with pH 3.25?

114. Determine the pH of 2.05 M $NaCH_2ClCOO$. (Use data from Table 16.3, as necessary.)

115. Several aqueous solutions are prepared. *Without consulting any tables in the text*, arrange these ten solutions in order of *increasing* pH: 1.0 M NaBr, 0.05 M CH_3COOH, 0.05 M NH_3, 0.02 M KCH_3COO, 0.05 M $Ba(OH)_2$, 0.05 M H_2SO_4, 0.10 M HI, 0.06 M NaOH, 0.05 M NH_4Cl, and 0.05 M $CH_2ClCOOH$.

116. A solution is found to have pH $= 5 \times$ pOH. Is this solution acidic or basic? What is $[H_3O^+]$ in the solution? Which of the following could be the solute in this solution: NH_3, CH_3COOH, or NH_4CH_3COO, and what would be its molarity?

117. Propionic acid, CH_3CH_2COOH, is 0.42% ionized in 0.80 M solution. The K_a for this acid is **(a)** 1.42×10^{-5}; **(b)** 1.42×10^{-7}; **(c)** 1.77×10^{-5}; **(d)** 6.15×10^{4}; **(e)** none of these.

118. The conjugate acid of HPO_4^{2-} is **(a)** PO_4^{3-}; **(b)** $H_2PO_4^-$; **(c)** H_3PO_4; **(d)** H_3O^+; **(e)** none of these.

119. The equilibria $OH^- + HClO \longrightarrow H_2O + ClO^-$ and $ClO^- + HNO_2 \longrightarrow HClO + NO_2^-$ both lie to the right. Which of the following is a list of acids ranked in order of decreasing strength?
(a) $HClO > HNO_2 > H_2O$
(b) $ClO^- > NO_2^- > OH^-$
(c) $NO_2^- > ClO^- > OH^-$
(d) $HNO_2 > HClO > H_2O$
(e) none of these

120. 3.00 mol of calcium chlorite is dissolved in enough water to produce 2.50 L of solution. $K_a = 2.9 \times 10^{-8}$ for HClO, and $K_a = 1.1 \times 10^{-2}$ for $HClO_2$. Compute the pH of the solution.

121. Appendix E describes a useful study aid known as concept mapping. Using the method presented in Appendix E, construct a concept map that summarizes the material discussed in Section 16-8.

Additional Aspects of Acid–Base Equilibria

CONTENTS

17-1 Common-Ion Effect in Acid–Base Equilibria
17-2 Buffer Solutions
17-3 Acid–Base Indicators
17-4 Neutralization Reactions and Titration Curves
17-5 Solutions of Salts of Polyprotic Acids
17-6 Acid–Base Equilibrium Calculations: A Summary

NaOH(aq) is slowly added to an aqueous solution containing HCl(aq) and the indicator phenolphthalein. The indicator color changes from colorless to red as the pH changes from 8.0 to 10.0. The equivalence point of the neutralization is reached when the solution turns a lasting pink (the pink seen here disappears when the flask is swirled to mix the reactants). The selection of indicators for acid–base titrations is one of the topics considered in this chapter.

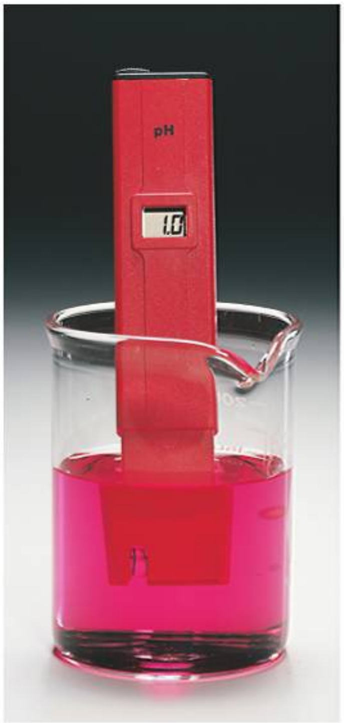
In our study of acid rain (see Focus On 16-1 on the MasteringChemistry website), we learned that a very small amount of atmospheric $CO_2(g)$ dissolves in rainwater. Yet this amount is sufficient to lower the pH of rainwater by nearly 2 units. And when acid-forming air pollutants, such as SO_2, SO_3, and NO_2, also dissolve in rainwater, it becomes even more acidic. A chemist would say that water has no "buffer capacity"—that is, its pH changes sharply when even small quantities of acids or bases are dissolved in it.

One of the main topics of this chapter is buffer solutions—solutions that can resist a change in pH when acids or bases are added to them. We will consider how such solutions are prepared, how they maintain a nearly constant pH, and how they are used. At the end of the chapter, we will consider perhaps the most important buffer system to humans: the buffer system that maintains the constant pH of blood.

A second topic that we will explore is acid–base titrations. Here, our aim will be to calculate how pH changes during a titration. We can use this information to select an appropriate indicator for a titration and to determine, in general, which acid–base titrations work well and which do not. For the most part, we will find the calculations in this chapter to be extensions of those in Chapter 16.

17-1 Common-Ion Effect in Acid–Base Equilibria

The questions answered in Chapter 16 were mostly of the type, "What is the pH of 0.10 M $HC_2H_3O_2$, of 0.10 M NH_3, of 0.10 M H_3PO_4, of 0.10 M NH_4Cl?" In each of these cases, we think of dissolving a *single* substance in aqueous solution and determining the concentrations of the species present at equilibrium. In most situations in this chapter, a solution of a weak acid or weak base initially contains a second source of one of the ions produced in the ionization of the acid or base. The added ions are said to be *common* to the weak acid or weak base. The presence of a common ion can have some important consequences.



▲ FIGURE 17-1
A weak acid–strong acid mixture
The solution pictured is 0.100 M CH_3COOH and 0.100 M HCl. The reading on the pH meter (1.0) indicates that essentially all the H_3O^+ comes from the strong acid HCl. The red color of the solution is that of thymol blue indicator. Compare this photo with Figure 16-7, in which the separate acids are shown.

▶ The common-ion effect is not restricted to weak acids and weak bases. Buffers are the most important examples of the common-ion effect in weak acids and weak bases.

Solutions of Weak Acids and Strong Acids

Consider a solution that is at the same time 0.100 M CH_3COOH and 0.100 M HCl. We can write separate equations for the ionizations of the acids, one weak and the other strong, and indicate the expected concentrations of molecules and ions in the solution.

$$\begin{array}{ccccccccc} CH_3COOH & + & H_2O & \rightleftharpoons & H_3O^+ & + & CH_3COO^- & & K_a = 1.8 \times 10^{-5} \\ (0.100 - x)\ M & & & & x\ M & & x\ M & & \\ HCl & + & H_2O & \longrightarrow & H_3O^+ & + & Cl^- & & \\ & & & & 0.100\ M & & 0.100\ M & & \end{array}$$

Of course, there can be only a single concentration of H_3O^+ in the solution, and this must be $[H_3O^+] = (0.100 + x)$ M. Because H_3O^+ is formed in both ionization processes, we say that it is a *common ion*. The weak acid–strong acid mixture described here is pictured in Figure 17-1. Although it might seem that the pH would be lower than 1.0, the figure indicates that this is not the case.

Concentrations of the species present in this mixture of a weak acid and a strong acid are calculated in Example 17-1, followed by comments on the significance of the result.

EXAMPLE 17-1 Demonstrating the Common-Ion Effect: A Solution of a Weak Acid and a Strong Acid

(a) Determine $[H_3O^+]$ and $[CH_3COO^-]$ in 0.100 M CH_3COOH. **(b)** Then determine these same quantities in a solution that is 0.100 M in both CH_3COOH and HCl.

Analyze

In part (a) we must determine the species in a weak acid solution, and in part (b) we investigate the effects of the addition of a strong acid. The two acids have the common ion H_3O^+.

Solve

(a) This calculation was done in Example 16-6 (page 712). We found that in 0.100 M CH_3COOH, $[H_3O^+] = [CH_3COO^-] = 1.3 \times 10^{-3}$ M.

(b) Instead of writing two separate ionization equations, as we did just prior to this example, let's write only the ionization equation for CH_3COOH and enter information about the common ion, H_3O^+, in the following format.

	CH_3COOH	+	H_2O	$\rightleftharpoons$	H_3O^+	+	CH_3COO^-
initial concns:							
weak acid:	0.100 M				—		—
strong acid:	—				0.100 M		—
changes:	$-x$ M				$+x$ M		$+x$ M
equil concns:	$(0.100 - x)$ M				$(0.100 + x)$ M		x M

As is customary, we begin with the assumption that x is very small compared with 0.100. Thus, $0.100 - x \approx 0.100 + x \approx 0.100$.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{(0.100 + x)\cdot x}{0.100 - x} = \frac{\cancel{0.100}\cdot x}{\cancel{0.100}} = 1.8 \times 10^{-5}$$

$$x = [CH_3COO^-] = 1.8 \times 10^{-5}\text{ M} \qquad 0.100 + x = [H_3O^+] = 0.100\text{ M}$$

Notice that x is only 0.018% of 0.100, and so the assumption that x is small compared with 0.100 is valid.

Assess

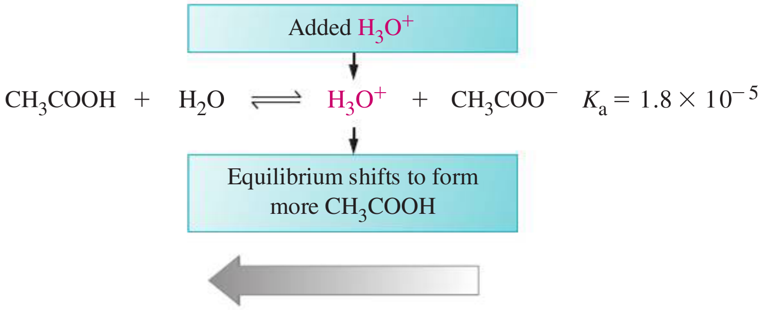
In this example the acetate ion concentration goes down after the addition of hydronium ion. In other words, ionization of acetic acid is suppressed by the addition of strong acid. The common-ion effect is not restricted to weak acids and weak bases. Buffers are the most important examples of the common-ion effect in weak acids and weak bases. This shift in equilibrium concentration because of the addition of a common ion is another illustration of Le Châtelier's principle.

PRACTICE EXAMPLE A: Determine $[H_3O^+]$ and $[HF]$ in 0.500 M HF. Then determine these concentrations in a solution that is 0.100 M HCl and 0.500 M HF.

PRACTICE EXAMPLE B: How many drops of 12 M HCl would you add to 1.00 L of 0.100 M CH_3COOH to make $[CH_3COO^-] = 1.0 \times 10^{-4}$ M? Assume that 1 drop = 0.050 mL and that the volume of solution remains 1.00 L after the 12 M HCl is diluted. [*Hint*: What must be the $[H_3O^+]$ in the solution?]

Now we see the consequence of adding a strong acid (HCl) to a weak acid (CH_3COOH): The concentration of the anion $[CH_3COO^-]$ is greatly reduced. Between parts (a) and (b) of Example 17-1, $[CH_3COO^-]$ is lowered from 10^{-3} M to 1.8×10^{-5} M—almost a 100-fold decrease. Another way to state this result is through Le Châtelier's principle (see Chapter 15, page 673). Increasing the concentration of one of the *products* of a reaction—the common ion—shifts the equilibrium condition in the *reverse* direction. The **common-ion effect** is the suppression of the ionization of a weak electrolyte caused by adding more of an ion that is a product of this ionization. The common-ion effect of H_3O^+ on the ionization of acetic acid is suggested as follows.

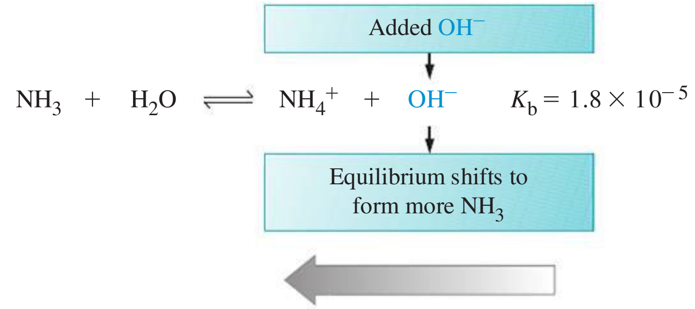
When a strong acid supplies the common ion H_3O^+, the equilibrium shifts to form more CH_3COOH.



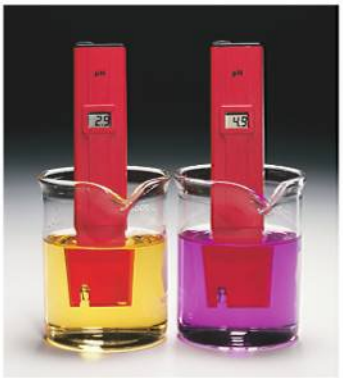
Added H_3O^+
$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^- \quad K_a = 1.8 \times 10^{-5}$
Equilibrium shifts to form more CH_3COOH

The ionization of a weak base, such as NH_3, is suppressed when a strong base, such as NaOH, is added. Here, OH^- is the common ion, and its increased concentration shifts the equilibrium to the left.

When a strong base supplies the common ion OH^-,
the equilibrium shifts to form more NH_3.



$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \qquad K_b = 1.8 \times 10^{-5}$$



(a) (b)

▲ FIGURE 17-2
A mixture of a weak acid and its salt
Bromphenol blue indicator is present in both solutions. Its color dependence on pH is

$\text{pH} < 3.0 < \text{pH} < 4.6 < \text{pH}$
Yellow Green Blue-Violet

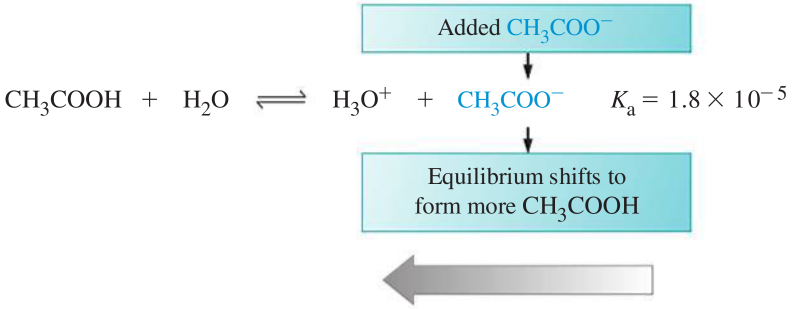
(a) 0.100 M CH_3COOH has a calculated pH of 2.89, but **(b)** if the solution is also 0.100 M in $NaCH_3COO$, the calculated pH is 4.74. (The readability of the pH meters used here is 0.1 unit, and their accuracy is probably somewhat less than that. The discrepancy between 4.74 and the 4.9 value shown here is a result of their limited accuracy.)

Solutions of Weak Acids and Their Salts

The salt of a weak acid is a strong electrolyte—its ions become completely dissociated from one another in aqueous solution. One of the ions, the *anion*, is an ion common to the ionization equilibrium of the weak acid. The presence of this common ion suppresses the ionization of the weak acid. For example, we can represent the effect of acetate salts on the acetic acid equilibrium as

When a salt supplies the common anion CH_3COO^-,
the equilibrium shifts to form more CH_3COOH.

$$NaCH_3COO(aq) \longrightarrow Na^+ + CH_3COO^-$$



$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^- \qquad K_a = 1.8 \times 10^{-5}$$

The common-ion effect of acetate ion on the ionization of acetic acid is depicted in Figure 17-2 and demonstrated in Example 17-2. In solving common-ion problems, such as Example 17-2, assume that ionization of the weak acid (or base) does not begin until both the weak acid (or base) and its salt have been placed in solution. Then consider that ionization occurs until equilibrium is reached.

▶ When concentrations of a weak acid and its conjugate base are the same, $K_a = [H_3O^+]$ and $\text{pH} = \text{p}K_a$.

EXAMPLE 17-2 Demonstrating the Common-Ion Effect: A Solution of a Weak Acid and a Salt of That Weak Acid

Calculate $[H_3O^+]$ and $[CH_3COO^-]$ in a solution that is 0.100 M in both CH_3COOH and $NaCH_3COO$.

Analyze

This example is very similar to Example 17-1; however, in this case we will be adding a salt of a weak acid and observing the shift in equilibrium. The setup shown here is very similar to that in Example 17-1(b), except that $NaCH_3COO$ is the source of the common ion. This is another illustration of Le Châtelier's principle.

Solve

Begin by setting up the ICE table.

	CH_3COOH	+	H_2O	$\rightleftharpoons$	H_3O^+	+	CH_3COO^-
initial concns:							
weak acid:	0.100 M				—		—
salt:	—				—		0.100 M
changes:	$-x$ M				$+x$ M		$+x$ M
equil concns:	$(0.100 - x)$ M				x M		$(0.100 + x)$ M

Because the salt suppresses the ionization of $HC_2H_3O_2$, we expect $[H_3O^+] = x$ to be very small and $0.100 - x \approx 0.100 + x \approx 0.100$. This proves to be a valid assumption.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{x \cdot (0.100 + x)}{0.100 - x} = \frac{x \cdot \cancel{0.100}}{\cancel{0.100}} = 1.8 \times 10^{-5}$$

$$x = [H_3O^+] = 1.8 \times 10^{-5}\text{ M} \qquad 0.100 + x = [CH_3COO^-] = 0.100\text{ M}$$

Assess

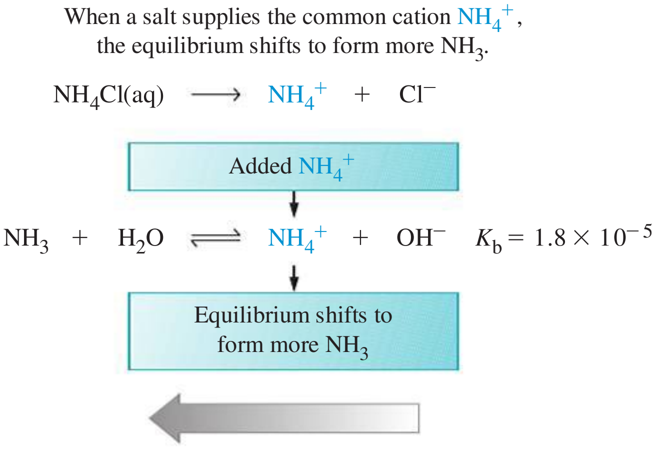
The ionization of CH_3COOH is reduced about 100-fold because of the salt that was added. The calculations we performed in this example are very similar to those we did in Example 17-1(b). An important difference, however, is that here we solved for $x = [H_3O^+]$. In Example 17-1(b), we solved for $x = [CH_3COO^-]$. Note that when the concentrations of a weak acid and its conjugate base are the same, $K_a = [H_3O^+]$ and $pH = pK_a$.

PRACTICE EXAMPLE A: Calculate $[H_3O^+]$ and $[HCOO^-]$ in a solution that is 0.100 M HCOOH and 0.150 M NaHCOO.

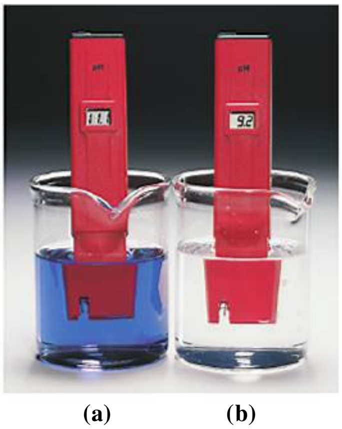
PRACTICE EXAMPLE B: What mass of $NaCH_3COO$ should be added to 1.00 L of 0.100 M CH_3COOH to produce a solution with pH = 5.00? Assume that the volume remains 1.00 L.

Solutions of Weak Bases and Their Salts

The common-ion effect of a salt of a weak base is similar to the weak acid–anion situation just described. The suppression of the ionization of NH_3 by the common *cation*, NH_4^+, is pictured in Figure 17-3 and represented as follows.



When a salt supplies the common cation NH_4^+, the equilibrium shifts to form more NH_3.
$NH_4Cl(aq) \longrightarrow NH_4^+ + Cl^-$
Added NH_4^+
$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad K_b = 1.8 \times 10^{-5}$
Equilibrium shifts to form more NH_3



(a) (b)

▲ FIGURE 17-3
A mixture of a weak base and its salt
Thymolphthalein indicator is blue if pH > 10 and colorless if pH < 10. **(a)** The pH of 0.100 M NH_3 is above 10 (calculated value: 11.11). **(b)** If the solution is also 0.100 M NH_4Cl, the pH drops below 10 (calculated value: 9.26). The ionization of NH_3 is suppressed in the presence of added NH_4^+. $[OH^-]$ decreases, $[H_3O^+]$ increases, and the pH is lowered.

17-1 CONCEPT ASSESSMENT

Without doing detailed calculations, determine which of the following will *raise* the pH when added to 1.00 L of 0.100 M $NH_3(aq)$: **(a)** 0.010 mol $NH_4Cl(s)$; **(b)** 0.010 mol $(CH_3CH_2)_2NH(l)$; **(c)** 0.010 mol HCl(g); **(d)** 1.00 L of 0.050 M $NH_3(aq)$; **(e)** 1.00 g $Ca(OH)_2(s)$. For NH_3, $pK_b = 4.74$; for $(CH_3CH_2)_2NH$, $pK_b = 3.16$.

17-2 Buffer Solutions

Figure 17-4 illustrates a statement made in the chapter introduction: Pure water has no buffer capacity. There are some aqueous solutions, however, called **buffer** (or buffered) **solutions**, whose pH values change only very slightly on the addition of small amounts of either an acid or a base.

What buffer solutions require are two components; one component is able to neutralize acids, and the other is able to neutralize bases. But the two components must not neutralize each other. This requirement rules out mixtures of a strong acid and a strong base. Instead, common buffer solutions are described as combinations of

▶ Recall the Brønsted–Lowry theory and the conjugate acid–base definitions.

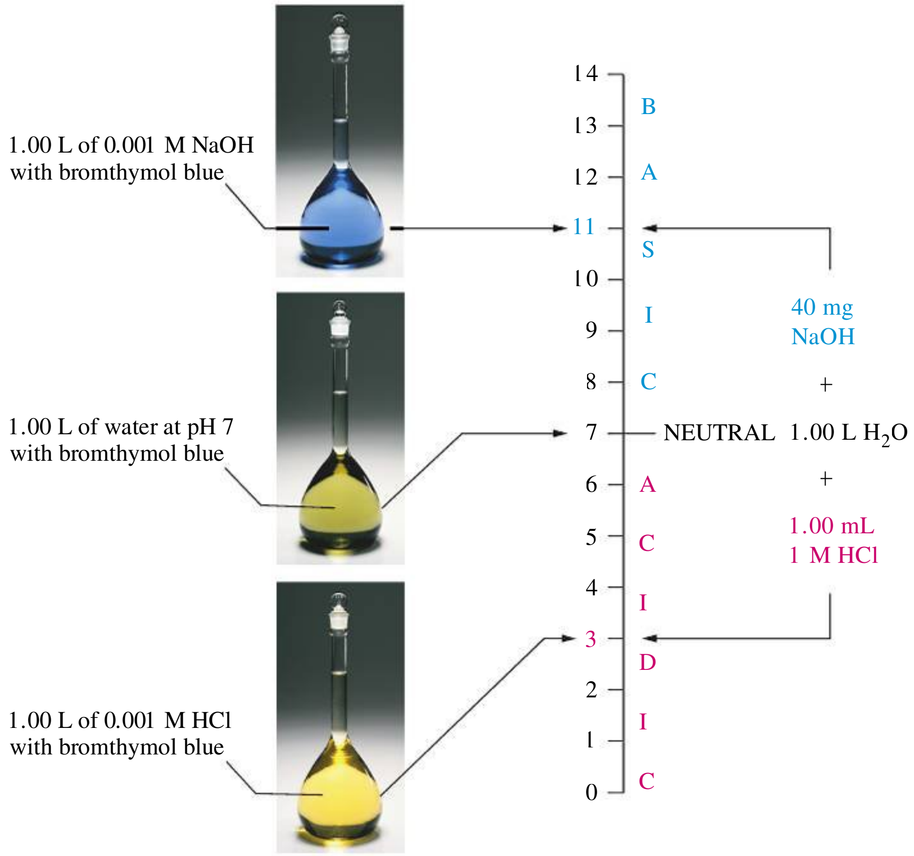
- a weak acid and its conjugate base, or
- a weak base and its conjugate acid

To show that such mixtures function as buffer solutions, let's consider a solution that has the equilibrium concentrations $[CH_3COOH] = [CH_3COO^-]$. As summarized in expression (17.1), in this solution $[H_3O^+] = K_a = 1.8 \times 10^{-5}$ M.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = 1.8 \times 10^{-5}$$

$$[H_3O^+] = K_a \times \frac{\cancel{[CH_3COOH]}}{\cancel{[CH_3COO^-]}} = 1.8 \times 10^{-5}\ \text{M} \qquad \textbf{(17.1)}$$

As a result, $\text{pH} = -\log[H_3O^+] = -\log K_a = -\log 1.8 \times 10^{-5} = 4.74$.



1.00 L of 0.001 M NaOH with bromthymol blue

40 mg NaOH
+
1.00 L H_2O
+
1.00 mL 1 M HCl

▶ FIGURE 17-4
Pure water has no buffering ability
Bromthymol blue indicator is blue at pH > 7, green at pH = 7, and yellow at pH < 7. Pure water has pH = 7.0. The addition of 0.001 mol H_3O^+ (1.00 mL of 1 M HCl) to 1.00 L water produces $[H_3O^+] =$ 0.001 M and pH = 3.0. The addition of 0.001 mol OH^- (40 mg NaOH) to 1.00 L of water produces $[OH^-] = 0.001$ M and pH = 11.0.

Now, imagine adding a *small* amount of a strong acid to this buffer solution. A reaction occurs in which a *small* amount of the base CH_3COO^- is converted to its conjugate acid CH_3COOH.

$$CH_3COO^- + H_3O^+ \longrightarrow CH_3COOH + H_2O$$

After the neutralization of the added H_3O^+, we find that in expression (17.1) $[CH_3COOH]$ has increased *slightly* and $[CH_3COO^-]$ has decreased *slightly*. The ratio $[CH_3COOH]/[CH_3COO^-]$ is only *slightly* greater than 1, and $[H_3O^+]$ has barely changed. The buffer solution has resisted a change in pH following the addition of a small amount of acid; the pH remains close to the original 4.74.

Next, imagine adding a *small* amount of a strong base to the original buffer solution with $[CH_3COOH] = [CH_3COO^-]$. A reaction occurs in which a *small* amount of the weak acid CH_3COOH is converted to its conjugate base CH_3COO^-.

$$CH_3COOH + OH^- \longrightarrow CH_3COO^- + H_2O$$

Here we find that $[CH_3COO^-]$ has increased *slightly*, and $[CH_3COOH]$ has decreased *slightly*. The ratio $[CH_3COOH]/[CH_3COO^-]$ is only *slightly* smaller than 1, and again $[H_3O^+]$ has barely changed. The buffer solution has resisted a change in pH following the addition of a small amount of base; again, the pH remains close to the original 4.74. The variation of the concentration of the weak acid and its conjugate base are illustrated in Figure 17-5.

Later in this section, we will be more specific about what constitutes *small* additions of an acid or a base and *slight* changes in the concentrations of the buffer components and pH. Also, we will discover that an acetic acid–sodium acetate buffer is good only for maintaining a nearly constant pH in a range of about 2 pH units centered on a $pH = pK_a = 4.74$. A buffer solution that maintains a nearly constant pH outside this range requires different buffer components, as suggested in Example 17-3.

We commonly need to calculate the pH of a buffer solution. At a minimum, such a calculation requires use of the ionization constant expression for a weak acid or weak base. Aspects of solution stoichiometry may also be required.

▲ FIGURE 17-5

How a buffer works

Acetate ion, the conjugate base of acetic acid, acts as a proton sink when strong acid is added. In this way, the ratio [conjugate base]/[acid] is kept approximately constant, so there is a minimal change in pH. Similarly, acetic acid acts as a proton donor when strong base is added, keeping the ratio [conjugate base]/[acid] approximately constant and minimizing the change in pH.

EXAMPLE 17-3 Predicting Whether a Solution Is a Buffer Solution

Show that an NH_3–NH_4Cl solution is a buffer solution. Over what pH range would you expect it to function?

Analyze

To show that a solution has buffer properties, first identify a component in the solution that neutralizes acids and a component that neutralizes bases.

Solve

In this example, these components are NH_3 and NH_4^+, respectively.

$$NH_3 + H_3O^+ \longrightarrow NH_4^+ + H_2O$$
$$NH_4^+ + OH^- \longrightarrow NH_3 + H_2O$$

In *all* aqueous solutions containing NH_3 and NH_4^+, we know that

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad \text{and}$$
$$K_b = \frac{[NH_4^+][OH^-]}{[NH_3]} = 1.8 \times 10^{-5}$$

If a solution has approximately equal concentrations of NH_4^+ and NH_3, then $[OH^-] \approx 1.8 \times 10^{-5}$ M; pOH ≈ 4.74; and pH ≈ 9.26. Ammonia–ammonium chloride solutions are *basic* buffer solutions that function over the approximate pH range of 8 to 10.

Assess

As we will soon see, not all NH_3–NH_4Cl buffer solutions will be effective buffers. The best buffers have large values for $[NH_3]$ and $[NH_4^+]$, with $[NH_3] \approx [NH_4^+]$.

PRACTICE EXAMPLE A: Describe how a mixture of a strong acid (such as HCl) and the salt of a weak acid (such as $NaCH_3COO$) can be a buffer solution. [*Hint:* What is the reaction that produces CH_3COOH?]

PRACTICE EXAMPLE B: Describe how a mixture of NH_3 and HCl can result in a buffer solution.

In Example 17-4, we first determine the stoichiometric concentrations of the buffer components. Then we perform an equilibrium calculation in the same fashion as in Examples 17-1 and 17-2.

EXAMPLE 17-4 Calculating the pH of a Buffer Solution

What is the pH of a buffer solution prepared by dissolving 25.5 g $NaCH_3COO$ in a sufficient volume of 0.550 M CH_3COOH to make 500.0 mL of the buffer?

Analyze

This example is very similar to Example 17-2. The difference is that we need to calculate the molarity of the acetate ion before solving the equilibrium part.

Solve

The molarity of CH_3COO^- corresponding to 25.5 g $NaCH_3COO$ in 500.0 mL of solution is calculated as follows.

$$\text{amount of } CH_3COO^- = 25.5 \text{ g } NaCH_3COO \times \frac{1 \text{ mol } NaCH_3COO}{82.04 \text{ g } NaCH_3COO}$$
$$\times \frac{1 \text{ mol } CH_3COO^-}{1 \text{ mol } NaCH_3COO}$$
$$= 0.311 \text{ mol } CH_3COO^-$$
$$[CH_3COO^-] = \frac{0.311 \text{ mol } CH_3COO^-}{0.500 \text{ L}} = 0.622 \text{ M } CH_3COO^-$$

Equilibrium Calculation:

	CH_3COOH	+	H_2O	$\rightleftharpoons$	H_3O^+	+	CH_3COO^-
initial concns:							
weak acid:	0.550 M				—		—
salt:	—				—		0.622 M
changes:	$-x$ M				$+x$ M		$+x$ M
equil concns:	$(0.550 - x)$ M				$+x$ M		$(0.622 + x)$ M

Let's assume that x is very small, so $0.550 - x \approx 0.550$ and $0.622 + x \approx 0.622$. We will find this assumption to be valid.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{(x)(0.622)}{0.550} = 1.8 \times 10^{-5}$$

$$x = [H_3O^+] = \frac{0.550}{0.622} \times 1.8 \times 10^{-5} = 1.6 \times 10^{-5}$$

$$\text{pH} = -\log[H_3O^+] = -\log(1.6 \times 10^{-5}) = 4.80$$

Notice that $x = 1.6 \times 10^{-5}$ is only 0.003% of 0.550, and so the assumption that x is small was justified.

Assess

We have seen that $\text{pH} = \text{p}K_a = 4.74$ when acetic acid and acetate ion are present in equal concentrations. Here the concentration of the conjugate *base* (acetate ion) is greater than that of the acetic acid. The solution should be somewhat more basic (less acidic) than $\text{pH} = 4.74$. A pH of 4.80 is a reasonable answer.

PRACTICE EXAMPLE A: What is the pH of a buffer solution prepared by dissolving 23.1 g NaHCOO in a sufficient volume of 0.432 M HCOOH to make 500.0 mL of the buffer?

PRACTICE EXAMPLE B: A handbook states that to prepare 100.0 mL of a particular buffer solution, mix 63.0 mL of 0.200 M CH_3COOH with 37.0 mL of 0.200 M $NaCH_3COO$. What is the pH of this buffer?

An important point worth noting in Example 17-4 is that if a solution is to be an effective buffer, the assumptions $(c - x) \approx c$ and $(c + x) \approx c$ will always be valid (c represents the numerical part of an expression of molarity). That is, the *equilibrium* concentrations of the buffer components will be very nearly the same as their *stoichiometric* concentrations. As a result, in Example 17-4 we could have gone directly from the stoichiometric concentrations of the buffer components to the expression

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = \frac{[H_3O^+](0.622)}{0.550} = 1.8 \times 10^{-5}$$

without setting up the ICE table. This procedure can be formalized through the special equation that is introduced next.

KEEP IN MIND

that stoichiometric concentration is based on the amount of solute dissolved.

An Equation for Buffer Solutions: The Henderson–Hasselbalch Equation

Although we can continue to use the format demonstrated in Example 17-4 for buffer calculations, it is often useful to describe a buffer solution by means of an equation known as the **Henderson–Hasselbalch equation**. Biochemists and molecular biologists commonly use this equation. To derive this variation of the ionization constant expression, let's consider a mixture of a hypothetical weak acid, HA (such as CH_3COOH), and its salt, NaA (such as $NaCH_3COO$). We start with the familiar expressions

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-$$

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

and rearrange the right side of the K_a expression to obtain

$$K_a = [H_3O^+] \times \frac{[A^-]}{[HA]}$$

Next, we take the *negative logarithm* of each side of this equation.

$$-\log K_a = -\log[H_3O^+] - \log\frac{[A^-]}{[HA]}$$

Now, recall that $pH = -\log[H_3O^+]$ and that $pK_a = -\log K_a$, which gives

$$pK_a = pH - \log\frac{[A^-]}{[HA]}$$

Solve for pH by rearranging the equation.

$$pH = pK_a + \log\frac{[A^-]}{[HA]}$$

A^- is the conjugate base of the weak acid HA, so we can write the more general equation (17.2), the Henderson–Hasselbalch equation.

$$pH = pK_a + \log\frac{[\text{conjugate base}]}{[\text{acid}]} \qquad \textbf{(17.2)}$$

▶ When the $[\text{conjugate base}] = [\text{acid}]$, then $pH = pK_a$. When we get to titrations, an indicator is chosen to change color at $pH = pK_a$ of the indicator.

KEEP IN MIND

that the Henderson–Hasselbalch equation is very useful but should probably not be committed to memory; it is easy to get the conjugate base and acid terms inverted. It is most important to understand the principles that lead to this equation, thereby avoiding the pitfalls of using the equation incorrectly or when it is not valid.

To apply this equation to an acetic acid–sodium acetate buffer, we use pK_a for CH_3COOH and these concentrations: $[CH_3COOH]$ for [acid] and $[CH_3COO^-]$ for [conjugate base]. To apply it to an ammonia–ammonium chloride buffer, we use pK_a for NH_4^+ and these concentrations: $[NH_4^+]$ for [acid] and $[NH_3]$ for [conjugate base].

Equation (17.2) is useful only when we can substitute *stoichiometric* or initial concentrations for equilibrium concentrations to give

$$pH = pK_a + \log\frac{[\text{conjugate base}]_{\text{initial}}}{[\text{acid}]_{\text{initial}}}$$

thus avoiding the need to set up an ICE table. This constraint places important limitations on the equation's validity, however. Later, we will see that there are also conditions that must be met if a mixture is to be an effective buffer solution. Although the following rules may be overly restrictive in some cases, a reasonable approach to the twin concerns of effective buffer action and the validity of equation (17.2) is to ensure that

1. the ratio [conjugate base]/[acid] is within the limits

$$0.10 < \frac{[\text{conjugate base}]}{[\text{acid}]} < 10 \qquad \textbf{(17.3)}$$

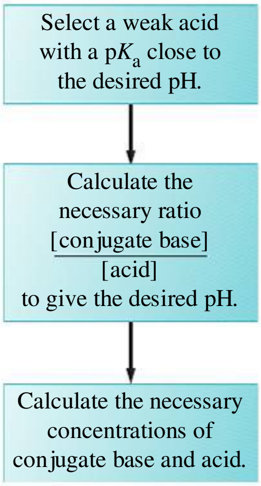
2. the molarity of each buffer component exceeds the value of K_a by a factor of at least 100

Viewed another way, equation (17.2) works only for cases in which the assumption $c - x \approx c$ is valid. If a quadratic equation is required to solve the equilibrium constant expression, equation (17.2) will likely fail.

Preparing Buffer Solutions

Suppose we need a buffer solution with $pH = 5.09$. Equation (17.2) suggests two alternatives. One is to find a weak acid, HA, that has $pK_a = 5.09$ and prepare a solution with equal molarities of the acid and its salt.

$$pH = pK_a + \log\frac{\cancel{[A^-]}}{\cancel{[HA]}} = 5.09 + \log 1 = 5.09$$



Select a weak acid with a pK_a close to the desired pH.
Calculate the necessary ratio $\frac{[\text{conjugate base}]}{[\text{acid}]}$ to give the desired pH.
Calculate the necessary concentrations of conjugate base and acid.

▲ One procedure to follow in making a buffer solution with a desired pH.

Although this alternative is simple in concept, generally, it is not practical. We are not likely to find a readily available, water-soluble weak acid with exactly $pK_a = 5.09$. The second alternative, summarized in the margin, is to use a cheap, common weak acid such as acetic acid, CH_3COOH ($pK_a = 4.74$), and establish an appropriate ratio of $[CH_3COO^-]/[CH_3COOH]$ to obtain a pH of 5.09. Example 17-5 demonstrates this second alternative.

EXAMPLE 17-5 Preparing a Buffer Solution of a Desired pH

What mass of $NaCH_3COO$ must be dissolved in 0.300 L of 0.25 M CH_3COOH to produce a solution with pH = 5.09? (Assume that the solution volume remains constant at 0.300 L.)

Analyze

Equilibrium among the buffer components is expressed by the equation

$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^- \qquad K_a = 1.8 \times 10^{-5}$$

and by the ionization constant expression for acetic acid.

$$K_a = \frac{[H_3O^+][CH_3COO^-]}{[CH_3COOH]} = 1.8 \times 10^{-5}$$

Each of the three concentration terms appearing in a K_a expression should be an equilibrium concentration. The $[H_3O^+]$ corresponding to a pH of 5.09 is the equilibrium concentration. For $[CH_3COOH]$, we will assume that the equilibrium concentration is equal to the stoichiometric or initial concentration. The value of $[CH_3COO^-]$ that we calculate with the K_a expression is the equilibrium concentration, and we will assume that it is also the same as the stoichiometric concentration. Thus, we assume that neither the ionization of CH_3COOH to form CH_3COO^- nor the hydrolysis of CH_3COO^- to form CH_3COOH produces much of a difference between the stoichiometric (initial) and equilibrium concentrations of the buffer components. These assumptions work well if the conditions stated in expression (17.3) are met.

Solve

The relevant concentration terms, then, are

$$\begin{aligned}[H_3O^+] &= 10^{-pH} = 10^{-5.09} = 8.1 \times 10^{-6}\ M\\ [CH_3COOH] &= 0.25\ M\\ [CH_3COO^-] &= ?\end{aligned}$$

The required acetate ion concentration in the buffer solution is

$$[CH_3COO^-] = K_a \times \frac{[CH_3COOH]}{[H_3O^+]} = 1.8 \times 10^{-5} \times \frac{0.25}{8.1 \times 10^{-6}} = 0.56\ M$$

We complete the calculation of the mass of sodium acetate with some familiar ideas of solution stoichiometry.

$$\text{mass} = 0.300\ L \times \frac{0.56\ mol\ CH_3COO^-}{1\ L} \times \frac{1\ mol\ NaCH_3COO}{1\ mol\ CH_3COO^-}$$
$$\times \frac{82.0\ g\ NaCH_3COO}{1\ mol\ NaCH_3COO} = 14\ g\ NaCH_3COO$$

Assess

We check the answer by inserting the acetate ion and acetic acid concentrations, along with the pK_a of acetic acid, into equation (17.2) to obtain pH = 5.09. The method described in Example 17-5 is one way to obtain a buffer solution. Another approach involves adding an appropriate amount of strong base (e.g., 0.052 mol NaOH) to 0.300 L of 0.025 M $CH_3COOH(aq)$.

PRACTICE EXAMPLE A: How many grams of $(NH_4)_2SO_4$ must be dissolved in 0.500 L of 0.35 M NH_3 to produce a solution with pH = 9.00? (Assume that the solution volume remains at 0.500 L.)

PRACTICE EXAMPLE B: In Practice Example 17-3A, we established that an appropriate mixture of a strong acid and the salt of a weak acid is a buffer solution. Show that a solution made by adding 33.05 g $NaCH_3COO \cdot 3\,H_2O(s)$ to 300 mL of 0.250 M HCl should have pH ≈ 5.1.

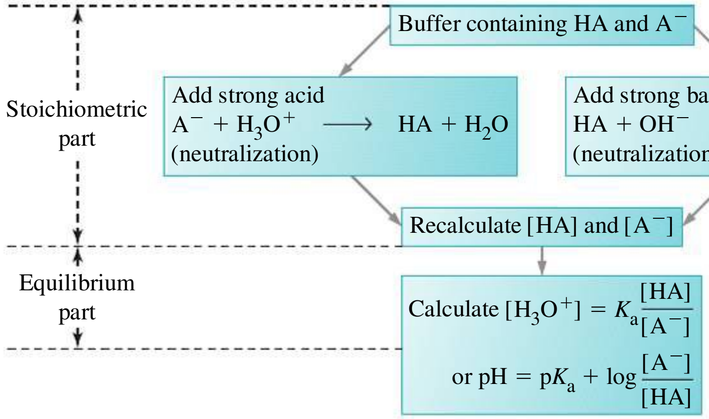
▲ FIGURE 17-6
Six methods for preparing buffer solutions
Depending on the pH range required and the type of experiment the buffer is to be used for, either a weak acid or a weak base can be used to prepare a buffer solution.

In Example 17-5, we achieved the desired ratio of $[CH_3COO^-]/[CH_3COOH]$ by adding 14 g of sodium acetate to the previously prepared 0.25 M CH_3COOH solution. This is a common method of obtaining a buffer solution. Other methods are sometimes useful as well. Sufficient NaOH(aq) could be added to $CH_3COOH(aq)$ to neutralize the acid partially, *producing* CH_3COO^- as a product. Or enough $NaCH_3COO(s)$ could be added to HCl(aq) to neutralize all the HCl, producing some CH_3COOH and leaving some CH_3COO^- in excess. As we saw in Chapter 16, amines are weak bases, so an aqueous mixture of an amine and its conjugate acid is a buffer solution. Buffer solutions based on amines can be prepared in ways analogous to those based on weak acids. The methods available for making buffer solutions are summarized in Figure 17-6.

Calculating pH Changes in Buffer Solutions

To calculate how the pH of a buffer solution changes when small amounts of a strong acid or base are added, we must first use *stoichiometric* principles to establish how much of one buffer component is consumed and how much of the other component is produced. Then the new concentrations of weak acid (or weak base) and its salt can be used to calculate the pH of the buffer solution. Essentially, this problem is solved in two steps. First, we assume that the neutralization reaction proceeds to *completion* and determine new stoichiometric concentrations. Then these new stoichiometric concentrations are substituted into the equilibrium constant expression and the expression is solved for $[H_3O^+]$, which is converted to pH. This method is applied in Example 17-6 and illustrated in Figure 17-7.



Stoichiometric part
Equilibrium part
Buffer containing HA and A$^-$
Add strong acid
$A^- + H_3O^+ \longrightarrow HA + H_2O$
(neutralization)
Add strong base
$HA + OH^- \longrightarrow A^- + H_2O$
(neutralization)
Recalculate [HA] and [A$^-$]
Calculate $[H_3O^+] = K_a\frac{[HA]}{[A^-]}$
or $pH = pK_a + \log\frac{[A^-]}{[HA]}$

▲ FIGURE 17-7
Calculation of the new pH of a buffer after strong acid or base is added
The stoichiometric and equilibrium parts of the calculation are indicated. This scheme can also be applied to the conjugate acid–base pair BH^+/B, where B is a base.

EXAMPLE 17-6 Calculating pH Changes in a Buffer Solution

What are the effects on the pH of adding **(a)** 0.0060 mol HCl and **(b)** 0.0060 mol NaOH to 0.300 L of a buffer solution that is 0.250 M CH_3COOH and 0.560 M $NaCH_3COO$?

Analyze

In parts (a) and (b) we complete essentially the same calculations. We should recognize that we are adding a strong acid or a strong base to the buffer solution. To investigate this effect we make a stoichiometric calculation, followed by an equilibrium calculation. The stoichiometric calculation is necessary to account for the neutralization of the base or acid components of the buffer.

Solve

To judge the effect of adding either (a) acid or (b) base on the pH of the buffer, the value we must keep in mind is the pH of the original buffer. Because the initial (or stoichiometric) concentrations of CH_3COOH and CH_3COO^- are large and not too different, the initial pH of the buffer can be obtained by substituting the initial concentrations into equation (17.2). (See the discussion following equation (17.2) on page 754.)

$$pH = pK_a + \log\frac{[CH_3COO^-]}{[CH_3COOH]}$$

$$= 4.74 + \log\frac{0.560}{0.250} = 4.74 + 0.35 = 5.09$$

(a) **Stoichiometric Calculation:** Let's calculate amounts in moles, and assume that the neutralization goes to completion. Essentially, this is a limiting reactant calculation, but perhaps simpler than many of those in Chapter 4. In neutralizing the added H_3O^+, 0.0060 mol CH_3COO^- is converted to 0.0060 mol CH_3COOH.

$$\begin{array}{lcccccccc}
 & \mathbf{CH_3COO^-} & + & \mathbf{H_3O^+} & \longrightarrow & \mathbf{CH_3COOH} & + & \mathbf{H_2O} \\
\text{original buffer:} & \underbrace{0.300\text{ L} \times 0.560\text{ M}}_{0.168\text{ mol}} & & & & \underbrace{0.300\text{ L} \times 0.250\text{ M}}_{0.0750\text{ mol}} & & \\
\text{add:} & & & 0.0060\text{ mol} & & & & \\
\text{changes:} & -0.0060\text{ mol} & & -0.0060\text{ mol} & & +0.0060\text{ mol} & & \\
\text{final buffer:} & & & & & & & \\
\quad\text{amounts:} & 0.162\text{ mol} & & \approx 0 & & 0.0810\text{ mol} & & \\
\quad\text{concns:} & \underbrace{0.162\text{ mol}/0.300\text{ L}}_{0.540\text{ M}} & & \approx 0 & & \underbrace{0.0810\text{ mol}/0.300\text{ L}}_{0.270\text{ M}} & &
\end{array}$$

(continued)

Equilibrium Calculation: We can calculate the pH with equation (17.2), using the new equilibrium concentrations.

$$\text{pH} = \text{p}K_a + \log\frac{[\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]}$$

$$= 4.74 + \log\frac{0.540}{0.270} = 4.74 + 0.30 = 5.04$$

(b) Stoichiometric Calculation: In neutralizing the added OH^-, 0.0060 mol CH_3COOH is converted to 0.0060 mol CH_3COO^-. The calculation of the new stoichiometric concentrations is shown on the last line of the following table.

	CH_3COOH	+	OH^-	$\longrightarrow$	CH_3COO^-	+	H_2O
original buffer:	$\underbrace{0.300\text{ L} \times 0.250\text{ M}}_{0.0750\text{ mol}}$				$\underbrace{0.300\text{ L} \times 0.560\text{ M}}_{0.168\text{ mol}}$		
add:			0.0060 mol				
changes:	−0.0060 mol		−0.0060 mol		+0.0060 mol		
final buffer:							
amounts:	0.0690 mol		≈0		0.174 mol		
concns:	$\underbrace{0.0690\text{ mol}/0.300\text{ L}}_{0.230\text{ M}}$		≈0		$\underbrace{0.174\text{ mol}/0.300\text{ L}}_{0.580\text{ M}}$		

Equilibrium Calculation: This is the same type of calculation as in part (a), but with slightly different concentrations.

$$\text{pH} = 4.74 + \log\frac{0.580}{0.230} = 4.74 + 0.40 = 5.14$$

Assess

The addition of 0.0060 mol HCl *lowers* the pH from 5.09 to 5.04, which is only a small change in pH. The addition of 0.0060 mol OH^- *raises* the pH from 5.09 to 5.14—another small change. Had we instead added 0.0060 mol HCl or 0.0060 mol NaOH to 0.300 L of water, the pH would have changed by more than 5 pH units. The most important factors to confirm in a calculation of this type are that the magnitude of the pH change is small and that the change occurs in the correct direction: *lowering* of the pH by an acid and *raising* of the pH by a base. The results are indeed reasonable.

PRACTICE EXAMPLE A: A 1.00 L volume of buffer is made with concentrations of 0.350 M NaHCOO (sodium formate) and 0.550 M HCOOH (formic acid). **(a)** What is the initial pH? **(b)** What is the pH after the addition of 0.0050 mol HCl(aq)? (Assume that the volume remains 1.00 L.) **(c)** What would be the pH after the addition of 0.0050 mol NaOH to the original buffer?

PRACTICE EXAMPLE B: How many milliliters of 6.0 M HNO_3 would you add to 300.0 mL of the buffer solution of Example 17-6 to change the pH from 5.09 to 5.03?

▶ Dilute and concentrated buffers will have the same pH, but as mentioned in the next section, a given volume of a dilute buffer will have a lower buffer capacity than the same volume of a more concentrated buffer.

Perhaps you have already noticed a way to simplify the calculation in Example 17-6. Because the buffer components are always present in the same solution of volume V, the numbers of moles can be substituted directly into equation (17.2) without regard for the particular value of V. Thus, in Example 17-6(b),

$$\text{pH} = 4.74 + \log\frac{[\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = 4.74 + \log\frac{0.174\ \cancel{\text{mol}/V}}{0.0690\ \cancel{\text{mol}/V}} = 4.74 + 0.40 = 5.14$$

This expression is also consistent with the observation that, on dilution, buffer solutions resist pH changes. Diluting a buffer solution means increasing its volume V by adding water. This action produces the same change in the numerator and the denominator of the ratio [conjugate base]/[acid]. The ratio itself remains unchanged, as does the pH.

Buffer Capacity and Buffer Range

It is not difficult to see that if we add more than 0.0750 mol OH^- to the buffer solution described in Example 17-6, the 0.0750 mol CH_3COOH will be completely converted to 0.0750 mol CH_3COO^-. An excess of OH^- will remain, and the solution will become rather strongly basic.

◀ Our eyes can see an indicator color change over a range of about 2 pH units.

Buffer capacity refers to the amount of acid or base that a buffer can neutralize before its pH changes appreciably. In general, the maximum buffer capacity exists when the concentrations of a weak acid and its conjugate base are kept *large* and *approximately equal to each other*. The **buffer range** is the pH range over which a buffer effectively neutralizes added acids and bases and maintains a fairly constant pH. As equation (17.2) suggests,

KEEP IN MIND

that as a rule of thumb, the amounts of the buffer components should be at least ten times as great as the amount of acid or base to be neutralized.

$$\mathrm{pH} = \mathrm{p}K_\mathrm{a} + \log\frac{[\text{conjugate base}]}{[\text{acid}]}$$

when the ratio $[\text{conjugate base}]/[\text{acid}] = 1$, $\mathrm{pH} = \mathrm{p}K_\mathrm{a}$. When the ratio falls to 0.10, the pH *decreases* by 1 pH unit from $\mathrm{p}K_\mathrm{a}$ because $\log 0.10 = -1$. If the ratio increases to a value of 10, the pH *increases* by 1 unit because $\log 10 = 1$. For practical purposes, this range of 2 pH units is the maximum range to which a buffer solution should be exposed. For acetic acid–sodium acetate buffers, the effective range is about pH 3.7–5.7; for ammonia–ammonium chloride buffers, it is about pH 8.3–10.3.

◀ The buffer range for the ammonia–ammonium chloride solution is based on the $\mathrm{p}K_\mathrm{a}$ of NH_4^+, 9.26.

Applications of Buffer Solutions

An important example of a buffered system is that found in blood, which must be maintained at a pH of 7.4 in humans. We will consider the buffering of blood in the Focus On feature for this chapter on the MasteringChemistry website. But buffers have other important applications, too.

Protein studies often must be performed in buffered media because the structures of protein molecules, including the magnitude and kind of electric charges they carry, depend on the pH (see Section 28-4). The typical enzyme is a protein capable of catalyzing a biochemical reaction, so enzyme activity is closely linked to protein structure and hence to pH. Most enzymes in the body have their maximum activity between pH 6 and pH 8. Studying enzyme activity in the laboratory usually means working with media buffered in this pH range.

The control of pH is often important in industrial processes. For example, in the mashing of barley malt, the first step of making beer, the pH of the solution must be maintained at 5.0 to 5.2, so that the protease and peptidase enzymes can hydrolyze the proteins from the barley. The inventor of the pH scale, Søren Sørensen, was a research scientist in a brewery.

We will consider the importance of buffer solutions in solubility/precipitation processes in Chapter 18.

▲ A master brewer inspecting wort temperature and pH in the making of beer.

17-2 CONCEPT ASSESSMENT

You are asked to make a buffer with a pH value close to 4 that would best resist an increase in pH. You can select one of the following acid–conjugate base pairs: acetic acid–acetate, $K_\mathrm{a} = 1.8 \times 10^{-5}$; ammonium ion–ammonia, $K_\mathrm{a} = 5.6 \times 10^{-10}$; or benzoic acid–benzoate, $K_\mathrm{a} = 6.3 \times 10^{-5}$; and you can mix them in the following acid–conjugate base ratios: 1:1, 2:1, or 1:2. What combination would make the best buffer?

17-3 Acid–Base Indicators

An **acid–base indicator** is a substance whose color depends on the pH of the solution to which it is added. Several of the photographs in this and the preceding chapter have shown acid–base indicators in use. The indicator chosen

◀ Two of the most important biological buffers are the phosphate and bicarbonate buffer systems. Proteins and nucleotides also function as buffers on the cellular level.

depended on just how acidic or basic the solution was. In this section, we will consider how an acid–base indicator works and how an appropriate indicator is selected for a pH measurement.

Acid–base indicators exist in two forms: (1) a weak acid, represented symbolically as HIn and having one color, and (2) its conjugate base, represented as In^- and having a different color. When just a small amount of indicator is added to a solution, the indicator does not affect the pH of the solution. Instead, the ionization equilibrium of the indicator is itself affected by the prevailing $[H_3O^+]$ in solution.

$$\underset{\text{Acid color}}{\mathrm{HIn}} + \mathrm{H_2O} \rightleftharpoons \mathrm{H_3O^+} + \underset{\text{Base color}}{\mathrm{In^-}}$$

From Le Châtelier's principle, we see that *increasing* $[H_3O^+]$ in a solution displaces the equilibrium to the left, increasing the proportion of HIn and hence the acid color. *Decreasing* $[H_3O^+]$ in a solution displaces the equilibrium to the right, increasing the proportion of In^- and hence the base color. The color of the solution depends on the relative proportions of the acid and base. The pH of the solution can be related to these relative proportions and to the pK_a of the indicator by means of an equation similar to equation (17.2).

$$\mathrm{pH} = \mathrm{p}K_{\mathrm{HIn}} + \log\frac{[\mathrm{In}^-]}{[\mathrm{HIn}]} \qquad \textbf{(17.4)}$$

▶ The acid "color" of a few indicators is colorless.

In general, if 90% or more of an indicator is in the form HIn, the solution will take on the acid color. If 90% or more is in the form In^-, the solution takes on the base (or anion) color. If the concentrations of HIn and In^- are about equal, the indicator is in the process of changing from one form to the other and has an intermediate color. The complete change in color occurs over a range of about 2 *pH units*, with $\mathrm{pH} = \mathrm{p}K_{\mathrm{HIn}}$ at about the middle of the range. The colors and pH ranges of several acid–base indicators are shown in Figure 17-8. A summary of these ideas is presented in Table 17.1, and an example of their use is given below.

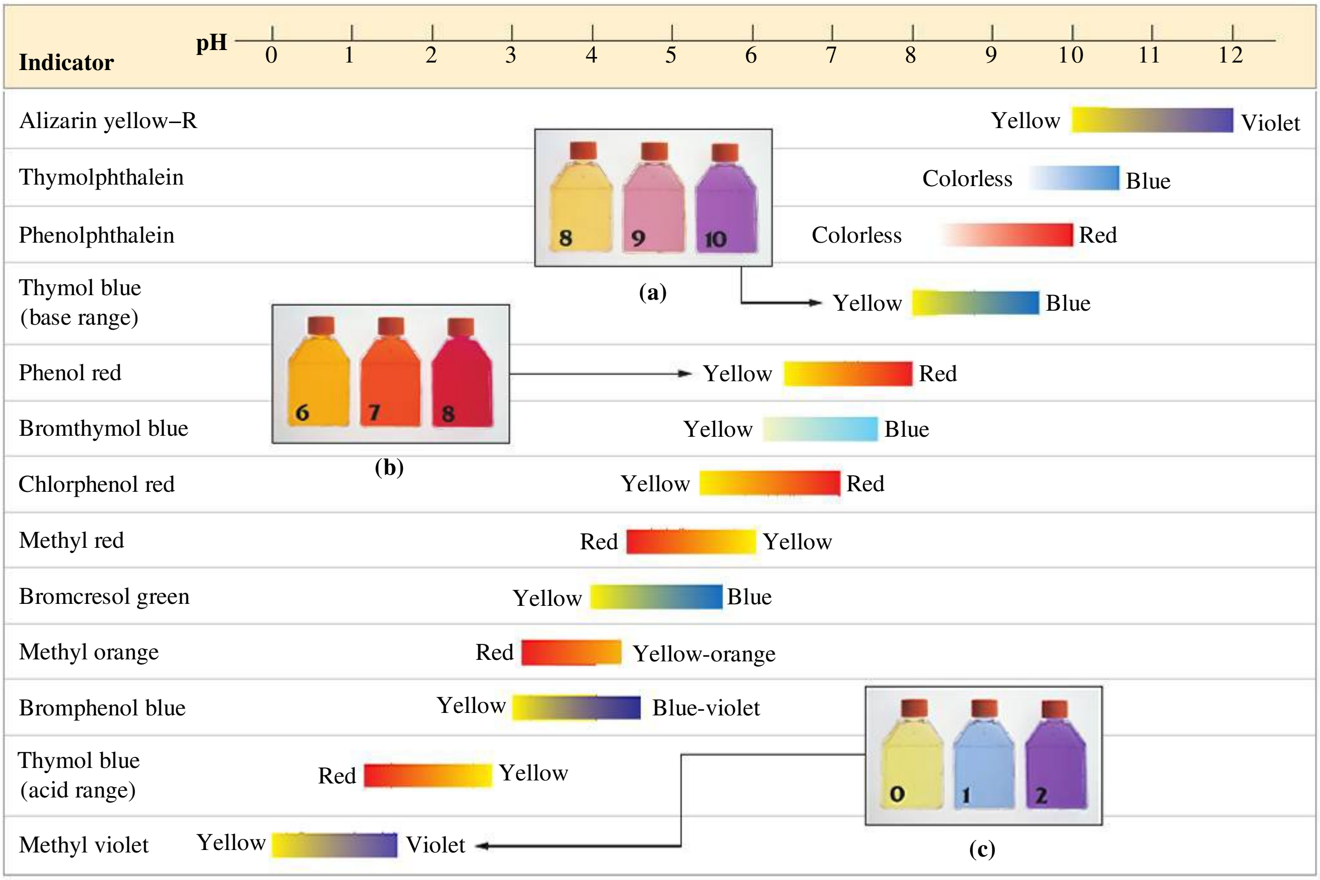
Bromthymol blue, $\mathrm{p}K_{\mathrm{HIn}} = 7.1$

$\mathrm{pH} < 6.1$ (yellow) $\mathrm{pH} \approx 7.1$ (green) $\mathrm{pH} > 8.1$ (blue)

An acid–base indicator is usually prepared as a solution (in water, ethanol, or some other solvent). In acid–base titrations, a few drops of the indicator solution are added to the solution being titrated. In other applications, porous paper is impregnated with an indicator solution and dried. When this paper is moistened with the solution being tested, it acquires a color determined by the pH of the solution. This paper is usually called *pH test paper*.

TABLE 17.1 pH and the Colors of Acid–Base Indicators

Acid Color	Intermediate Color	Base Color
$[\mathrm{In}^-]/[\mathrm{HIn}] < 0.10$ $\mathrm{pH} < \mathrm{p}K_{\mathrm{HIn}} + \log 0.10$ $\mathrm{pH} < \mathrm{p}K_{\mathrm{HIn}} - 1$	$[\mathrm{In}^-]/[\mathrm{HIn}] \approx 1$ $\mathrm{pH} \approx \mathrm{p}K_{\mathrm{HIn}} + \log 1$ $\mathrm{pH} \approx \mathrm{p}K_{\mathrm{HIn}}$	$[\mathrm{In}^-]/[\mathrm{HIn}] > 10$ $\mathrm{pH} > \mathrm{p}K_{\mathrm{HIn}} + \log 10$ $\mathrm{pH} > \mathrm{p}K_{\mathrm{HIn}} + 1$



▲ FIGURE 17-8
pH and color changes for some common acid–base indicators
The indicators pictured and the pH values at which they change color are **(a)** thymol blue (pH 8–10); **(b)** phenol red (pH 6–8); and **(c)** methyl violet (pH 0–2).

17-3 CONCEPT ASSESSMENT

(1) Given that an indicator is itself a weak acid or base, why does adding it to a solution not change the nature of the equilibrium?

(2) Starting with about 10 mL of dilute NaCl(aq) containing a couple of drops of phenol red indicator, what color would the solution be for each of the following actions: **(a)** first 10 drops of 1.0 M HCl(aq) are added to the solution; **(b)** next 15 drops of 1.0 M $NaCH_3COO$(aq) are added to solution **(a)**; **(c)** then one drop of 1.0 M KOH(aq) is added to solution **(b)**; and **(d)** 10 more drops of 1.0 M KOH(aq) are added to solution **(c)**.

Applications

Acid–base indicators are most useful when only an approximate pH determination is needed. For example, they are used in soil-testing kits to establish the approximate pH of soils. Soils are usually acidic in regions of high rainfall and heavy vegetation, and they are alkaline in more arid regions. The pH can vary considerably with local conditions, however. If a soil is found to be too acidic for a certain crop, its pH can be raised by adding slaked lime $[Ca(OH)_2]$. To reduce the pH of a soil, organic matter might be added.

In swimming pools, chlorinating agents are most effective at a pH of about 7.4. At this pH, the growth of algae is avoided, and the corrosion of pool plumbing is minimized. Phenol red (see Figure 17-8) is a common indicator

▲ Testing swimming pool water for its chlorine content and pH.

used in testing swimming pool water. If chlorination is carried out with $Cl_2(g)$, the pool water becomes acidic as a result of the reaction of Cl_2 with H_2O: $Cl_2 + 2\,H_2O \longrightarrow H_3O^+ + Cl^- + HOCl$. In this case, a basic substance, such as sodium carbonate, is used to raise the pH. Another widely used chlorinating agent is sodium hypochlorite, $NaOCl(aq)$, made by the reaction of $Cl_2(g)$ with excess $NaOH(aq)$: $Cl_2 + 2\,OH^- \longrightarrow Cl^- + OCl^- + H_2O$. The excess NaOH raises the pH of the pool water. The pH is adjusted by adding an acid, such as HCl or H_2SO_4.

17-4 Neutralization Reactions and Titration Curves

As we learned in the discussion of the stoichiometry of titration reactions (Section 5-7), the **equivalence point** of a neutralization reaction is the point at which both acid and base have been consumed and *neither* is in excess.

In a titration, one of the solutions to be neutralized—say, the acid—is placed in a flask or beaker, together with a few drops of an acid–base indicator. The other solution (the base) used in a titration is added from a buret and is called the **titrant**. The titrant is added to the acid, first rapidly and then drop by drop, up to the equivalence point (recall Figure 5-17). The equivalence point is located by noting the color change of the acid–base indicator. The point in a titration at which the indicator changes color is called the **end point** of the indicator. The end point must match the equivalence point of the neutralization. That is, if the indicator's end point is near the equivalence point of the neutralization, the color change marked by that end point will signal the attainment of the equivalence point. This match can be achieved by use of an indicator whose color change occurs over a pH range that includes the pH of the equivalence point.

A graph of pH versus volume of titrant (the solution in the buret) is called a **titration curve**. Titration curves are most easily constructed by measuring the pH during a titration with a pH meter and plotting the data with a recorder. In this section we will emphasize calculating the pH at various points in a titration. These calculations will serve as a review of aspects of acid–base equilibria considered earlier in this chapter and in the preceding chapter.

The Millimole

In a typical titration, the volume of solution delivered from a buret is less than 50 mL (usually about 20–25 mL). The molarity of the solution used for the titration is generally less than 1 M. The typical amount of OH^- (or H_3O^+) delivered from the buret during a titration is only a few thousandths of a mole—for example, 5.00×10^{-3} mol. In calculations it is often easier to work with millimoles instead of moles. The symbol **mmol** stands for a **millimole**, which is one thousandth of a mole, or 10^{-3} mol.

Recall from Chapter 4 that molarity is defined as the number of moles per liter. We can use an alternative definition of molarity by converting from moles to millimoles and from liters to milliliters.

$$\text{M} = \frac{\text{mol}}{\text{L}} = \frac{\text{mol}/1000}{\text{L}/1000} = \frac{\text{mmol}}{\text{mL}}$$

Thus, the expression from Chapter 4 that the amount of solute is the product of molarity and solution volume (page 126) can be based either on $\text{mol/L} \times \text{L} = \text{mol}$ or on $\text{mmol/mL} \times \text{mL} = \text{mmol}$.

Titration of a Strong Acid with a Strong Base

Suppose that 25.00 mL of 0.100 M HCl (a strong acid) is placed in a small flask or beaker and that 0.100 M NaOH (a strong base) is added to it from a buret.

The pH of the accumulated solution can be calculated at different points in the titration, and these pH values can be plotted against the volume of NaOH added. From this titration curve we can establish the pH at the equivalence point and identify an appropriate indicator for the titration. Some typical calculations are outlined in Example 17-7.

EXAMPLE 17-7 Calculating Points on a Titration Curve: Strong Acid Titrated with a Strong Base

What is the pH at each of the following points in the titration of 25.00 mL of 0.100 M HCl with 0.100 M NaOH?

(a) before the addition of any NaOH (*initial pH*)

(b) after the addition of 24.00 mL 0.100 M NaOH (*before the equivalence point*)

(c) after the addition of 25.00 mL 0.100 M NaOH (*the equivalence point*)

(d) after the addition of 26.00 mL 0.100 M NaOH (*beyond the equivalence point*)

Analyze

Parts (a) to (d) correspond to four different stages of the titration. In part (a) we calculate the initial pH of the HCl solution before the titration begins. In part (b) most but not all the acid has been neutralized. In part (c) all the acid is neutralized, which corresponds to the equivalence point. In part (d) we are past the equivalence point and are dealing with a solution containing an unreacted strong base.

Solve

First, let's write the titration equation in the ionic and net ionic form.

Ionic form: $H_3O^+(aq) + Cl^-(aq) + Na^+(aq) + OH^-(aq) \longrightarrow Na^+(aq) + Cl^-(aq) + 2\,H_2O(l)$

Net ionic form: $H_3O^+(aq) + OH^-(aq) \longrightarrow 2\,H_2O(l)$

(a) Before any NaOH is added, we are dealing with 0.100 M HCl. This solution has $[H_3O^+] = 0.100$ M and pH = 1.00.

(b) The number of millimoles of H_3O^+ to be titrated is

$$25.00\text{ mL} \times \frac{0.100\text{ mmol } H_3O^+}{1\text{ mL}} = 2.50\text{ mmol } H_3O^+$$

The number of millimoles of OH^- present in 24.00 mL of 0.100 M NaOH is

$$24.00\text{ mL} \times \frac{0.100\text{ mmol}}{1\text{ mL}} = 2.40\text{ mmol } OH^-$$

Now we can represent the net ionic equation of the neutralization reaction in a familiar format.

	H_3O^+	+	OH^-	$\longrightarrow$	$2\,H_2O$
initially present:	2.50 mmol		—		
add:			2.40 mmol		
changes:	−2.40 mmol		−2.40 mmol		
after reaction:	0.10 mmol		≈0		

The remaining 0.10 mmol of H_3O^+ is present in 49.00 mL of solution (25.00 mL original + 24.00 mL added base).

$$[H_3O^+] = \frac{0.10\text{ mmol } H_3O^+}{49.00\text{ mL}} = 2.0 \times 10^{-3}\text{ M}$$

$$\text{pH} = -\log[H_3O^+] = -\log(2.0 \times 10^{-3}) = 2.70$$

(c) The equivalence point is the point at which the HCl is completely neutralized and no excess NaOH is present. As seen in the ionic form of the equation for the neutralization reaction, the solution at the equivalence point is simply NaCl(aq). And, as we learned in Section 16-7, because neither Na^+ nor Cl^- hydrolyzes in water, pH = 7.00.

(continued)

(d) To determine the pH of the solution beyond the equivalence point, we can return to the format in (b), except that now OH^- is in excess. The amount of OH^- added is 26.00 mL × 0.100 mmol/L = 2.60 mmol.

	H_3O^+	+	OH^-	$\longrightarrow$	$2\ H_2O$
initially present:	2.50 mmol		—		
add:			2.60 mmol		
changes:	−2.50 mmol		−2.50 mmol		
after reaction:	≈0		0.10 mmol		

The excess 0.10 mmol of NaOH is present in 51.00 mL of solution (25.00 mL original acid + 26.00 mL added base). The concentration of OH^- in this solution is

$$[OH^-] = \frac{0.10\ \text{mmol}\ OH^-}{51.00\ \text{mL}} = 2.0 \times 10^{-3}\ \text{M}$$

$$\text{pOH} = -\log(2.0 \times 10^{-3}) = 2.70 \qquad \text{pH} = 14.00 - 2.70 = 11.30$$

Assess

In strong acid–strong base titrations, changes in pH are abrupt and occur mostly right before and right after the equivalence point. For a strong acid–strong base titration, the pH at the equivalence point is equal to 7.

PRACTICE EXAMPLE A: For the titration of 25.00 mL of 0.150 M HCl with 0.250 M NaOH, calculate **(a)** the initial pH; **(b)** the pH when neutralization is 50.0% complete; **(c)** the pH when neutralization is 100.0% complete; and **(d)** the pH when 1.00 mL of NaOH is added beyond the equivalence point.

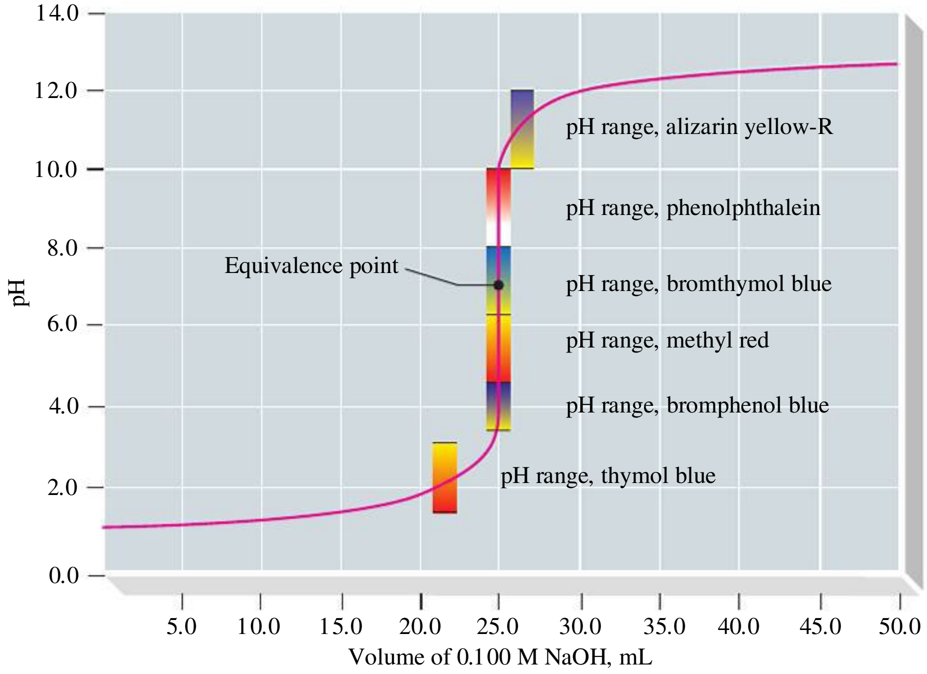
PRACTICE EXAMPLE B: For the titration of 50.00 mL of 0.00812 M Ba(OH) with 0.0250 M HCl, calculate **(a)** the initial pH; **(b)** the pH when neutralization is 50.0% complete; **(c)** the pH when neutralization is 100.0% complete.

Figure 17-9 presents pH versus volume data and the titration curve for the HCl—NaOH titration. From this figure, we can establish these principal features of the titration curve for the titration of a *strong acid with a strong base.*

- The pH has a low value at the beginning of the titration.
- The pH changes slowly until just before the equivalence point.

Titration Data

mL NaOH(aq)	pH
0.00	1.00
10.00	1.37
20.00	1.95
22.00	2.19
24.00	2.70
25.00	7.00
26.00	11.30
28.00	11.75
30.00	11.96
40.00	12.36
50.00	12.52



▶ FIGURE 17-9
Titration curve for the titration of a strong acid with a strong base—25.00 mL of 0.100 M HCl with 0.100 M NaOH
All indicators whose color ranges fall along the steep portion of the titration curve are suitable for this titration. Thymol blue changes color too soon; alizarin yellow-R, too late.

- At the equivalence point, the pH rises very sharply, perhaps by 6 units for an addition of only 0.10 mL (2 drops) of base.
- Beyond the equivalence point, the pH again rises only slowly.
- Any acid–base indicator whose color changes in the pH range from about 4 to 10 is suitable for this titration.

In the titration of a strong base with a strong acid, we can obtain a titration curve essentially identical to Figure 17-9 by plotting pOH against volume of titrant (the strong acid). Also, we can make a set of statements similar to those listed above, except that pOH would be substituted for pH. Alternatively, if pH is plotted against volume of titrant (the strong acid), the titration curve looks like Figure 17-9 flipped over from top to bottom, as shown in Figure 17-10.

Titration of a Weak Acid with a Strong Base

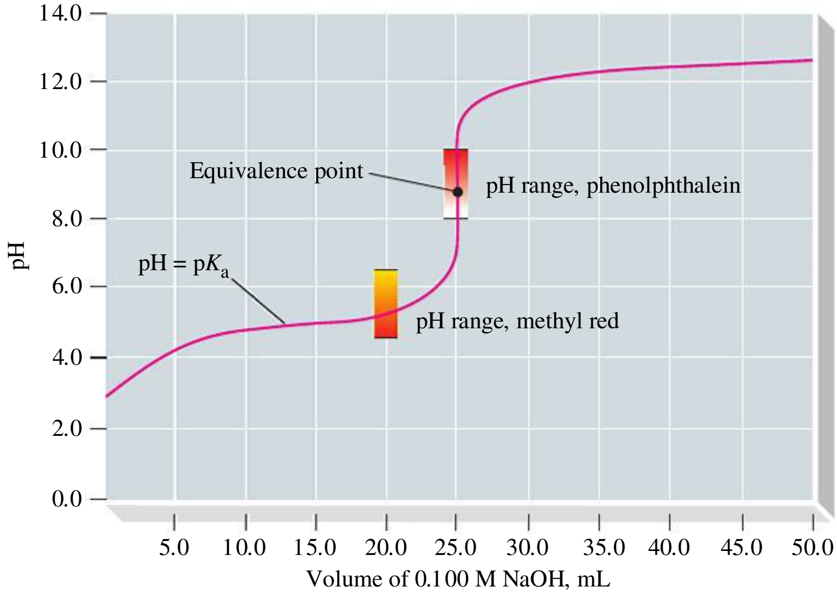
Several important differences exist between the titration of a weak acid with a strong base and a strong acid with a strong base, but one feature is *unchanged* when we compare the two titrations.

> For equal volumes of acid solutions of the same molarity, the volume of base required to titrate to the equivalence point is independent of the strength of the acid.

We can think of the neutralization of a weak acid, such as CH_3COOH as involving the direct transfer of protons from CH_3COOH molecules to OH^- ions. In the neutralization of a strong acid, the protons are transferred from H_3O^+ ions. In either case, the acid and base react in a 1 : 1 mole ratio.

$$CH_3COOH + OH^- \longrightarrow H_2O + CH_3COO^-$$
$$H_3O^+ + OH^- \longrightarrow H_2O + H_2O$$

Calculations for the titration of a weak acid with a strong base can be divided into a stoichiometric part and an equilibrium part to take into account the partial ionization of the weak acid. The calculation strategy is analogous to that adopted when we considered the addition of a strong base to a buffer solution. In Example 17-8 and in Figure 17-11, we consider the titration of 25.00 mL of 0.100 M CH_3COOH with 0.100 M NaOH.



◀ FIGURE 17-11
Titration curve for the titration of a weak acid with a strong base—25.00 mL of 0.100 M CH_3COOH with 0.100 M NaOH
Phenolphthalein is a suitable indicator for this titration, but methyl red is not. When exactly half of the acid is neutralized, $[CH_3COOH] = [CH_3COO^-]$ and pH = pK_a 4.74.

EXAMPLE 17-8 Calculating Points on a Titration Curve: Weak Acid Titrated with a Strong Base

What is the pH at each of the following points in the titration of 25.00 mL of 0.100 M $HC_2H_3O_2$ with 0.100 M NaOH?

(a) before the addition of any NaOH (*initial pH*)
(b) after the addition of 10.00 mL 0.100 M NaOH (*before equivalence point*)
(c) after the addition of 12.50 mL 0.100 M NaOH (*half-neutralization*)
(d) after the addition of 25.00 mL 0.100 M NaOH (*equivalence point*)
(e) after the addition of 26.00 mL 0.100 M NaOH (*beyond equivalence point*)

Analyze

Titrations between weak acids and strong bases or strong acids and weak bases have four regions of interest. The first is the initial pH, which we calculate in the same way we would calculate the pH for a solution of a weak acid or weak base. The second is the buffer region; the third is the hydrolysis region; and the fourth is beyond the equivalence point.

Solve

(a) The initial $[H_3O^+]$ is obtained by the calculation in Example 16-6 (page 712). $pH = -\log(1.3 \times 10^{-3}) = 2.89$.

(b) The number of millimoles of CH_3COOH to be neutralized is

$$25.00\ \text{mL} \times \frac{0.100\ \text{mmol}\ CH_3COOH}{1\ \text{mL}} = 2.50\ \text{mmol}\ CH_3COOH$$

At this point in the titration, the number of millimoles of OH^- added is

$$10.00\ \text{mL} \times \frac{0.100\ \text{mmol}\ OH^-}{1\ \text{mL}} = 1.00\ \text{mmol}\ OH^-$$

The total solution volume = 25.00 mL original acid + 10.00 mL added base = 35.00 mL. We enter this information at appropriate points into the following setup.

Stoichiometric Calculation:

	CH_3COOH	+	OH^-	$\longrightarrow$	CH_3COO^-	+	H_2O
initially present:	2.50 mmol		—		—		
add:			1.00 mmol				
changes:	−1.00 mmol		−1.00 mmol		+1.00 mmol		
after reaction:							
mmol:	1.50 mmol				1.00 mmol		
concns:	1.50 mmol/35.00 mL		≈0		1.00 mmol/35.00 mL		
	0.0429 M				0.0286 M		

Equilibrium Calculation: The most direct approach is to recognize that the acetic acid–sodium acetate solution is a buffer solution whose pH can be calculated with the Henderson–Hasselbalch equation. Use of that equation is justified for two reasons: (1) The ratio: $[CH_3COO^-]/[CH_3COOH] = 0.0286/0.0429 = 0.667$ (satisfying the requirement on page 754 that it be between 0.10 and 10), and (2) CH_3COO^- and CH_3COOH exceed $K_a (1.8 \times 10^{-5})$ by the factors 1.6×10^3 and 2.4×10^3, respectively (satisfying the requirement on page 715 that the factor exceed 100). So

$$pH = pK_a + \log\frac{[A^-]}{[HA]} = 4.74 + \log\frac{0.0286}{0.0429} = 4.74 - 0.18 = 4.56$$

Simpler still would be to substitute the numbers of millimoles of CH_3COO^- and CH_3COOH directly into the Henderson–Hasselbalch equation, without converting to molarities. That is,

$$pH = pK_a + \log\frac{[A^-]}{[HA]}$$
$$= 4.74 + \log\frac{1.00\ \cancel{\text{mmol}/V}}{1.50\ \cancel{\text{mmol}/V}} = 4.74 - 0.18 = 4.56$$

(c) When we have added 12.50 mL of 0.100 M NaOH, we have added 12.50 × 0.100 = 1.25 mmol OH^-. As the following setup shows, this is enough base to neutralize exactly *half* of the acid.

	CH_3COOH	+	OH^-	$\longrightarrow$	CH_3COO^-	+	H_2O
initially present:	2.50 mmol		—		—		
add:			1.25 mmol				
changes:	−1.25 mmol		−1.25 mmol		+1.25 mmol		
after reaction:	1.25 mmol				1.25 mmol		

Again, applying the Henderson–Hasselbalch equation, we get

$$\begin{aligned} pH &= pK_a + \log\frac{[CH_3COO^-]}{[CH_3COOH]} \\ &= 4.74 + \log\frac{1.25\ \cancel{mmol/V}}{1.25\ \cancel{mmol/V}} = 4.74 + \log 1 = 4.74 \end{aligned}$$

(d) At the equivalence point, neutralization is complete and 2.50 mmol $NaCH_3COO$ has been produced in 50.00 mL of solution, leading to 0.0500 M $NaCH_3COO$ The question becomes, "What is the pH of 0.0500 M $NaCH_3COO$?" To answer this question, we must recognize that CH_3COO^- hydrolyzes (and Na^+ does not). The hydrolysis reaction and value of K_b are

$$CH_3COO^- + H_2O \rightleftharpoons CH_3COOH + OH^-$$

$$K_b = \frac{K_w}{K_a} = \frac{1.0 \times 10^{-14}}{1.8 \times 10^{-5}} = 5.6 \times 10^{-10}$$

With a format similar to that used in the hydrolysis calculation of Example 16-13 (page 726), we obtain the following expression, where $x = [OH^-]$ and $x \ll 0.0500$.

$$K_b = \frac{[CH_3COOH]}{[CH_3COO^-]} = \frac{x \cdot x}{0.0500 - x} = 5.6 \times 10^{-10}$$

$$x^2 = 2.8 \times 10^{-11} \qquad x = [OH^-] = 5.3 \times 10^{-6}\ M$$

$$pOH = -\log(5.3 \times 10^{-6}) = 5.28$$

$$pH = 14.00 - pOH = 14.00 - 5.28 = 8.72$$

(e) The amount of OH^- added is 26.00 mL × 0.100 mmol/mL = 2.60 mmol. The volume of solution is 25.00 mL acid + 26.00 mL base = 51.00 mL. The 2.60 mmol OH^- neutralizes the 2.50 mmol of available acid, and 0.10 mmol OH^- remains in *excess*. Beyond the equivalence point, the pH of the solution is determined by the excess strong base.

$$[OH^-] = \frac{0.10\ mmol\ OH^-}{51.00\ mL} = 2.0 \times 10^{-3}\ M$$

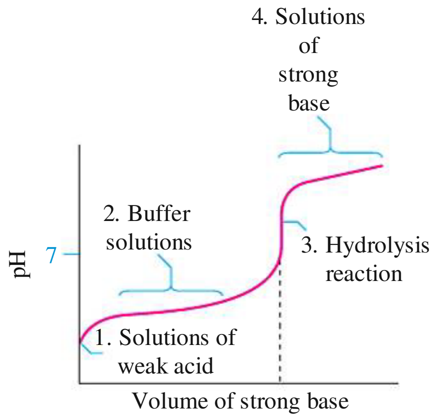
$$pOH = -\log(2.0 \times 10^{-3}) = 2.70 \qquad pH = 14.00 - 2.70 = 11.30$$

Assess

In this example the pH at the equivalence point is *not* 7 as it was in the strong acid–strong base problem. We could have predicted this result before performing a single calculation. At the equivalence point, the principal species in solution is CH_3COO^-, the conjugate base of a weak acid (CH_3COOH). Recalling that the conjugate of weak is weak, we conclude that CH_3COO^- is a weak base and thus, the pH at the equivalence point must be greater than 7.

PRACTICE EXAMPLE A: A 20.00 mL sample of 0.150 M HF solution is titrated with 0.250 M NaOH. Calculate **(a)** the initial pH and the pH when neutralization is **(b)** 25.0%, **(c)** 50.0%, **(d)** 100.0% complete. [*Hint*: What is the initial amount of HF, and what amount remains unneutralized at the points in question?]

PRACTICE EXAMPLE B: For the titration of 50.00 mL of 0.106 M NH_3 with 0.225 M HCl, calculate **(a)** the initial pH and the pH when neutralization is **(b)** 25.0% complete; **(c)** 50.0% complete; **(d)** 100.0% complete.



▶ FIGURE 17-12
Constructing the titration curve for a weak acid with a strong base
The calculations needed to plot this graph, illustrated in Example 17-8, can be divided into *four* types.

1. pH of a pure weak acid (initial pH)
2. pH of a buffer solution of a weak acid and its salt (over a broad range before the equivalence point)
3. pH of a salt solution undergoing hydrolysis (equivalence point)
4. pH of a solution of a strong base (over a broad range beyond the equivalence point)

Here are the principal features of the titration curve for a weak acid titrated with a strong base (Fig. 17-11).

- The initial pH is higher (less acidic) than in the titration of a strong acid. (The weak acid is only partially ionized.)
- There is an initial rather sharp increase in pH at the start of the titration. (The anion produced by the neutralization of the weak acid is a common ion that reduces the extent of ionization of the acid.)
- Over a long section of the curve preceding the equivalence point, the pH changes only gradually. (Solutions corresponding to this portion of the curve are buffer solutions.)
- Because $[\mathrm{HA}] = [\mathrm{A}^-]$ at the point of half-neutralization, $\mathrm{pH} = \mathrm{p}K_\mathrm{a}$.
- At the equivalence point, $\mathrm{pH} > 7$. (The conjugate base of a weak acid hydrolyzes, producing OH^-.)
- Beyond the equivalence point, the titration curve is identical to that of a strong acid with a strong base. (In this portion of the titration, the pH is established entirely by the concentration of unreacted OH^-.)
- The steep portion of the titration curve at the equivalence point occurs over a relatively short pH range (from about pH 7 to pH 10).
- The selection of indicators available for the titration is more limited than in a strong acid–strong base titration. (Indicators that change color below pH 7 cannot be used.)

As illustrated in Example 17-8 and suggested by Figure 17-12, the necessary calculations for a weak acid–strong base titration curve are of four distinct types, depending on the portion of the titration curve being described. One type of titration that generally cannot be performed successfully is that of a weak acid with a weak base (or vice versa). The equivalence point cannot be located precisely because the change in pH with volume of titrant is too gradual.

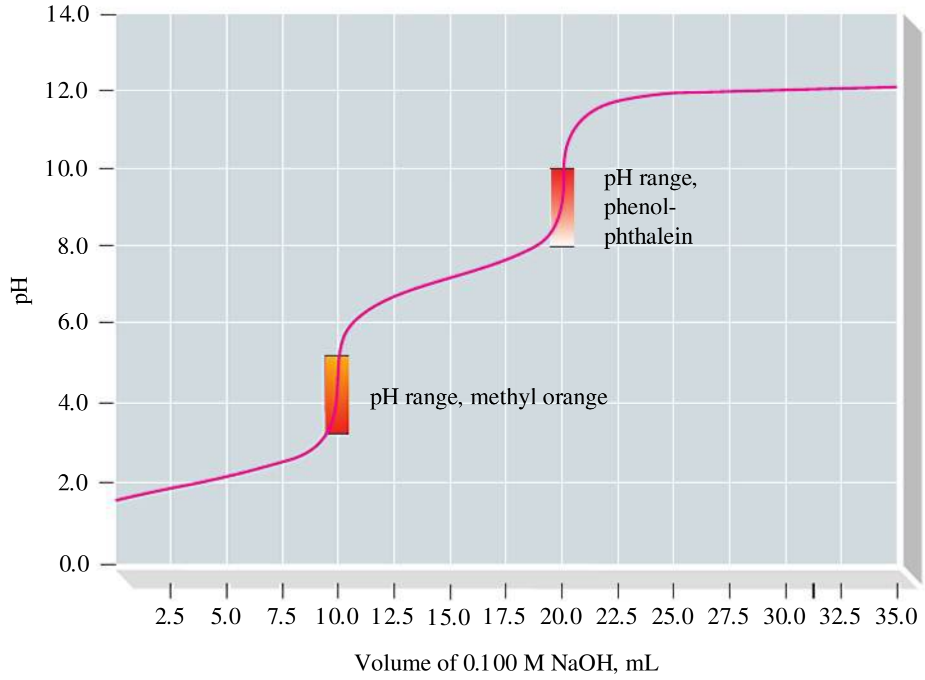
17-4 CONCEPT ASSESSMENT

To raise the pH of 1.00 L of 0.50 M HCl(aq) *significantly*, which of the following would you add to the solution and why? **(a)** 0.50 mol $\mathrm{CH_3COOH}$; **(b)** 1.00 mol NaCl; **(c)** 0.60 mol $\mathrm{NaCH_3COO}$; **(d)** 0.40 mol NaOH.

Titration of a Weak Polyprotic Acid

The most striking evidence that a polyprotic acid ionizes in distinct steps comes by way of its titration curve. For a polyprotic acid, we expect to see a separate equivalence point for each acidic hydrogen. Thus, we expect to see three equivalence points when $\mathrm{H_3PO_4}$ is titrated with NaOH(aq). In the neutralization of phosphoric acid by sodium hydroxide, essentially all the $\mathrm{H_3PO_4}$ molecules are

▶ This stepwise neutralization is observed only if successive ionization constants ($K_{\mathrm{a}_1}, K_{\mathrm{a}_2}, \ldots$) differ significantly in magnitude (for example, by a factor of 10^3 or more). Otherwise, the second neutralization step begins before the first step is completed, and so on.



▲ FIGURE 17-13

Titration of a weak polyprotic acid—10.0 mL of 0.100 M H_3PO_4 with 0.100 M NaOH

A 10.0 mL volume of 0.100 M NaOH is required to reach the first equivalence point. The additional volume of 0.100 M NaOH required to reach the second equivalence point is also 10.0 mL. The pH does not increase sharply in the vicinity of the third equivalence point (30 mL).

first converted to the salt, NaH_2PO_4. Then all the NaH_2PO_4 is converted to Na_2HPO_4; and finally the Na_2HPO_4 is converted to Na_3PO_4.

The titration of 10.0 mL of 0.100 M H_3PO_4 with 0.100 M NaOH is pictured in Figure 17-13. Notice that the first two equivalence points come at equal intervals on the volume axis, at 10.0 mL and at 20.0 mL. Although we expect a third equivalence point at 30.0 mL, it is not realized in this titration. The pH of the strongly hydrolyzed Na_3PO_4 solution at the third equivalence point—approaching pH 13—is higher than can be reached by adding 0.100 M NaOH to water. $Na_3PO_4(aq)$ is nearly as basic as the NaOH(aq) used in the titration (as we will see in Section 17-5).

Let's focus on a few details of this titration. For each mole of H_3PO_4, 1 mol NaOH is required to reach the first equivalence point. At this first equivalence point, the solution is essentially $NaH_2PO_4(aq)$. This is an *acidic* solution because $K_{a_2} > K_b$ for $H_2PO_4^-$: the reaction that produces H_3O^+ predominates over the one that produces OH^-.

$$H_2PO_4^- + H_2O \rightleftharpoons H_3O^+ + HPO_4^{2-} \qquad K_{a_2} = 6.3 \times 10^{-8}$$
$$H_2PO_4^- + H_2O \rightleftharpoons H_3PO_4 + OH^- \qquad K_b = 1.4 \times 10^{-12}$$

The pH at the equivalence point falls within the pH range over which the color of methyl orange indicator changes from red to orange.

An additional mole of NaOH is required to convert 1 mol $H_2PO_4^-$ to 1 mol HPO_4^{2-}. At this second equivalence point in the titration of H_3PO_4, the solution is basic because $K_b > K_{a_3}$ for HPO_4^{2-}.

$$HPO_4^{2-} + H_2O \rightleftharpoons H_2PO_4^- + OH^- \qquad K_b = 1.6 \times 10^{-7}$$
$$HPO_4^{2-} + H_2O \rightleftharpoons H_3O^+ + PO_4^{3-} \qquad K_{a_3} = 4.2 \times 10^{-13}$$

Phenolphthalein is an appropriate indicator for this equivalence point; the color of this indicator changes from colorless to light pink.

17-5 CONCEPT ASSESSMENT

Sketch the titration curve for 1,2-ethanediamine, $NH_2CH_2CH_2NH_2(aq)$, with HCl(aq) and label all important points on the titration curve. For 1,2-ethanediamine, $pK_{b_1} = 4.08$; $pK_{b_2} = 7.15$.

17-5 Solutions of Salts of Polyprotic Acids

In discussing the neutralization of phosphoric acid by a strong base, we found that the first equivalence point should come in a somewhat acidic solution and the second in a mildly basic solution. We reasoned that the third equivalence point could be reached only in a strongly basic solution. The pH at this third equivalence point is not difficult to calculate. It corresponds to that of $Na_3PO_4(aq)$, and PO_4^{3-} can ionize (hydrolyze) only as a base.

$$PO_4^{3-} + H_2O \rightleftharpoons HPO_4^{2-} + OH^- \qquad K_b = K_w/K_{a_3} = 2.4 \times 10^{-2}$$

EXAMPLE 17-9 Determining the pH of a Solution Containing the Anion (A^{n-}) of a Polyprotic Acid

Sodium phosphate, Na_3PO_4, is an ingredient of some preparations used to clean painted walls before they are repainted. What is the pH of 0.025 M $Na_3PO_4(aq)$?

Analyze

PO_4^{3-} is a weak base that will react with water to form HPO_4^{2-} and OH^-, thereby making the solution basic. We don't have to consider additional reactions, such as the reaction of HPO_4^{2-} and H_2O to give $H_2PO_4^-$ and OH^-, because as discussed on page 719, most of the OH^- in solution will come from the reaction of PO_4^{3-} and H_2O. The value of K_b for PO_4^{3-} is large enough, however, that we will *not* be able to make the usual simplifying approximation that $0.025 - x \approx 0.025$.

Solve

In the usual fashion, we can write

	PO_4^{3-} + H_2O ⇌	HPO_4^{2-} +	OH^-	$K_b = 2.4 \times 10^{-2}$
initial concns:	0.025 M	—	—	
changes:	$-x$ M	$+x$ M	$+x$ M	
equil concns:	$(0.025 - x)$ M	x M	x M	

$$K_b = \frac{[HPO_4^{2-}][OH^-]}{[PO_4^{3-}]} = \frac{x \cdot x}{0.025 - x} = 2.4 \times 10^{-2}$$

Solving the quadratic equation $x^2 + 0.024x - (0.025)(0.024) = 0$ yields $x = [OH^-] = 0.015$ M. Thus,

$$pOH = -\log[OH^-] = -\log(0.015) = 1.82$$
$$pH = 14.00 - 1.82 = 12.18$$

Assess

Notice that more than half (about 61%) of the PO_4^{3-} reacts. In solving this problem, we assumed that most of the OH^- in solution comes from the reaction of PO_4^{3-} and H_2O. That is, the subsequent reaction of HPO_4^{2-} and H_2O does not contribute a significant amount of OH^-. Can we test the validity of this approximation? Of course we can. On page 769, we saw that

$$HPO_4^{2-} + H_2O \rightleftharpoons H_2PO_4^- + OH^- \qquad K_b = [H_2PO_4^-][OH^-]/[HPO_4^{2-}] = 1.6 \times 10^{-7}$$

Using $[HPO_4^{2-}] \approx [OH^-] \approx 0.015$ M (from above), we obtain $[H_2PO_4^-] \approx 1.6 \times 10^{-7}$. The amount of $H_2PO_4^-$ (and OH^-) generated from the reaction of HPO_4^{2-} and H_2O is, as predicted, very small. The approximation is valid.

PRACTICE EXAMPLE A: Using data from Table 16.4, calculate the pH of 1.0 M Na_2CO_3.

PRACTICE EXAMPLE B: Using data from Table 16.4, calculate the pH of 0.500 M Na_2SO_3.

It is more difficult to calculate the pH values of $NaH_2PO_4(aq)$ and $Na_2HPO_4(aq)$ than of $Na_3PO_4(aq)$. This is because with both $H_2PO_4^-$ and HPO_4^{2-}, two equilibria must be considered *simultaneously*: ionization as an acid and ionization as a base (hydrolysis). For solutions that are reasonably concentrated (say, 0.10 M or greater), the pH values prove to be *independent* of the solution concentration. Shown here (with pK_a values from Table 16.4) are general expressions, printed in blue, and their application to $H_2PO_4^-(aq)$ and $HPO_4^{2-}(aq)$:

$$\text{for } H_2PO_4^-: \quad pH = \frac{1}{2}(pK_{a_1} + pK_{a_2}) = \frac{1}{2}(2.15 + 7.20) = 4.68 \qquad \textbf{(17.5)}$$

$$\text{for } HPO_4^{2-}: \quad pH = \frac{1}{2}(pK_{a_2} + pK_{a_3}) = \frac{1}{2}(7.20 + 12.38) = 9.79 \qquad \textbf{(17.6)}$$

17-1 ARE YOU WONDERING...

How to derive equations (17.5) and (17.6)?

Here is good place to use the general problem-solving method introduced in Section 16-6 (page 721). Consider a solution of NaH_2PO_4, of molarity M. The principal concentrations that we must account for are $[Na^+]$, $[H_3O^+]$, $[H_3PO_4]$, $[H_2PO_4^-]$, $[HPO_4^{2-}]$, and $[OH^-]$. Of these, two have very simple values: $[Na^+] = M$, and $[OH^-] = K_w/[H_3O^+]$. Additionally, we can write the following equations.

1. *Acid Ionization*: $H_2PO_4^- + H_2O \rightleftharpoons H_3O^+ + HPO_4^{2-}$
$$K_{a_2} = \frac{[H_3O^+][HPO_4^{2-}]}{[H_2PO_4^-]}$$
2. *Hydrolysis*: $H_2PO_4^- + H_2O \rightleftharpoons H_3PO_4 + OH^-$
$$K_b = K_w/K_{a_1} = \frac{[H_3PO_4][OH^-]}{[H_2PO_4^-]}$$
3. *Material Balance*: The total concentration of the phosphorus-containing species is the stoichiometric molarity, M. Also, $[Na^+] = M$. We can write $[H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [PO_4^{3-}] = M = [Na^+]$
4. *Electroneutrality Condition*: $[H_3O^+] + [Na^+] = [H_2PO_4^-] + 2 \times [HPO_4^{2-}] + 3 \times [PO_4^{3-}] + [OH^-]$.

The material balance equation and the electroneutrality condition can both be simplified by neglecting the terms involving $[PO_4^{3-}]$ and $[OH^-]$.

Solving the set o fequations: Begin by substituting equation (3) into equation (4).

$$\begin{aligned}[H_3O^+] &= [H_2PO_4^-] + 2 \times [HPO_4^{2-}] - [H_3PO_4] - [H_2PO_4^-] - [HPO_4^{2-}] \\ &= [HPO_4^{2-}] - [H_3PO_4]\end{aligned}$$

To continue from here, rearrange equation (1) to obtain $[HPO_4^{2-}]$ in terms of $[H_3O^+]$, $[H_2PO_4^-]$, and K_{a_2}; then rearrange equation (2) to obtain $[H_3PO_4]$ in terms of $[H_3O^+]$, $[H_2PO_4^-]$, and K_{a_1}. Next, substitute the results into the expression, $[H_3O^+] = [HPO_4^{2-}] - [H_3PO_4]$. At this point, you will have an equation in terms of $[H_3O^+]$, $[H_2PO_4^-]$, K_{a_1}, and K_{a_2} and both $[PO_4^{3-}]$ and $[OH^-]$. Assume that $K_{a1} + [H_2PO_4^-] \approx [H_2PO_4^-]$ and you will get an equation from which you can derive equation (17.5). The remainder of this derivation and the derivation of equation (17.6) are left for you to do (see Exercise 79).

◀ The K_a and K_b values for $H_2PO_4^-$ (see page 769) tell us that there is a greater tendency for $H_2PO_4^-$ to act as an acid. The solution will be acidic and $[OH^-]$ will be less than 10^{-7} M. Also, we expect $[PO_4^{3-}]$ to be very small. To obtain PO_4^{3-}, $H_2PO_4^-$ must ionize twice. However, because $H_2PO_4^-$ is a weak acid, only a small fraction will ionize to HPO_4^{2-} and an even smaller fraction will ionize further to PO_4^{3-}.

17-6 Acid–Base Equilibrium Calculations: A Summary

In this and the preceding chapter, we have considered a variety of acid–base equilibrium calculations. When you are faced with a new problem-solving situation, you might find it helpful to relate the new problem to a type that you have encountered before. It is best not to rely exclusively on "labeling" a problem, however. Some problems might not fit a recognizable category. Instead, keep in mind some principles that apply regardless of the particular problem, as suggested by these questions.

1. **Which species are potentially present in solution, and how large are their concentrations likely to be?**

   In a solution containing similar amounts of HCl and CH_3COOH, the only significant *ionic* species are H_3O^+ and Cl^-. HCl is a completely ionized strong acid, and in the presence of a strong acid, the weak acid $HC_2H_3O_2$ is only very slightly ionized because of the common-ion effect. In a mixture containing similar amounts of two *weak* acids of similar strengths, such as CH_3COOH and HNO_2, each acid partially ionizes. All of these concentrations would be significant: $[CH_3COOH]$, $[CH_3COO^-]$, $[HNO_2]$, $[NO_2^-]$, and $[H_3O^+]$. In a solution containing phosphoric acid or a phosphate salt (or both), H_3PO_4, $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-}, OH^-, H_3O^+, and possibly other cations might be present. If the solution is simply $H_3PO_4(aq)$, however, the only species present in significant concentrations are those associated with the first ionization: H_3PO_4, H_3O^+, and $H_2PO_4^-$. If the solution is instead described as $Na_3PO_4(aq)$, the significant species are Na^+, PO_4^{3-}, and the ions associated with the hydrolysis of PO_4^{3-}, that is, HPO_4^{2-} and OH^-.

▶ Body temperature is 37 °C and at that temperature K_w does not equal 1.0×10^{-14}. Refer to Exercise 83 on page 781.

2. **Are reactions possible among any of the solution components; if so, what is their stoichiometry?**

   Suppose that you are asked to calculate $[OH^-]$ in a solution that is prepared to be 0.10 M NaOH and 0.20 M NH_4Cl. Before you answer that $[OH^-] = 0.10$ M, consider whether a solution can be *simultaneously* 0.10 M in OH^- and 0.20 M in NH_4^+. It cannot; any solution containing both NH_4^+ and OH^- must also contain NH_3. The OH^- and NH_4^+ react in a 1 : 1 mole ratio until OH^- is almost totally consumed:

   $$NH_4^+ + OH^- \longrightarrow NH_3 + H_2O$$

   You are now dealing with the buffer solution 0.10 M NH_3–0.10 M NH_4^+.

3. **Which equilibrium equations apply to the particular situation? Which are the most significant?**

   One equation that applies to all acids and bases in aqueous solutions is $K_w = [H_3O^+][OH^-] = 1.0 \times 10^{-14}$. In many calculations, however, this equation is not significant compared with others. One situation in which it is significant is in calculating $[OH^-]$ in an *acidic* solution or $[H_3O^+]$ in a *basic* solution. After all, an acid does not produce OH^-, and a base does not produce H_3O^+. Another situation in which K_w is likely to be significant is in a solution with a pH near 7.

Often you will find that the ionization equilibrium with the largest K value is the most significant, but this will not always be the case. The amounts of the various species in solution are also an important consideration. When one drop of 1.00 M H_3PO_4 ($K_{a_1} = 7.1 \times 10^{-3}$) is added to 1.00 L of 0.100 M CH_3COOH ($K_a = 1.8 \times 10^{-5}$), the acetic acid ionization is most important in establishing the pH of the solution. The solution contains far more acetic acid than it does phosphoric acid.

17-6 CONCEPT ASSESSMENT

A solution is formed by mixing 200.0 mL of 0.100 M KOH with 100.0 mL of a solution that is both 0.200 M in CH_3COOH and 0.050 M in HI. *Without doing detailed calculations*, identify in the final solution **(a)** all the solute species present, **(b)** the two most abundant solute species, and **(c)** the two least abundant species.

Maintaining the proper pH in blood is important to one's health. To find out how the body maintains a normal pH in blood, go to the Focus On feature for Chapter 17, Buffers in Blood, on the MasteringChemistry site.

Summary

17-1 Common-Ion Effect in Acid–Base Equilibria—The ionization of a weak electrolyte is suppressed by the addition of an ion that is the product of the ionization and is known as the **common-ion effect**. This effect is a manifestation of Le Châtelier's principle, introduced in Chapter 15.

17-2 Buffer Solutions—Solutions that resist changes in pH upon the addition of small amounts of an acid or base are referred to as **buffer solutions**. The finite amount of acid or base that a buffer solution can neutralize is known as the **buffer capacity**, while the pH range over which the buffer solution neutralizes the added acid or base is referred to as **buffer range**. Pure water has no buffer capacity (Fig. 17-4). Key to the functioning of a buffer solution is the presence of either a weak acid and its conjugate base or a weak base and its conjugate acid (Fig. 17-5). Calculating the pH of a buffer solution can be accomplished by using the ICE method developed in Chapter 15 or by application of the **Henderson–Hasselbalch equation** (expression 17.2). Determination of the pH of a buffer solution after the addition of a strong acid or base requires a stoichiometric calculation followed by an equilibrium calculation (Fig. 17-7).

17-3 Acid-Base Indicators—Substances whose colors depend on the pH of a solution are known as **acid–base indicators**. Acid–base indicators exist in solution as a weak acid (HIn) and its conjugate base (In^-). Each form has a different color and the proportions of the two forms determine the color of the solution, which in turn depends on the pH of the solution. The pH range over which an acid–base indicator changes color is determined by the K_a of the specific indicator (Fig. 17-8).

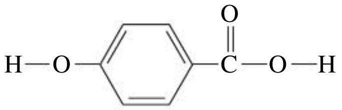
17-4 Neutralization Reactions and Titration Curves—As described in Chapter 5, the concentration of an acidic or basic solution of unknown concentration can be determined by titration with a base or acid of precisely known concentration. In this process a precisely measured volume of the solution of known concentration, the **titrant**, is added through a buret into a precisely measured quantity of the "unknown" contained in a beaker or flask. Typically, the amounts of reactants in a titration are of the order of 10^{-3} mol, that is, **millimoles (mmol)**. A **titration curve** is a graph of a measured property of the reaction mixture as a function of the volume of titrant added—pH for an acid–base titration (Fig. 17-9). The point at which neither reactant is in excess in a titration is known as the **equivalence point**. The **end point** of an acid–base titration can be located through the change in color of an indicator. The indicator must be chosen such that its color change occurs as close to the equivalence point as possible. Strong acid-strong base titration curves (Figs. 17-9 and 17-10) are different from weak acid-strong base titration curves (Fig. 17-11). The two main differences are seen in the latter type, a buffer region and a hydrolysis reaction at the equivalence point (Fig. 17-12).

17-5 Solutions of Salts of Polyprotic Acids—Calculating the pH of solutions containing the salts of polyprotic acids is made difficult by the fact that two or more equilibria occur simultaneously. Yet for certain solutions, the calculations can be reduced to a simple form (expressions 17.5 and 17.6).

17-6 Acid–Base Equilibrium Calculations: A Summary—As a general summary of acid–base equilibrium calculations, the essential factors are identifying all the species in solution, their concentrations, the possible reactions between them, and the stoichiometry and equilibrium constants of those reactions.

Integrative Example

The structural formula shown is *para*-hydroxybenzoic acid, a weak diprotic acid used as a food preservative. Titration of 25.00 mL of a dilute aqueous solution of this acid requires 16.24 mL of 0.0200 M NaOH to reach the first equivalence point. The measured pH after the addition of 8.12 mL of the base is 4.57; after 16.24 mL, the pH is 7.02. Determine the values of pK_{a_1} and pK_{a_2} of *para*-hydroxybenzoic acid and the pH values for the two equivalence points in the titration.



Analyze

This is a titration of a polyprotic weak acid with a strong base, and the titration curve for this problem should look very similar to Figure 17-13. In the titration of a weak acid by a strong base we know that at the point of half-neutralization, $\text{pH} = \text{p}K_a$ and therefore $\text{p}K_{a_1}$ should be the pH at 8.12 mL. For $\text{p}K_{a_2}$, we will use expression 17.5 since at this point in the titration we will have an aqueous solution of HOC_6H_4COONa, which is a salt of a polyprotic acid. The pH of the first equivalence point is given and to find the pH of the second equivalence point we must perform an ICE calculation similar to the one in Example 16-13.

Solve

The volume of base needed to reach the first equivalence point is 16.24 mL; at this point, the $\text{pH} = 7.02$. A volume of 8.12 mL is needed to half-neutralize the acid in its first ionization step; at this point the $\text{pH} = \text{p}K_{a_1}$, that is, $\text{p}K_{a_1} = 4.57$.

At the first equivalence point, the solution is $HOC_6H_4COONa(aq)$ with $\text{pH} = 7.02$. Recognizing this as the salt produced in neutralizing a polyprotic acid in its first ionization, we use equation (17.5) to solve for $\text{p}K_{a_2}$. That is, the pH of an aqueous solution of the ion $HOC_6H_6COO^-$ is given by the expression

$$\text{pH} = \tfrac{1}{2}(\text{p}K_{a_1} + \text{p}K_{a_2}) = \tfrac{1}{2}(4.57 + \text{p}K_{a_2}) = 7.02$$

$$\text{p}K_{a_2} = (2 \times 7.02) - 4.57 = 9.47$$

Determining the pH at the second equivalence point involves additional calculations. We begin by noting that at the second equivalence point the solution is one of $NaOC_6H_4COONa$. The pH of the solution is established by the hydrolysis of $^-OC_6H_4COO^-$.

$$^-OC_6H_4COO^- + H_2O \rightleftharpoons HOC_6H_4COO^- + OH^-$$

$$K_b = K_w/K_{a_2}$$

To evaluate K_b, let's first obtain K_{a_2} from $\text{p}K_{a_2}$.

$$\text{p}K_{a_2} = -\log K_{a_2} = 9.47 \text{ and } K_{a_2} = 10^{-9.47} = 3.4 \times 10^{-10}$$

$$K_b = K_w/K_{a_2} = 1.0 \times 10^{-14}/3.4 \times 10^{-10} = 2.9 \times 10^{-5}$$

We can get the pH of this solution by first calculating $[OH^-]$ and pOH. However, to do this, we still need one more piece of data—the molarity of the $NaOC_6H_4COONa(aq)$. We can get this from data for titration to the first equivalence point.

$$? \text{ mmol } OH^- = 16.24 \text{ mL} \times 0.0200 \text{ mmol } OH^-/\text{mL} = 0.325 \text{ mmol } OH^-$$

$$? \text{ mmol } HOC_6H_4COOH = 0.325 \text{ mmol } OH^- \times 1 \text{ mmol } HOC_6H_4COOH/\text{mmol } OH^- = 0.325 \text{ mmol } HOC_6H_4COOH$$

The amount of $^-OC_6H_4COO^-$ at the second equivalence point is the same as the amount of acid at the start of the titration.

$$0.325 \text{ mmol } ^-OC_6H_4COO^-$$

The volume of solution at the second equivalence point is

$$25.00 \text{ mL} + 16.24 \text{ mL} + 16.24 \text{ mL} = 57.48 \text{ mL}.$$

Thus,

$$[^-OC_6H_4COO^-] = 0.325 \text{ mmol } ^-OC_6H_4COO^-/57.48 \text{ mL} = 5.65 \times 10^{-3} \text{ M}.$$

Now we can return to the hydrolysis equation and the expression for K_b, using the method of Example 16-13.

$$\begin{array}{llccc}
 & {}^{-}OC_6H_4COO^{-} + H_2O & \rightleftharpoons & HOC_6H_4COO^{-} & + \ OH^{-} \\
\text{initial concns:} & 5.65 \times 10^{-3}\ \text{M} & & — & — \\
\text{changes:} & -x\ \text{M} & & +x\ \text{M} & +x\ \text{M} \\
\text{equil concns:} & (5.65 \times 10^{-3} - x)\ \text{M} & & x\ \text{M} & x\ \text{M}
\end{array}$$

$$K_b = \frac{x \cdot x}{(5.65 \times 10^{-3} - x)} = 2.9 \times 10^{-5}$$

The solution to this quadratic equation is $x = [OH^-] = 3.9 \times 10^{-4}$, corresponding to pOH = 3.41 and pH = 10.59.

Assess

The polyprotic acid, *para*-hydroxybenzoic acid, has two functional groups, a carboxylic acid and a phenolic group. Each group has an ionizable proton. Given just two basic pieces of titration data, we used concepts from this and the preceding chapter to determine the pK_a values for both ionizable groups as well as the pH at the two equivalence points. As a check, note that the pK_a values of these groups are comparable to the values for their parent compounds, acetic acid and phenol (see Table 16.3).

PRACTICE EXAMPLE A: 7.500 g of a weak acid HA is added to sufficient distilled water to produce 500.0 mL of solution with pH = 2.716. This solution is titrated with NaOH(aq). Halfway to the equivalence point, pH = 4.602. What is the freezing point of the solution?

PRACTICE EXAMPLE B: The following titration curve was obtained as part of a general chemistry laboratory experiment for an unknown that weighed 0.8 g. The titrant was either a 0.2 M strong base or 0.2 M strong acid. Estimate the molar mass of the unknown and its ionization constant.

Exercises

The Common-Ion Effect

(*Use data from Table 16.3 as necessary.*)

1. For a solution that is 0.275 M CH_3CH_2COOH (propionic acid, $K_a = 1.3 \times 10^{-5}$) and 0.0892 M HI, calculate **(a)** $[H_3O^+]$; **(b)** $[OH^-]$; **(c)** CH_3CH_2COO; **(d)** $[I^-]$.
2. For a solution that is 0.164 M NH_3 and 0.102 M NH_4Cl, calculate **(a)** $[OH^-]$; **(b)** $[NH_4{}^+]$; **(c)** $[Cl^-]$; **(d)** $[H_3O^+]$.
3. Calculate the *change* in pH that results from adding **(a)** 0.100 mol $NaNO_2$ to 1.00 L of 0.100 M HNO_2(aq); **(b)** 0.100 mol $NaNO_3$ to 1.00 L of 0.100 M HNO_3(aq). Why are the changes not the same? Explain.
4. In Example 16-8, we calculated the percent ionization of CH_3COOH in **(a)** 1.0 M; **(b)** 0.10 M; and **(c)** 0.010 M CH_3COOH solutions. Recalculate those percent ionizations if each solution also contains 0.10 M $NaCH_3COO$. Explain why the results are different from those of Example 16-8.

5. Calculate $[H_3O^+]$ in a solution that is **(a)** 0.035 M HCl and 0.075 M HOCl; **(b)** 0.100 M $NaNO_2$ and 0.0550 M HNO_2; **(c)** 0.0525 M HCl and 0.0768 M $NaCH_3COO$.

6. Calculate $[OH^-]$ in a solution that is **(a)** 0.0062 M $Ba(OH)_2$ and 0.0105 M $BaCl_2$; **(b)** 0.315 M $(NH_4)_2SO_4$ and 0.486 M NH_3; **(c)** 0.196 M NaOH and 0.264 M NH_4Cl.

Buffer Solutions

(*Use data from Tables 16.3 and 16.4 as necessary.*)

7. What concentration of formate ion, $[HCOO^-]$, should be present in 0.366 M HCOOH to produce a buffer solution with pH = 4.06?

$$HCOOH + H_2O \rightleftharpoons H_3O^+ + HCOO^- \qquad K_a = 1.8 \times 10^{-4}$$

8. What concentration of ammonia, $[NH_3]$, should be present in a solution with $[NH_4^+] = 0.732$ M to produce a buffer solution with pH = 9.12? For NH_3, $K_b = 1.8 \times 10^{-5}$.

9. Calculate the pH of a buffer that is
(a) 0.012 M $C_6H_5COOH(K_a = 6.3 \times 10^{-5})$ and 0.033 M NaC_6H_5COO;
(b) 0.408 M NH_3 and 0.153 M NH_4Cl.

10. Lactic acid, CH_3CH_2COOH, is found in sour milk. A solution containing 1.00 g $NaCH_3CH_2COO$ in 100.0 mL of 0.0500 M $HC_3H_5O_3$ has a pH = 4.11. What is K_a of lactic acid?

11. Indicate which of the following aqueous solutions are buffer solutions, and explain your reasoning. [*Hint:* Consider any reactions that might occur between solution components.]
(a) 0.100 M NaCl
(b) 0.100 M NaCl–0.100 M NH_4Cl
(c) 0.100 M CH_3NH_2–0.150 M $CH_3NH_3{}^+Cl^-$
(d) 0.100 M HCl–0.050 M $NaNO_2$
(e) 0.100 M HCl–0.200 M $NaCH_3COO$
(f) 0.100 M CH_3COOH–0.125 M $NaCH_3CH_2COO$

12. The $H_2PO_4{}^-$–$HPO_4{}^{2-}$ combination plays a role in maintaining the pH of blood.
(a) Write equations to show how a solution containing these ions functions as a buffer.
(b) Verify that this buffer is most effective at pH 7.2.
(c) Calculate the pH of a buffer solution in which $[H_2PO_4{}^-] = 0.050$ M and $[HPO_4{}^{2-}] = 0.150$ M. [*Hint:* Focus on the second step of the phosphoric acid ionization.]

13. What is the pH of a solution obtained by adding 1.15 mg of aniline hydrochloride ($C_6H_5NH_3{}^+Cl^-$) to 3.18 L of 0.105 M aniline ($C_6H_5NH_2$)? [*Hint:* Check any assumptions that you make.]

14. What is the pH of a solution prepared by dissolving 8.50 g of aniline hydrochloride ($C_6H_5NH_3{}^+Cl^-$) in 750 mL of 0.215 M aniline, ($C_6H_5NH_2$)? Would this solution be an effective buffer? Explain.

15. You wish to prepare a buffer solution with pH = 9.45.
(a) How many grams of $(NH_4)_2SO_4$ would you add to 425 mL of 0.258 M NH_3 to do this? Assume that the solution's volume remains constant.
(b) Which buffer component, and how much (in grams), would you add to 0.100 L of the buffer in part (a) to change its pH to 9.30? Assume that the solution's volume remains constant.

16. You prepare a buffer solution by dissolving 2.00 g each of benzoic acid, C_6H_5COOH, and sodium benzoate, NaC_6H_5COO, in 750.0 mL of water.
(a) What is the pH of this buffer? Assume that the solution's volume is 750.0 mL.
(b) Which buffer component, and how much (in grams), would you add to the 750.0 mL of buffer solution to change its pH to 4.00?

17. If 0.55 mL of 12 M HCl is added to 0.100 L of the buffer solution in Exercise 15(a), what will be the pH of the resulting solution?

18. If 0.35 mL of 15 M NH_3 is added to 0.750 L of the buffer solution in Exercise 16(a), what will be the pH of the resulting solution?

19. You are asked to prepare a buffer solution with a pH of 3.50. The following solutions, all 0.100 M, are available to you: HCOOH, CH_3COOH, H_3PO_4, NaCHOO, $NaCH_3COO$, and NaH_2PO_4. Describe how you would prepare this buffer solution. [*Hint:* What volumes of which solutions would you use?]

20. You are asked to reduce the pH of the 0.300 L of buffer solution in Example 17-5 from 5.09 to 5.00. How many milliliters of which of these solutions would you use: 0.100 M NaCl, 0.150 M HCl, 0.100 M $NaCH_3COO$, 0.125 M NaOH? Explain your reasoning.

21. Given 1.00 L of a solution that is 0.100 M CH_3CH_2COOH and 0.100 M CH_3CH_2COO,
(a) Over what pH range will this solution be an effective buffer?
(b) What is the buffer capacity of the solution? That is, how many millimoles of strong acid or strong base can be added to the solution before any significant change in pH occurs?

22. Given 125 mL of a solution that is 0.0500 M CH_3NH_2 and 0.0500 M $CH_3NH_3{}^+Cl^-$,
(a) Over what pH range will this solution be an effective buffer?
(b) What is the buffer capacity of the solution? That is, how many millimoles of strong acid or strong base can be added to the solution before any significant change in pH occurs?

23. A solution of volume 75.0 mL contains 15.5 mmol $HCHO_2$ and 8.50 mmol NaHCOO.
(a) What is the pH of this solution?
(b) If 0.25 mmol $Ba(OH)_2$ is added to the solution, what will be the pH?
(c) If 1.05 mL of 12 M HCl is added to the original solution, what will be the pH?

24. A solution of volume 0.500 L contains 1.68 g NH_3 and 4.05 g $(NH_4)_2SO_4$.
(a) What is the pH of this solution?
(b) If 0.88 g NaOH is added to the solution, what will be the pH?
(c) How many milliliters of 12 M HCl must be added to 0.500 L of the original solution to change its pH to 9.00?

25. A handbook lists various procedures for preparing buffer solutions. To obtain a $\mathrm{pH} = 9.00$, the handbook says to mix 36.00 mL of 0.200 M NH_3 with 64.00 mL of 0.200 M NH_4Cl.
(a) Show by calculation that the pH of this solution is 9.00.
(b) Would you expect the pH of this solution to remain at $\mathrm{pH} = 9.00$ if the 100.00 mL of buffer solution were diluted to 1.00 L? To 1000 L? Explain.
(c) What will be the pH of the original 100.00 mL of buffer solution if 0.20 mL of 1.00 M HCl is added to it?
(d) What is the maximum volume of 1.00 M HCl that can be added to 100.00 mL of the original buffer solution so that the pH does not drop below 8.90?

26. An acetic acid–sodium acetate buffer can be prepared by the reaction

$$\underset{\text{(From NaCH}_3\text{COO)}}{CH_3COO^-} + \underset{\text{(From HCl)}}{H_3O^+} \longrightarrow CH_3COOH + H_2O$$

(a) If 12.0 g $NaCH_3COO$ is added to 0.300 L of 0.200 M HCl, what is the pH of the resulting solution?
(b) If 1.00 g $Ba(OH)_2$ is added to the solution in part (a), what is the new pH?
(c) What is the maximum mass of $Ba(OH)_2$ that can be neutralized by the buffer solution of part (a)?
(d) What is the pH of the solution in part (a) following the addition of 5.50 g $Ba(OH)_2$?

Acid–Base Indicators

(*Use data from Tables 16.3 and 16.4 as necessary.*)

27. A handbook lists the following data:

		Color Change
Indicator	K_{HIn}	Acid → Anion
Bromphenol blue	1.4×10^{-4}	yellow → blue
Bromcresol green	2.1×10^{-5}	yellow → blue
Bromthymol blue	7.9×10^{-8}	yellow → blue
2,4-Dinitrophenol	1.3×10^{-4}	colorless → yellow
Chlorphenol red	1.0×10^{-6}	yellow → red
Thymolphthalein	1.0×10^{-10}	colorless → blue

(a) Which of these indicators change color in acidic solution, which in basic solution, and which near the neutral point?
(b) What is the approximate pH of a solution if bromcresol green indicator turns green? if chlorphenol red turns orange?

28. With reference to the indicators listed in Exercise 27, what would be the color of each combination?
(a) 2,4-dinitrophenol in 0.100 M HCl(aq)
(b) chlorphenol red in 1.00 M NaCl(aq)
(c) thymolphthalein in 1.00 M NH_3(aq)
(d) bromcresol green in seawater (recall Figure 17-8)

29. In the use of acid–base indicators,
(a) Why is it generally sufficient to use a *single* indicator in an acid–base titration, but often necessary to use *several* indicators to establish the approximate pH of a solution?
(b) Why must the quantity of indicator used in a titration be kept as small as possible?

30. The indicator methyl red has a $pK_{HIn} = 4.95$. It changes from red to yellow over the pH range from 4.4 to 6.2.
(a) If the indicator is placed in a buffer solution of $\mathrm{pH} = 4.55$, what percent of the indicator will be present in the acid form, HIn, and what percent will be present in the base or anion form, In^-?
(b) Which form of the indicator has the "stronger" (that is, more visible) color—the acid (red) form or base (yellow) form? Explain.

31. Phenol red indicator changes from yellow to red in the pH range from 6.6 to 8.0. *Without making detailed calculations*, state what color the indicator will assume in each of the following solutions: **(a)** 0.10 M KOH; **(b)** 0.10 M CH_3COOH; **(c)** 0.10 M NH_4NO_3; **(d)** 0.10 M HBr; **(e)** 0.10 M NaCN; **(f)** 0.10 M CH_3COOH–0.10 M $NaCH_3COO$.

32. Thymol blue indicator has *two* pH ranges. It changes color from red to yellow in the pH range from 1.2 to 2.8, and from yellow to blue in the pH range from 8.0 to 9.6. What is the color of the indicator in each of the following situations?
(a) The indicator is placed in 350.0 mL of 0.205 M HCl.
(b) To the solution in part (a) is added 250.0 mL of 0.500 M $NaNO_2$.
(c) To the solution in part (b) is added 150.0 mL of 0.100 M NaOH.
(d) To the solution in part (c) is added 5.00 g $Ba(OH)_2$.

33. In the titration of 10.00 mL of 0.04050 M HCl with 0.01120 M $Ba(OH)_2$ in the presence of the indicator 2,4-dinitrophenol, the solution changes from colorless to yellow when 17.90 mL of the base has been added. What is the approximate value of pK_{HIn} for 2,4-dinitrophenol? Is this a good indicator for the titration?

34. Solution **(a)** is 100.0 mL of 0.100 M HCl and solution **(b)** is 150.0 mL of 0.100 M $NaCH_3COO$. A few drops of thymol blue indicator are added to each solution. What is the color of each solution? What is the color of the solution obtained when these two solutions are mixed?

Neutralization Reactions

35. A 25.00 mL sample of H_3PO_4(aq) requires 31.15 mL of 0.2420 M KOH for titration to the second equivalence point. What is the molarity of the H_3PO_4(aq)?

36. A 20.00 mL sample of H_3PO_4(aq) requires 18.67 mL of 0.1885 M NaOH for titration from the first to the second equivalence point. What is the molarity of the H_3PO_4(aq)?

37. Two aqueous solutions are mixed: 50.0 mL of 0.0150 M H_2SO_4 and 50.0 mL of 0.0385 M NaOH. What is the pH of the resulting solution?

38. Two solutions are mixed: 100.0 mL of HCl(aq) with pH 2.50 and 100.0 mL of NaOH(aq) with pH 11.00. What is the pH of the resulting solution?

Titration Curves

39. Calculate the pH at the points in the titration of 25.00 mL of 0.160 M HCl when **(a)** 10.00 mL and **(b)** 15.00 mL of 0.242 M KOH have been added.

40. Calculate the pH at the points in the titration of 20.00 mL of 0.275 M KOH when **(a)** 15.00 mL and **(b)** 20.00 mL of 0.350 M HCl have been added.

41. Calculate the pH at the points in the titration of 25.00 mL of 0.132 M HNO_2 when **(a)** 10.00 mL and **(b)** 20.00 mL of 0.116 M NaOH have been added. For HNO_2, $K_a = 7.2 \times 10^{-4}$.

$$HNO_2 + OH^- \longrightarrow H_2O + NO_2^-$$

42. Calculate the pH at the points in the titration of 20.00 mL of 0.318 M NH_3 when **(a)** 10.00 mL and **(b)** 15.00 mL of 0.475 M HCl have been added. For NH_3, $K_b = 1.8 \times 10^{-5}$.

$$NH_3(aq) + HCl(aq) \longrightarrow NH_4^+(aq) + Cl^-(aq)$$

43. Explain why the volume of 0.100 M NaOH required to reach the equivalence point in the titration of 25.00 mL of 0.100 M HA is the same regardless of whether HA is a strong or a weak acid, yet the pH at the equivalence point is not the same.

44. Explain whether the equivalence point of each of the following titrations should be below, above, or at pH 7: **(a)** $NaHCO_3(aq)$ titrated with NaOH(aq); **(b)** HCl(aq) titrated with $NH_3(aq)$; **(c)** KOH(aq) titrated with HI(aq).

45. Sketch the titration curves of the following mixtures. Indicate the initial pH and the pH corresponding to the equivalence point. Indicate the volume of titrant required to reach the equivalence point, and select a suitable indicator from Figure 17-8.
(a) 25.0 mL of 0.100 M KOH with 0.200 M HI
(b) 10.0 mL of 1.00 M NH_3 with 0.250 M HCl

46. Determine the following characteristics of the titration curve for 20.0 mL of 0.275 M $NH_3(aq)$ titrated with 0.325 M HI(aq).
(a) the initial pH
(b) the volume of 0.325 M HI(aq) at the equivalence point
(c) the pH at the half-neutralization point
(d) the pH at the equivalence point

47. In the titration of 20.00 mL of 0.175 M NaOH, calculate the number of milliliters of 0.200 M HCl that must be added to reach a pH of **(a)** 12.55, **(b)** 10.80, **(c)** 4.25. [*Hint:* Solve an algebraic equation in which the number of milliliters is *x*. Which reactant is in excess at each pH?]

48. In the titration of 25.00 mL of 0.100 M CH_3COOH, calculate the number of milliliters of 0.200 M NaOH that must be added to reach a pH of **(a)** 3.85, **(b)** 5.25, **(c)** 11.10. [*Hint:* Solve an algebraic equation in which the number of milliliters is *x*. Which reactant is in excess at each pH?]

49. Sketch a titration curve (pH versus mL of titrant) for each of the following three hypothetical weak acids when titrated with 0.100 M NaOH. Select suitable indicators for the titrations from Figure 17-8. [*Hint:* Select a few key points at which to estimate the pH of the solution.]
(a) 10.00 mL of 0.100 M HX; $K_a = 7.0 \times 10^{-3}$
(b) 10.00 mL of 0.100 M HY; $K_a = 3.0 \times 10^{-4}$
(c) 10.00 mL of 0.100 M HZ; $K_a = 2.0 \times 10^{-8}$

50. Sketch a titration curve (pH versus mL of titrant) for each of the following hypothetical weak bases when titrated with 0.100 M HCl. (Think of these bases as involving the substitution of organic groups, R, for one of the H atoms of NH_3.) Select suitable indicators for the titrations from Figure 17-8. [*Hint:* Select a few key points at which to estimate the pH of the solution.]
(a) 10.00 mL of 0.100 M RNH_2; $K_b = 1 \times 10^{-3}$
(b) 10.00 mL of 0.100 M $R'NH_2$; $K_b = 3 \times 10^{-6}$
(c) 10.00 mL of 0.100 M $R''NH_2$; $K_b = 7 \times 10^{-8}$

51. For the titration of 25.00 mL of 0.100 M NaOH with 0.100 M HCl, calculate the pOH at a few representative points in the titration, sketch the titration curve of pOH versus volume of titrant, and show that it has exactly the same form as Figure 17-9. Then, using this curve and the simplest method possible, sketch the titration curve of pH versus volume of titrant.

52. For the titration of 25.00 mL 0.100 M NH_3 with 0.100 M HCl, calculate the pOH at a few representative points in the titration, sketch the titration curve of pOH versus volume of titrant, and show that it has exactly the same form as Figure 17-11. Then, using this curve and the simplest method possible, sketch the titration curve of pH versus volume of titrant.

Salts of Polyprotic Acids

(*Use data from Table 16.4 or Appendix D as necessary.*)

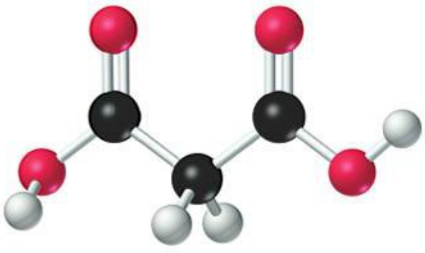
53. Is a solution that is 0.10 M $Na_2S(aq)$ likely to be acidic, basic, or pH neutral? Explain.

54. Is a solution of sodium dihydrogen citrate, NaH_2Cit, likely to be acidic, basic, or neutral? Explain. Citric acid, H_3Cit, is $H_3C_6H_5O_7$.

55. Sodium phosphate, Na_3PO_4, is made commercially by first neutralizing phosphoric acid with sodium carbonate to obtain Na_2HPO_4. The Na_2HPO_4 is further neutralized to Na_3PO_4 with NaOH.
(a) Write net ionic equations for these reactions.
(b) Na_2CO_3 is a much cheaper base than is NaOH. Why do you suppose that NaOH must be used as well as Na_2CO_3 to produce Na_3PO_4?

56. Both sodium hydrogen carbonate (sodium bicarbonate) and sodium hydroxide can be used to neutralize acid spills. What is the pH of 1.00 M $NaHCO_3(aq)$ and of 1.00 M NaOH(aq)? On a per-liter basis, do these two solutions have an equal capacity to neutralize acids? Explain. On a per-gram basis, do the two solids, $NaHCO_3(s)$ and $NaOH(s)$, have an equal capacity to neutralize acids? Explain. Why do you suppose that $NaHCO_3$ is often preferred to NaOH in neutralizing acid spills?

57. The pH of a solution of 19.5 g of malonic acid in 0.250 L is 1.47. The pH of a 0.300 M solution of sodium hydrogen malonate is 4.26. What are the values of K_{a_1} and K_{a_2} for malonic acid?

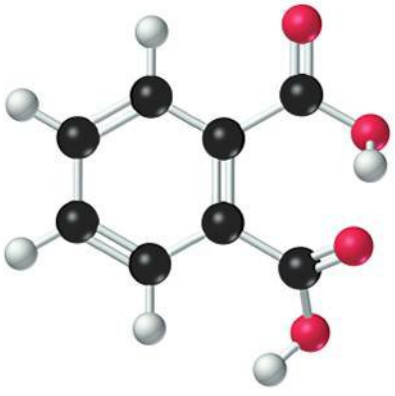


Malonic acid

58. The ionization constants of *ortho*-phthalic acid are $K_{a_1} = 1.1 \times 10^{-3}$ and $K_{a_2} = 3.9 \times 10^{-6}$.

1. $C_6H_4(COOH)_2 + H_2O \rightleftharpoons H_3O^+ + HC_8H_4O_4^-$
2. $HC_8H_4O_4^- + H_2O \rightleftharpoons H_3O^+ + C_6H_4(COO^-)_2$

What are the pH values of the following aqueous solutions: **(a)** 0.350 M potassium hydrogen *ortho*-phthalate; **(b)** a solution containing 36.35 g potassium *ortho*-phthalate per liter?



ortho-Phthalic acid

General Acid–Base Equilibria

59. What stoichiometric concentration of the indicated substance is required to obtain an aqueous solution with the pH value shown: **(a)** $Ba(OH)_2$ for pH = 11.88; **(b)** CH_3COOH in 0.294 M $NaCH_3COO$ for pH = 4.52?

60. What stoichiometric concentration of the indicated substance is required to obtain an aqueous solution with the pH value shown: **(a)** aniline, $C_6H_5NH_2$, for pH = 8.95; **(b)** NH_4Cl for pH = 5.12?

61. Using appropriate equilibrium constants but *without doing detailed calculations*, determine whether a solution can be simultaneously:
(a) 0.10 M NH_3 and 0.10 M NH_4Cl, with pH = 6.07
(b) 0.10 M $NaC_2H_3O_2$ and 0.058 M HI
(c) 0.10 M KNO_2 and 0.25 M KNO_3
(d) 0.050 M $Ba(OH)_2$ and 0.65 M NH_4Cl
(e) 0.018 M C_6H_5COOH and 0.018 M NaC_6H_5COO, with pH = 4.20
(f) 0.68 M KCl, 0.42 M KNO_3, 1.2 M NaCl, and 0.55 M $NaCH_3COO$, with pH = 6.4

62. This single equilibrium equation applies to different phenomena described in this or the preceding chapter.

$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^-$$

Of these four phenomena, ionization of pure acid, common-ion effect, buffer solution, and hydrolysis, indicate which occurs if
(a) $[H_3O^+]$ and $[CH_3COOH]$ are high, but $[CH_3COO^-]$ is very low.
(b) $[CH_3COO^-]$ is high, but $[CH_3COOH]$ and $[H_3O^+]$ are very low.
(c) $[CH_3COOH]$ is high, but $[H_3O^+]$ and $[CH_3COO^-]$ are low.
(d) $[CH_3COOH]$ and $[CH_3COO^-]$ are high, but $[H_3O^+]$ is low.

Integrative and Advanced Exercises

63. Sodium hydrogen sulfate, $NaHSO_4$, is an acidic salt with a number of uses, such as metal pickling (removal of surface deposits). $NaHSO_4$ is made by the reaction of H_2SO_4 with NaCl. To determine the percent NaCl impurity in $NaHSO_4$, a 1.016 g sample is titrated with NaOH(aq); 36.56 mL of 0.225 M NaOH is required.
(a) Write the net ionic equation for the neutralization reaction.
(b) Determine the percent NaCl in the sample titrated.
(c) Select a suitable indicator(s) from Figure 17-8.

64. You are given 250.0 mL of 0.100 M CH_3CH_2COOH (propionic acid, $K_a = 1.35 \times 10^{-5}$). You want to adjust its pH by adding an appropriate solution. What volume would you add of **(a)** 1.00 M HCl to lower the pH to 1.00; **(b)** 1.00 M $NaCH_3CH_2COO$ to raise the pH to 4.00; **(c)** water to raise the pH by 0.15 unit?

65. Even though the carbonic acid–hydrogen carbonate buffer system is crucial to the maintenance of the pH of blood, it has no practical use as a laboratory buffer solution. Can you think of a reason(s) for this? [*Hint:* Refer to data in Practice Example A of the Integrative Example in Chapter 16.]

66. Thymol blue in its acid range is not a suitable indicator for the titration of HCl by NaOH. Suppose that a student uses thymol blue by mistake in the titration of Figure 17-9 and that the indicator end point is taken to be pH = 2.0.

(a) Would there be a sharp color change, produced by the addition of a single drop of NaOH(aq)?

(b) Approximately what percent of the HCl remains unneutralized at pH = 2.0?

67. Rather than calculate the pH for different volumes of titrant, a titration curve can be established by calculating the volume of titrant required to reach certain pH values. Determine the volumes of 0.100 M NaOH required to reach the following pH values in the titration of 20.00 mL of 0.150 M HCl: pH = **(a)** 2.00; **(b)** 3.50; **(c)** 5.00; **(d)** 10.50; **(e)** 12.00. Then plot the titration curve.

68. Use the method of Exercise 67 to determine the volume of titrant required to reach the indicated pH values in the following titrations.

(a) 25.00 mL of 0.250 M NaOH titrated with 0.300 M HCl; pH = 13.00, 12.00, 10.00, 4.00, 3.00

(b) 50.00 mL of 0.0100 M benzoic acid (C_6H_5COOH) titrated with 0.0500 M KOH: pH = 4.50, 5.50, 11.50 ($K_a = 6.3 \times 10^{-5}$)

69. A buffer solution can be prepared by starting with a weak acid, HA, and converting some of the weak acid to its salt (for example, NaA) by titration with a strong base. The *fraction* of the original acid that is converted to the salt is designated f.

(a) Derive an equation similar to equation (17.2) but expressed in terms of f rather than concentrations.

(b) What is the pH at the point in the titration of phenol, C_6H_5OH, at which $f = 0.27$ (pK_a of phenol = 10.00)?

70. You are asked to prepare a KH_2PO_4–Na_2HPO_4 solution that has the same pH as human blood, 7.40.

(a) What should be the ratio of concentrations $[HPO_4^{2-}]/[H_2PO_4^-]$ in this solution?

(b) Suppose you have to prepare 1.00 L of the solution described in part (a) and that this solution must be isotonic with blood (have the same osmotic pressure as blood). What masses of KH_2PO_4 and of $Na_2HPO_4 \cdot 12H_2O$ would you use? [*Hint:* Refer to the definition of isotonic on page 580. Recall that a solution of NaCl with 9.2 g NaCl/L solution is isotonic with blood, and assume that NaCl is completely ionized in aqueous solution.]

71. You are asked to bring the pH of 0.500 L of 0.500 M NH_4Cl(aq) to 7.00. How many drops (1 drop = 0.05 mL) of which of the following solutions would you use: 10.0 M HCl or 10.0 M NH_3?

72. Because an acid–base indicator is a weak acid, it can be titrated with a strong base. Suppose you titrate 25.00 mL of a 0.0100 M solution of the indicator *p*-nitrophenol, $HOC_6H_4NO_2$, with 0.0200 M NaOH. The pK_a of *p*-nitrophenol is 7.15, and it changes from colorless to yellow in the pH range from 5.6 to 7.6.

(a) Sketch the titration curve for this titration.

(b) Show the pH range over which *p*-nitrophenol changes color.

(c) Explain why *p*-nitrophenol cannot serve as its own indicator in this titration.

73. The neutralization of NaOH by HCl is represented in equation (1), and the neutralization of NH_3 by HCl in equation (2).

1. $OH^- + H_3O^+ \rightleftharpoons 2\,H_2O \qquad K = ?$
2. $NH_3 + H_3O^+ \rightleftharpoons NH_4^+ + H_2O \qquad K = ?$

(a) Determine the equilibrium constant K for each reaction.

(b) Explain why each neutralization reaction can be considered to go to completion.

74. The titration of a weak acid by a weak base is not a satisfactory procedure because the pH does not increase sharply at the equivalence point. Demonstrate this fact by sketching a titration curve for the neutralization of 10.00 mL of 0.100 M CH_3COOH with 0.100 M NH_3.

75. At times, a salt of a weak base can be titrated by a strong base. Use appropriate data from the text to sketch a titration curve for the titration of 10.00 mL of 0.0500 M $C_6H_5NH_3^+Cl^-$ with 0.100 M NaOH.

76. Sulfuric acid is a diprotic acid, strong in the first ionization step and weak in the second ($K_{a_2} = 1.1 \times 10^{-2}$). By using appropriate calculations, determine whether it is feasible to titrate 10.00 mL of 0.100 M H_2SO_4 to two distinct equivalence points with 0.100 M NaOH.

77. Carbonic acid is a weak diprotic acid (H_2CO_3) with $K_{a_1} = 4.43 \times 10^{-7}$ and $K_{a_2} = 4.73 \times 10^{-11}$. The equivalence points for the titration come at approximately pH 4 and 9. Suitable indicators for use in titrating carbonic acid or carbonate solutions are methyl orange and phenolphthalein.

(a) Sketch the titration curve that would be obtained in titrating a sample of $NaHCO_3$(aq) with 1.00 M HCl.

(b) Sketch the titration curve for Na_2CO_3(aq) with 1.00 M HCl.

(c) What volume of 0.100 M HCl is required for the complete neutralization of 1.00 g $NaHCO_3$(s)?

(d) What volume of 0.100 M HCl is required for the complete neutralization of 1.00 g Na_2CO_3(s)?

(e) A sample of NaOH contains a small amount of Na_2CO_3. For titration to the phenolphthalein end point, 0.1000 g of this sample requires 23.98 mL of 0.1000 M HCl. An additional 0.78 mL is required to reach the methyl orange end point. What is the percent Na_2CO_3, by mass, in the sample?

78. Piperazine is a diprotic weak base used as a corrosion inhibitor and an insecticide. Its ionization is described by the following equations.

$$HN(C_4H_8)\,NH + H_2O \rightleftharpoons [HN(C_4H_8)\,NH_2]^+ + OH^- \qquad pK_{b_1} = 4.22$$

$$[HN(C_4H_8)\,NH_2]^+ + H_2O \rightleftharpoons [H_2N(C_4H_8)\,NH_2]^{2+} + OH^- \qquad pK_{b_2} = 8.67$$

The piperazine used commercially is a hexahydrate, $C_4H_{10}N_2 \cdot 6H_2O$. A 1.00-g sample of this hexahydrate is dissolved in 100.0 mL of water and titrated with 0.500 M HCl. Sketch a titration curve for this titration, indicating **(a)** the initial pH; **(b)** the pH at the half-neutralization point of the first neutralization; **(c)** the volume of HCl(aq) required to reach the first equivalence point; **(d)** the pH at the first equivalence point; **(e)** the pH at the point at which the second step of the neutralization is half-completed; **(f)** the volume of 0.500 M HCl(aq) required to reach the second equivalence point of the titration; **(g)** the pH at the second equivalence point.

79. Complete the derivation of equation (17.5) outlined in Are You Wondering 17-1. Then derive equation (17.6).

80. Explain why equation (17.5) fails when applied to dilute solutions—for example, when you calculate the pH of 0.010 M NaH_2PO_4. [*Hint:* Refer also to Exercise 79.]

81. A solution is prepared that is 0.150 M CH_3COOH and 0.250 M NaHCOO.
(a) Show that this is a buffer solution.
(b) Calculate the pH of this buffer solution.
(c) What is the final pH if 1.00 L of 0.100 M HCl is added to 1.00 L of this buffer solution?

82. A series of titrations of lactic acid, $CH_3CH(OH)COOH$ ($pK_a = 3.86$) is planned. About 1.00 mmol of the acid will be titrated with NaOH(aq) to a final volume of about 100 mL at the equivalence point. **(a)** Which acid–base indicator from Figure 17-8 would you select for the titration? To assist in locating the equivalence point in the titration, a buffer solution is to be prepared having the same pH as that at the equivalence point. A few drops of the indicator in this buffer will produce the color to be matched in the titrations. **(b)** Which of the following combinations would be suitable for the buffer solutions: $CH_3COOH–CH_3COO^-$, $H_2PO_4^-–HPO_4^{2-}$, or $NH_4^+–NH_3$? **(c)** What ratio of conjugate base to acid is required in the buffer?

83. Hydrogen peroxide, H_2O_2, is a somewhat stronger acid than water. Its ionization is represented by the equation

$$H_2O_2 + H_2O \rightleftharpoons H_3O^+ + HO_2^-$$

In 1912, the following experiments were performed to obtain an approximate value of pK_a for this ionization at 0 °C. A sample of H_2O_2 was shaken together with a mixture of water and 1-pentanol. The mixture settled into two layers. At equilibrium, the hydrogen peroxide had distributed itself between the two layers such that the water layer contained 6.78 times as much H_2O_2 as the 1-pentanol layer. In a second experiment, a sample of H_2O_2 was shaken together with 0.250 M NaOH(aq) and 1-pentanol. At equilibrium, the concentration of H_2O_2 was 0.00357 M in the 1-pentanol layer and 0.259 M in the aqueous layer. In a third experiment, a sample of H_2O_2 was brought to equilibrium with a mixture of 1-pentanol and 0.125 M NaOH(aq); the concentrations of the hydrogen peroxide were 0.00198 M in the 1-pentanol and 0.123 M in the aqueous layer. For water at 0 °C, $pK_w = 14.94$. Find an approximate value of pK_a for H_2O_2 at 0 °C. [*Hint:* The hydrogen peroxide concentration in the aqueous layers is the total concentration of H_2O_2 and HO_2^-. Assume that the 1-pentanol solutions contain no ionic species.]

84. Sodium ammonium hydrogen phosphate, $NaNH_4HPO_4$, is a salt in which one of the ionizable H atoms of H_3PO_4 is replaced by Na^+, another is replaced by NH_4^+, and the third remains in the anion HPO_4^{2-}. Calculate the pH of 0.100 M $NaNH_4HPO_4$(aq).
[*Hint:* You can use the general method introduced on page 720. First, identify all the species that could be present and the equilibria involving these species. Then identify the two equilibrium expressions that will predominate and eliminate all the species whose concentrations are likely to be negligible. At that point, only a few algebraic manipulations are required.]

85. Consider a solution containing two weak monoprotic acids with dissociation constants K_{HA} and K_{HB}. Find the charge balance equation for this system, and use it to derive an expression that gives the concentration of H_3O^+ as a function of the concentrations of HA and HB and the various constants.

86. Calculate the pH of a solution that is 0.050 M acetic acid and 0.010 M phenylacetic acid.

87. A very common buffer agent used in the study of biochemical processes is the weak base TRIS, $(HOCH_2)_3\,CNH_2$, which has a pK_b of 5.91 at 25 °C. A student is given a sample of the hydrochloride of TRIS together with standard solutions of 10 M NaOH and HCl.
(a) Using TRIS, how might the student prepare 1 L of a buffer of pH = 7.79?
(b) In one experiment, 30 mmol of protons are released into 500 mL of the buffer prepared in part (a). Is the capacity of the buffer sufficient? What is the resulting pH?
(c) Another student accidentally adds 20 mL of 10 M HCl to 500 mL of the buffer solution prepared in part (a). Is the buffer ruined? If so, how could the buffer be regenerated?

88. The Henderson–Hasselbalch equation can be written as

$$\mathrm{pH} = \mathrm{p}K_a - \log\left(\frac{1}{\alpha} - 1\right) \text{ where } \alpha = \frac{[A^-]}{[A^-] + [HA]}.$$

Thus, the degree of ionization (α) of an acid can be determined if both the pH of the solution and the pK_a of the acid are known.
(a) Use this equation to plot the pH versus the degree of ionization for the second ionization constant of phosphoric acid ($K_a = 6.3 \times 10^{-8}$).
(b) If pH = pK_a what is the degree of ionization?
(c) If the solution had a pH of 6.0 what would the value of α be?

89. The pH of ocean water depends on the amount of atmospheric carbon dioxide. The dissolution of carbon dioxide in ocean water can be approximated by the following chemical reactions (Henry's Law constant for CO_2 is $K_H = [CO_2(aq)]/[CO_2(g)] = 0.8317$.):

$$CO_2(g) \rightleftharpoons CO_2(aq) \quad \textbf{(1)}$$

$$CaCO_3(s) \rightleftharpoons Ca^{2+}(aq) + CO_3^{-}(aq) \quad \textbf{(2)}$$

$$H_3O^+(aq) + CO_3^{-}(aq) \rightleftharpoons HCO_3^-(aq) + H_2O(l) \quad \textbf{(3)}$$

$$H_3O^+(aq) + HCO_3^-(aq) \rightleftharpoons CO_2(aq) + 2\,H_2O(l) \quad \textbf{(4)}$$

(a) Use the equations above to determine the hydronium ion concentration as a function of $[CO_2(g)]$ and $[Ca^{2+}]$.
(b) During preindustrial conditions, we will assume that the equilibrium concentration of $[CO_2(g)] = 280$ ppm and $[Ca^{2+}] = 10.24$ mM. Calculate the pH of a sample of ocean water.

90. A sample of water contains 23.0 g L^{-1} of Na^+(aq), 10.0 g L^{-1} of Ca^{2+}(aq), 40.2 g L^{-1} CO_3^{2-}(aq), and 9.6 g L^{-1} SO_4^{2-}(aq). What is the pH of the solution if the only other ions present are H_3O^+ and OH^-?

91. In 1922 Donald D. van Slyke (*J. Biol. Chem.*, **52**, 525) defined a quantity known as the buffer index: $\beta = dC_b/d(\mathrm{pH})$, where dC_b represents the increment of moles of strong base to one liter of the buffer. For the addition of a strong acid, he wrote $\beta = -dC_a/d(\mathrm{pH})$.

By applying this idea to a monoprotic acid and its conjugate base, we can derive the following expression:

$$\beta = 2.303\left(\frac{K_w}{[H_3O^+]} + [H_3O^+] + \frac{CK_a[H_3O^+]}{(K_a + [H_3O^+])^2}\right)$$

where C is the total concentration of monoprotic acid and conjugate base.

(a) Use the above expression to calculate the buffer index for the acetic acid buffer with a total acetic acid and acetate ion concentration of 2.0×10^{-2} and a $pH = 5.0$.

(b) Use the buffer index from part (a) and calculate the pH of the buffer after the addition of of a strong acid. (*Hint:* Let $dC_a/d(pH) \approx \Delta C_a/\Delta pH$.)

(c) Make a plot of β versus pH for a 0.1 M acetic acid buffer system. Locate the maximum buffer index as well as the minimum buffer indices.

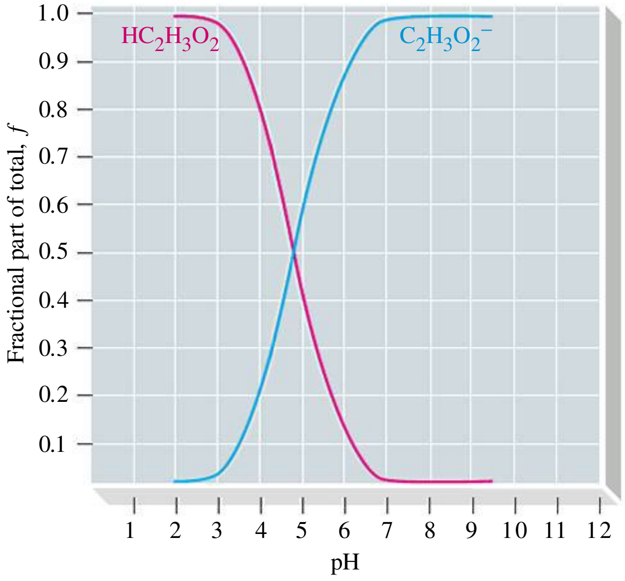
Feature Problems

92. The graph below, which is related to a titration curve, shows the fraction (f) of the stoichiometric amount of acetic acid present as non-ionized CH_3COOH and as acetate ion, CH_3COO^-, as a function of the pH of the solution containing these species.

(a) Explain the significance of the point at which the two curves cross. What are the fractions and the pH at that point?

(b) Sketch a comparable set of curves for carbonic acid, H_2CO_3. [*Hint:* How many carbonate-containing species should appear in the graph? How many points of intersection should there be? at what pH values?]

(c) Sketch a comparable set of curves for phosphoric acid, H_3PO_4. [*Hint:* How many phosphate-containing species should appear in the graph? How many points of intersection should there be? at what pH values?]

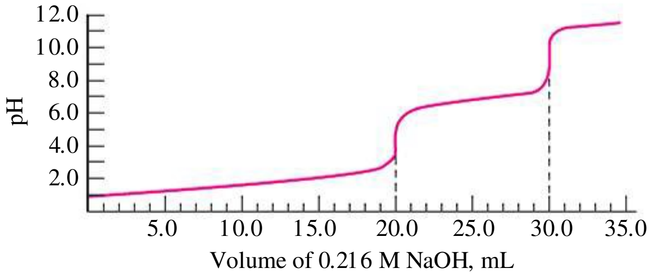


93. In some cases, the titration curve for a mixture of *two* acids has the same appearance as that for a single acid; in other cases it does not.

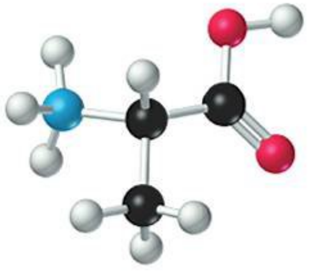
(a) Sketch the titration curve (pH versus volume of titrant) for the titration with 0.200 M NaOH of 25.00 mL of a solution that is 0.100 M in HCl and 0.100 M in HNO_3. Does this curve differ in any way from what would be obtained in the titration of 25.00 mL of 0.200 M HCl with 0.200 M NaOH? Explain.

(b) The titration curve shown was obtained when 10.00 mL of a solution containing both HCl and H_3PO_4 was titrated with 0.216 M NaOH. From this curve, determine the stoichiometric molarities of both the HCl and the H_3PO_4.

(c) A 10.00 mL solution that is 0.0400 M H_3PO_4 and 0.0150 M NaH_2PO_4 is titrated with 0.0200 M NaOH. Sketch the titration curve.

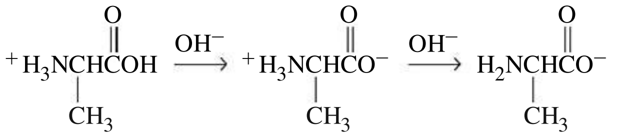


94. Amino acids contain both an acidic carboxylic acid group (—COOH) and a basic amino group (—NH_2). The amino group can be *protonated* (that is, it has an extra proton attached) in a strongly acidic solution. This produces a diprotic acid of the form H_2A^+, as exemplified by the protonated amino acid alanine.



Protonated alanine

The protonated amino acid has two ionizable protons that can be titrated with OH^-.



$${}^+H_3N\underset{CH_3}{\underset{|}{C}}H\overset{O}{\overset{\|}{C}}OH \xrightarrow{OH^-} {}^+H_3N\underset{CH_3}{\underset{|}{C}}H\overset{O}{\overset{\|}{C}}O^- \xrightarrow{OH^-} H_2N\underset{CH_3}{\underset{|}{C}}H\overset{O}{\overset{\|}{C}}O^-$$

Protonated form of alanine (H_2A^+)

Neutral form of alanine (HA)

Anionic form of alanine (A^-)

For the —COOH group, $pK_{a_1} = 2.34$; for the —NH_3^+ group, $pK_{a_2} = 9.69$. Consider the titration of a 0.500 M solution of alanine hydrochloride with

0.500 M NaOH solution. What is the pH of **(a)** the 0.500 M alanine hydrochloride; **(b)** the solution at the first half-neutralization point; **(c)** the solution at the first equivalence point?

The dominant form of alanine present at the first equivalence point is electrically neutral despite the positive charge and negative charge it possesses. The point at which the neutral form is produced is called the *isoelectric point*. Confirm that the pH at the isoelectric point is

$$\text{pH} = \frac{1}{2}(\text{p}K_{a_1} + \text{p}K_{a_2})$$

What is the pH of the solution **(d)** halfway between the first and second equivalence points? **(e)** at the second equivalence point?

(f) Calculate the pH values of the solutions when the following volumes of the 0.500 M NaOH have been added to 50 mL of the 0.500 M alanine hydrochloride solution: 10.0 mL, 20.0 mL, 30.0 mL, 40.0 mL, 50.0 mL, 60.0 mL, 70.0 mL, 80.0 mL, 90.0 mL, 100.0 mL, and 110.0 mL.

(g) Sketch the titration curve for the 0.500 M solution of alanine hydrochloride, and label significant points on the curve.

Self-Assessment Exercises

95. In your own words, define or explain the following terms or symbols: **(a)** mmol; **(b)** HIn; **(c)** equivalence point of a titration; **(d)** titration curve.

96. Briefly describe each of the following ideas, phenomena, or methods: **(a)** the common-ion effect; **(b)** the use of a buffer solution to maintain a constant pH; **(c)** the determination of pK_a of a weak acid from a titration curve; **(d)** the measurement of pH with an acid–base indicator.

97. Explain the important distinctions between each pair of terms: **(a)** buffer capacity and buffer range; **(b)** hydrolysis and neutralization; **(c)** first and second equivalence points in the titration of a weak diprotic acid; **(d)** equivalence point of a titration and end point of an indicator.

98. Write equations to show how each of the following buffer solutions reacts with a small added amount of a strong acid or a strong base: **(a)** HCOOH−KHCOO; **(b)** $C_6H_5NH_2-C_6H_5NH_3^+Cl^-$; **(c)** $KH_2PO_4-Na_2HPO_4$.

99. Sketch the titration curves that you would expect to obtain in the following titrations. Select a suitable indicator for each titration from Figure 17-8.
(a) NaOH(aq) titrated with HNO_3(aq)
(b) NH_3(aq) titrated with HCl(aq)
(c) CH_3COOH(aq) titrated with KOH(aq)
(d) NaH_2PO_4(aq) titrated with KOH(aq)

100. A 25.00-mL sample of 0.0100 M C_6H_5COOH ($K_a = 6.3 \times 10^{-5}$) is titrated with 0.0100 M $Ba(OH)_2$. Calculate the pH **(a)** of the initial acid solution; **(b)** after the addition of 6.25 mL of 0.0100 M $Ba(OH)_2$; **(c)** at the equivalence point; **(d)** after the addition of a total of 15.00 mL of 0.0100 M $Ba(OH)_2$.

101. To *repress* the ionization of formic acid, HCOOH(aq), which of the following should be added to the solution? **(a)** NaCl; **(b)** NaOH; **(c)** NaHCOO; **(d)** $NaNO_3$

102. To *increase* the ionization of formic acid, HCOOH(aq), which of the following should be added to the solution? **(a)** NaCl; **(b)** NaHCOO; **(c)** H_2SO_4; **(d)** $NaHCO_3$

103. To convert NH_4^+(aq) to NH_3(aq), **(a)** add H_3O^+; **(b)** raise the pH; **(c)** add KNO_3(aq); **(d)** add NaCl.

104. During the titration of equal concentrations of a weak base and a strong acid, at what point would the pH = pK_a? **(a)** the initial pH; **(b)** halfway to the equivalence point; **(c)** at the equivalence point; **(d)** past the equivalence point.

105. Calculate the pH of the buffer formed by mixing equal volumes $[C_2H_5NH_2] = 1.49$ M with $[HClO_4] = 1.001$ M. $K_b = 4.3 \times 10^{-4}$.

106. Calculate the pH of a 0.5 M solution of $Ca(HSe)_2$, given that H_2Se has $K_{a_1} = 1.3 \times 10^{-4}$ and $K_{a_2} = 1 \times 10^{-11}$.

107. The effect of adding 0.001 mol KOH to 1.00 L of a solution that is 0.10 M NH_3–0.10 M NH_4Cl is to **(a)** raise the pH very slightly; **(b)** lower the pH very slightly; **(c)** raise the pH by several units; **(d)** lower the pH by several units.

108. The most acidic of the following 0.10 M salt solutions is **(a)** Na_2S; **(b)** $NaHSO_4$; **(c)** $NaHCO_3$; **(d)** Na_2HPO_4.

109. If an indicator is to be used in an acid–base titration having an equivalence point in the pH range 8 to 10, the indicator must **(a)** be a weak base; **(b)** have $K_a = 1 \times 10^{-9}$; **(c)** ionize in two steps; **(d)** be added to the solution only after the solution has become alkaline.

110. Indicate whether you would expect the equivalence point of each of the following titrations to be below, above, or at pH **7.** Explain your reasoning. **(a)** $NaHCO_3$(aq) is titrated with NaOH(aq); **(b)** HCl(aq) is titrated with NH_3(aq); **(c)** KOH(aq) is titrated with HI(aq).

111. Using the method presented in Appendix E, construct a concept map relating the concepts in Sections 17-2, 17-3, and 17-4.

Stalactite and stalagmite formations in a cavern in the Guangxi Province, People's Republic of China. Stalactites and stalagmites are formed from calcium salts deposited as underground water seeps into the cavern and evaporates.

The dissolution and precipitation of limestone ($CaCO_3$) underlie a variety of natural phenomena, such as the formation of limestone caverns. Whether a solution containing Ca^{2+} and $CO_3{}^{2-}$ ions undergoes precipitation depends on the concentrations of these ions. In turn, the $CO_3{}^{2-}$ ion concentration depends on the pH of the solution. To develop a better understanding of the conditions under which $CaCO_3$ dissolves or precipitates, we must consider equilibrium relationships between Ca^{2+} and $CO_3{}^{2-}$, and between $CO_3{}^{2-}$, H_3O^+, and $HCO_3{}^-$. This requirement suggests a need to combine ideas about acid–base equilibria from Chapters 16 and 17 with ideas about the new types of equilibria to be introduced in this chapter.

Silver chloride is a familiar precipitate in the general chemistry laboratory, yet it does *not* precipitate from a solution that has a moderate to high concentration of $NH_3(aq)$. The silver ion and ammonia combine instead to form a species, called a *complex ion*, that remains in solution. Complex-ion formation and equilibria involving complex ions are additional topics discussed in this chapter.

18-1 Solubility Product Constant, K_{sp}

Gypsum ($CaSO_4 \cdot 2\,H_2O$) is a calcium mineral that is slightly soluble in water. Groundwater that comes into contact with gypsum often contains some dissolved calcium sulfate. This water cannot be used for certain applications, such as in evaporative cooling systems in power plants because the calcium sulfate might precipitate from the water and block pipes. The equilibrium between $Ca^{2+}(aq)$ and $SO_4{}^{2-}(aq)$ and undissolved $CaSO_4(s)$ can be represented as

$$CaSO_4(s) \rightleftharpoons Ca^{2+}(aq) + SO_4{}^{2-}(aq)$$

We can write the equilibrium constant expression for this equilibrium as we learned to do in Chapter 15 (page 659)—that is,

$$K = \frac{a_{Ca^{2+}} a_{SO_4{}^{2-}}}{a_{CaSO_4}}$$

The activity of a pure solid is 1. Because the concentrations of the ions are very small, we can set their activities equal to their molar concentrations. With these substitutions, we obtain expression (18.1).

$$K_{sp} = [Ca^{2+}][SO_4{}^{2-}] = 9.1 \times 10^{-6} \text{ (at 25 °C)} \qquad \textbf{(18.1)}$$

The **solubility product constant, K_{sp}**, is the constant for the equilibrium established between a solid solute and its ions in a saturated solution. Table 18.1 lists several K_{sp} values and the solubility equilibria to which they apply.

◀ Solubility products vary with temperature.

TABLE 18.1 Several Solubility Product Constants at 25 °C[a]

Solute	Solubility Equilibrium	K_{sp}
Aluminum hydroxide	$Al(OH)_3(s) \rightleftharpoons Al^{3+}(aq) + 3\,OH^-(aq)$	1.3×10^{-33}
Barium carbonate	$BaCO_3(s) \rightleftharpoons Ba^{2+}(aq) + CO_3{}^{2-}(aq)$	5.1×10^{-9}
Barium sulfate	$BaSO_4(s) \rightleftharpoons Ba^{2+}(aq) + SO_4{}^{2-}(aq)$	1.1×10^{-10}
Calcium carbonate	$CaCO_3(s) \rightleftharpoons Ca^{2+}(aq) + CO_3{}^{2-}(aq)$	2.8×10^{-9}
Calcium fluoride	$CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2\,F^-(aq)$	5.3×10^{-9}
Calcium sulfate	$CaSO_4(s) \rightleftharpoons Ca^{2+}(aq) + SO_4{}^{2-}(aq)$	9.1×10^{-6}
Chromium(III) hydroxide	$Cr(OH)_3(s) \rightleftharpoons Cr^{3+}(aq) + 3\,OH^-(aq)$	6.3×10^{-31}
Iron(III) hydroxide	$Fe(OH)_3(s) \rightleftharpoons Fe^{3+}(aq) + 3\,OH^-(aq)$	4×10^{-38}
Lead(II) chloride	$PbCl_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,Cl^-(aq)$	1.6×10^{-5}
Lead(II) chromate	$PbCrO_4(s) \rightleftharpoons Pb^{2+}(aq) + CrO_4{}^{2-}(aq)$	2.8×10^{-13}
Lead(II) iodide	$PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,I^-(aq)$	7.1×10^{-9}
Magnesium carbonate	$MgCO_3(s) \rightleftharpoons Mg^{2+}(aq) + CO_3{}^{2-}(aq)$	3.5×10^{-8}
Magnesium fluoride	$MgF_2(s) \rightleftharpoons Mg^{2+}(aq) + 2\,F^-(aq)$	3.7×10^{-8}
Magnesium hydroxide	$Mg(OH)_2(s) \rightleftharpoons Mg^{2+}(aq) + 2\,OH^-(aq)$	1.8×10^{-11}
Magnesium phosphate	$Mg_3(PO_4)_2(s) \rightleftharpoons 3\,Mg^{2+}(aq) + 2\,PO_4{}^{3-}(aq)$	1×10^{-25}
Mercury(I) chloride	$Hg_2Cl_2(s) \rightleftharpoons Hg_2{}^{2+}(aq) + 2\,Cl^-(aq)$	1.3×10^{-18}
Silver bromide	$AgBr(s) \rightleftharpoons Ag^+(aq) + Br^-(aq)$	5.0×10^{-13}
Silver carbonate	$Ag_2CO_3(s) \rightleftharpoons 2\,Ag^+(aq) + CO_3{}^{2-}(aq)$	8.5×10^{-12}
Silver chloride	$AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq)$	1.8×10^{-10}
Silver chromate	$Ag_2CrO_4(s) \rightleftharpoons 2\,Ag^+(aq) + CrO_4{}^{2-}(aq)$	1.1×10^{-12}
Silver iodide	$AgI(s) \rightleftharpoons Ag^+(aq) + I^-(aq)$	8.5×10^{-17}
Strontium carbonate	$SrCO_3(s) \rightleftharpoons Sr^{2+}(aq) + CO_3{}^{2-}(aq)$	1.1×10^{-10}
Strontium sulfate	$SrSO_4(s) \rightleftharpoons Sr^{2+}(aq) + SO_4{}^{2-}(aq)$	3.2×10^{-7}

[a] A more extensive listing of K_{sp} values is given in Appendix D.

EXAMPLE 18-1 Writing Solubility Product Constant Expressions for Slightly Soluble Solutes

Write the solubility product constant expression for the solubility equilibrium of

(a) Calcium fluoride, CaF_2 (one of the substances used when a fluoride treatment is applied to teeth)
(b) Copper arsenate, $Cu_3(AsO_4)_2$ (used as an insecticide and fungicide).

Analyze

The equation for the solubility equilibrium is written for one mole of the slightly soluble solute. That is, the coefficient "1" is understood for the slightly soluble solute. The coefficients for the ions in solution are whatever is needed to balance the equation. The coefficients then establish the powers to which the ion concentrations are raised in the K_{sp} expression.

Solve

(a) $CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2\,F^-(aq) \qquad K_{sp} = [Ca^{2+}][F^-]^2$

(b) $Cu_3(AsO_4)_2(s) \rightleftharpoons 3\,Cu^{2+}(aq) + 2\,AsO_4^{3-}(aq) \qquad K_{sp} = [Cu^{2+}]^3[AsO_4^{3-}]^2$

Assess

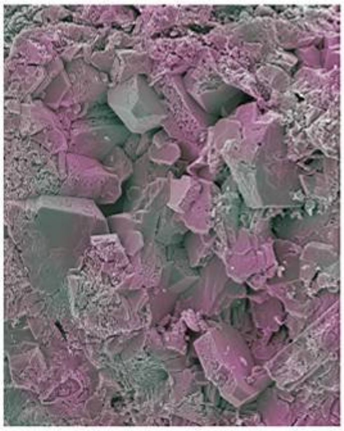
Note that the concentration of the reactant is not included in the K_{sp} expression. Recall that for the activity of a solid or a liquid we do not include its concentration in the equilibrium constant expression.

PRACTICE EXAMPLE A: Write the solubility product constant expression for **(a)** $MgCO_3$ (one of the components of dolomite, a form of limestone) and **(b)** Ag_3PO_4 (used in photographic emulsions).

PRACTICE EXAMPLE B: A handbook lists $K_{sp} = 1 \times 10^{-7}$ for calcium hydrogen phosphate, a substance used in dentifrices and as an animal feed supplement. Write **(a)** the equation for the solubility equilibrium and **(b)** the solubility product constant expression for this slightly soluble solute.

18-1 CONCEPT ASSESSMENT

A large excess of $MgF_2(s)$ is maintained in contact with 1.00 L of pure water to produce a saturated solution of MgF_2. When an additional 1.00 L of pure water is added to the mixture and equilibrium re-established, compared with the original saturated solution, will $[Mg^{2+}]$ be (a) the same; (b) twice as large; (c) half as large; (d) some unknown fraction of the original $[Mg^{2+}]$? Explain.



▲ Some calcium salts, such as calcium fluoride and calcium hydrogen phosphate, have beneficial uses, but another calcium salt, calcium oxalate (CaC_2O_4), can be harmful. The photo is a scanning electron microscope image of calcium oxalate crystals, a common type of kidney stone that can form in the human kidney.

18-2 Relationship Between Solubility and K_{sp}

Is there a relationship between the solubility product constant, K_{sp}, of a solute and the solute's *molar solubility*—its molarity in a saturated aqueous solution? As shown in Examples 18-2 and 18-3, there is a definite relationship between them. As discussed in Section 18-4, calculations involving K_{sp} are generally more subject to error than are those involving other equilibrium constants, but the results are suitable for many purposes. In Example 18-2, we start with an experimentally determined solubility and obtain a value of K_{sp}.

The "inverse" of Example 18-2 is the calculation of the solubility of a solute from its K_{sp} value. When this is done, as in Example 18-3, the result is always a molar solubility—a molarity. Additional conversions are required to obtain solubility in units other than moles per liter, as in Practice Example 18-3B.

EXAMPLE 18-2 Calculating K_{sp} of a Slightly Soluble Solute from Its Solubility

A handbook lists the aqueous solubility of $CaSO_4$ at 25 °C as 0.20 g $CaSO_4$/100 mL. What is the K_{sp} of $CaSO_4$ at 25 °C?

$$CaSO_4(s) \rightleftharpoons Ca^{2+}(aq) + SO_4^{2-}(aq) \qquad K_{sp} = ?$$

Analyze

We need to construct a conversion pathway that begins with finding $[Ca^{2+}]$ and $[SO_4^{2-}]$, which we can then substitute into the K_{sp} expression.

$$\text{g } CaSO_4/100\text{ mL} \longrightarrow \text{mol } CaSO_4/\text{L} \longrightarrow [Ca^{2+}] \text{ and } [SO_4^{2-}] \longrightarrow K_{sp}$$

Solve

The first step is to convert the mass of $CaSO_4$ in a 100 mL volume to molar solubility. This is accomplished by using the inverse of the molar mass of $CaSO_4$ and replacing 100 mL with 0.100 L.

$$\frac{\text{mol } CaSO_4}{\text{L satd soln}} = \frac{0.20\text{ g } CaSO_4}{0.100\text{ L soln}} \times \frac{1\text{ mol } CaSO_4}{136\text{ g } CaSO_4}$$
$$= 0.015\text{ M } CaSO_4$$

Using stoichiometric ratios (shown in blue), determine $[Ca^{2+}]$ and $[SO_4^{2-}]$.

$$[Ca^{2+}] = \frac{0.015\text{ mol } CaSO_4}{1\text{ L}} \times \frac{1\text{ mol } Ca^{2+}}{1\text{ mol } CaSO_4} = 0.015\text{ M}$$
$$[SO_4^{2-}] = \frac{0.015\text{ mol } CaSO_4}{1\text{ L}} \times \frac{1\text{ mol } SO_4^{2-}}{1\text{ mol } CaSO_4} = 0.015\text{ M}$$

Substitute these ion concentrations into the solubility product expression.

$$K_{sp} = [Ca^{2+}][SO_4^{2-}] = (0.015)(0.015) = 2.3 \times 10^{-4}$$

Assess

The K_{sp} result determined here is significantly different from the value in equation (18.1). The reason for this discrepancy is that ion activities need to be taken into account.

PRACTICE EXAMPLE A: A handbook lists the aqueous solubility of AgOCN as 7 mg/100 mL at 20 °C. What is the K_{sp} of AgOCN at 20 °C?

PRACTICE EXAMPLE B: A handbook lists the aqueous solubility of lithium phosphate at 18 °C as 0.034 g Li_3PO_4/100 mL soln. What is the K_{sp} of Li_3PO_4 at 18 °C?

EXAMPLE 18-3 Calculating the Solubility of a Slightly Soluble Solute from Its K_{sp} Value

Lead(II) iodide, PbI_2, is a dense, golden yellow, "insoluble" solid used in bronzing and in ornamental work requiring a golden color (such as mosaic gold). Calculate the molar solubility of lead(II) iodide in water at 25 °C, given that $K_{sp} = 7.1 \times 10^{-9}$.

Analyze

The solubility equilibrium equation

$$PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,I^-(aq)$$

shows that for each mole of PbI_2 that dissolves, *one* mole of Pb^{2+} and *two* moles of I^- appear in solution. If we let s represent the number of moles of PbI_2 dissolved per liter of saturated solution, we have

$$[Pb^{2+}] = s \quad \text{and} \quad [I^-] = 2s$$

(continued)

Solve

These concentrations must also satisfy the K_{sp} expression.

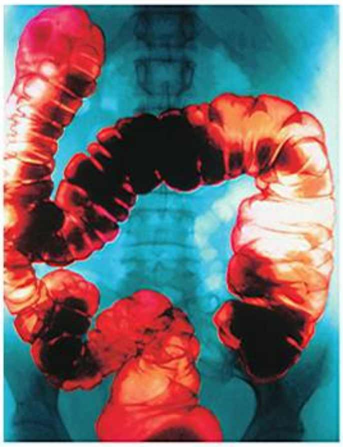
$$\begin{aligned} K_{sp} &= [Pb^{2+}][I^-]^2 = (s)(2s)^2 = 7.1 \times 10^{-9} \\ 4s^3 &= 7.1 \times 10^{-9} \\ s^3 &= 1.8 \times 10^{-9} \\ s &= (1.8 \times 10^{-9})^{1/3} = 1.2 \times 10^{-3} \\ &= \text{molar solubility of } PbI_2 = 1.2 \times 10^{-3}\,M \end{aligned}$$

Assess

One key part of this problem is making sure that we account for the correct number of moles of each species. In this case we had 2 moles of iodide ion for every 1 mole of lead.

PRACTICE EXAMPLE A: The K_{sp} of $Cu_3(AsO_4)_2$ at 25 °C is 7.6×10^{-36}. What is the molar solubility of $Cu_3(AsO_4)_2$ in H_2O at 25 °C?

PRACTICE EXAMPLE B: How many milligrams of $BaSO_4$ are dissolved in a 225 mL sample of saturated $BaSO_4(aq)$? $K_{sp} = 1.1 \times 10^{-10}$.



▲ Barium sulfate, $BaSO_4$, is a good absorber of X-rays. As a component of a “barium milk shake,” $BaSO_4$ coats the intestinal tract so that this soft tissue will show up when X-rayed. Even though $Ba^{2+}(aq)$ is poisonous, $BaSO_4(s)$ is harmless because its aqueous solubility is very low.

18-1 ARE YOU WONDERING...

When comparing molar solubilities, is a solute with a larger value of K_{sp} always more soluble than one with a smaller value?

If the solutes being compared are of the same type (for example, all are of the type MX or all are of the type, MX_2), their molar solubilities will be related in the same way to their K_{sp} values. Then, the solute with the largest K_{sp} value will have the greatest molar solubility. Thus, AgCl ($K_{sp} = 1.8 \times 10^{-10}$) is more soluble than AgBr ($K_{sp} = 5.0 \times 10^{-13}$). For these particular solutes, the molar solubility is $s = \sqrt{K_{sp}}$.

If the solutes are *not* of the same type, you'll have to calculate, or at least estimate, each molar solubility and compare the results. Thus, even though its solubility product constant is smaller, Ag_2CrO_4 ($K_{sp} = 1.1 \times 10^{-12}$) is more soluble than AgCl ($K_{sp} = 1.8 \times 10^{-10}$). For Ag_2CrO_4, the molar solubility is $s = (K_{sp}/4)^{1/3} = 6.5 \times 10^{-5}$ M, whereas for AgCl, it is $s = \sqrt{K_{sp}} = 1.3 \times 10^{-5}$ M.

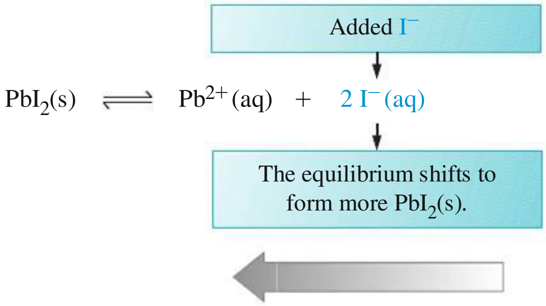
18-2 CONCEPT ASSESSMENT

Of the compounds CaF_2, $CaCl_2$, AgF, and AgCl, which would be considered insoluble? Explain.

18-3 Common-Ion Effect in Solubility Equilibria

In Examples 18-2 and 18-3, the ions in the saturated solutions came from a single source, the pure solid solute. Suppose that to the saturated solution of PbI_2 in Example 18-3, we add some I^-—a *common ion*—from a source such as KI(aq). The situation is similar to our first encounter with the common-ion effect in Chapter 17.

According to Le Châtelier's principle, an equilibrium mixture responds to a forced increase in the concentration of one of its reactants by shifting in the direction in which that reactant is consumed. In the lead(II) iodide solubility equilibrium, addition of the common ion, I^-, causes the reverse reaction to be favored, leading to a new equilibrium.



$$PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,I^-(aq)$$

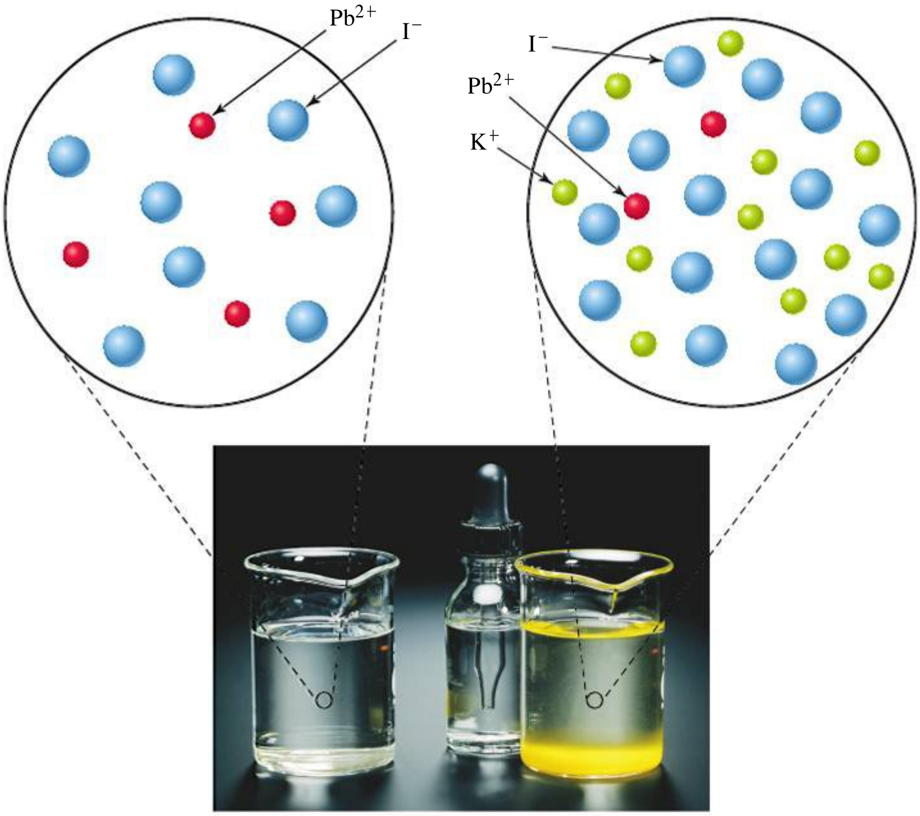
The addition of the common ion shifts the equilibrium of a slightly soluble ionic compound toward the undissolved compound, causing more to precipitate. Thus, the solubility of the compound is reduced.

The solubility of a slightly soluble ionic compound is lowered in the presence of a second solute that furnishes a common ion.

The common-ion effect is illustrated in Figure 18-1, and it is applied quantitatively in Example 18-4.

The solubility of PbI_2 in the presence of 0.10 M I^-, as calculated in Example 18-4, is about 2000 times less than its value in pure water (Example 18-3). If you work out Practice Example 18-4A, you will see that the effect of added Pb^{2+} in reducing the solubility of PbI_2 is not as striking as that of I^-, but it is significant nevertheless.

◀ Here K^+ does not take part in the process and is generally not included in the solubility equations. Such ions must always be present to ensure electrical neutrality of the solution. These ions are sometimes called "spectator ions."



(a)

(b)

◀ FIGURE 18-1
The common-ion effect in solubility equilibrium
(a) A clear saturated solution of lead(II) iodide from which excess undissolved solute has been filtered off. **(b)** When a small volume of a concentrated solution of KI (containing the common ion, I^-) is added, a small quantity of $PbI_2(s)$ precipitates. A common ion reduces the solubility of a sparingly soluble solute.

EXAMPLE 18-4 Calculating the Solubility of a Slightly Soluble Solute in the Presence of a Common Ion

What is the molar solubility of PbI_2 in 0.10 M KI(aq)?

Analyze

To solve this problem, let's set up an ICE table with s instead of x to represent changes in concentrations. Think of producing a saturated solution of PbI_2, but instead of using pure water as the solvent, we will use 0.10 M KI(aq). Thus, we begin with $[I^-] = 0.10\ M$. Now let s represent the amount of PbI_2, in moles, that dissolves to produce 1 L of saturated solution. The additional concentrations appearing in this solution are s mol Pb^{2+}/L and $2s$ mol I^-/L.

Solve

The ICE table is

	$PbI_2(s) \rightleftharpoons$	$Pb^{2+}(aq)$ +	$2\,I^-(aq)$
initial concns, M:			0.10
from PbI_2, M:		s	$2s$
equil concns, M:		s	$(0.10 + 2s)$

The usual K_{sp} relationship must be satisfied.

$$K_{sp} = [Pb^{2+}][I^-]^2 = (s)(0.10 + 2s)^2 = 7.1 \times 10^{-9}$$

To simplify the solution to this equation, let's assume that s is much smaller than 0.10 M, so that $0.10 + 2s \approx 0.10$.

$$s(0.10)^2 = 7.1 \times 10^{-9}$$

$$s = \frac{7.1 \times 10^{-9}}{(0.10)^2} = 7.1 \times 10^{-7}\ M = \text{molar solubility of } PbI_2$$

Assess

Our assumption is well justified: 7.1×10^{-7} is much smaller than 0.10.

PRACTICE EXAMPLE A: What is the molar solubility of PbI_2 in 0.10 M $Pb(NO_3)_2(aq)$? [*Hint:* To which ion concentration should the solubility be related?]

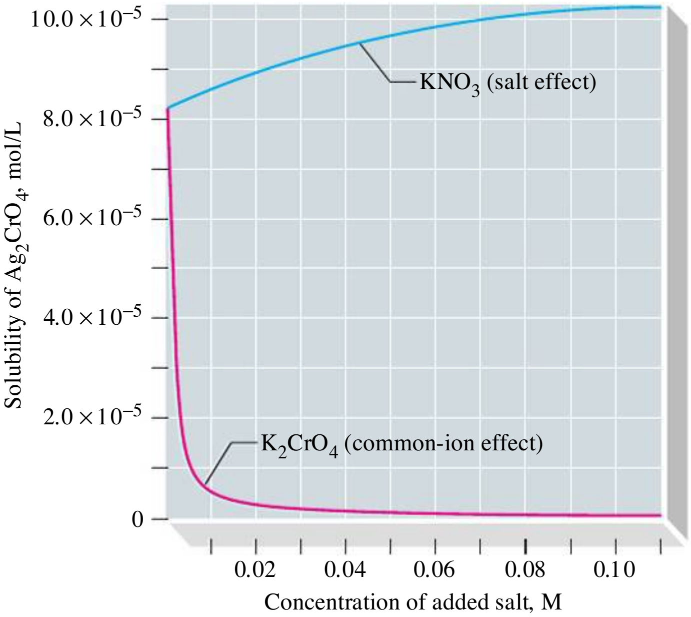
PRACTICE EXAMPLE B: What is the molar solubility of $Fe(OH)_3$ in a buffered solution with pH = 8.20?

A typical error in such problems as Example 18-4 is to double the common-ion concentration—that is, to write $[I^-] = (2 \times 0.10)$ M instead of $[I^-] = 0.10$ M. Although it is true that in *any* aqueous solution of PbI_2, the $[I^-]$ derived from PbI_2 is *twice* the molarity of the PbI_2, the $[I^-]$ that comes from a soluble strong electrolyte is determined only by the molarity of the strong electrolyte. Thus, $[I^-]$ in 0.10 M KI(aq) is 0.10 M. In 0.10 M KI(aq) that is also saturated with PbI_2, the *total* $[I^-] = (0.10 + 2s)$ M. In short, no relationship exists between the stoichiometry of the dissolution of PbI_2, which requires a factor of 2 in establishing $[I^-]$, and that of KI, which does not.

18-4 Limitations of the K_{sp} Concept

We have repeatedly used the term *slightly soluble* in describing the solutes for which we have written K_{sp} expressions. You might wonder if we can write K_{sp} expressions for moderately or highly soluble ionic compounds, such as NaCl, KNO_3, and NaOH. The answer is yes, but the K_{sp} must be based on ion *activities* rather than on concentrations. In ionic solutions of moderate to high concentrations, activities and concentrations are generally far from equal (recall Section 13-9). For example, in 0.1 M KCl(aq) the activity is roughly 24% of the molarity. If we cannot use molarities in place of activities, much of the simplicity of the solubility product concept is lost. Thus, K_{sp}

▶ The difference between stoichiometric concentration and effective concentration increases as more solute is dissolved in the solvent. There are no interactions between solute particles in an ideal solution where stoichiometric and effective concentrations are equal. These interactions increase as more solute is dissolved.



◀ FIGURE 18-2

Comparison of the common-ion effect and the salt effect on the molar solubility of Ag_2CrO_4

The presence of CrO_4^{2-} ions, derived from $K_2CrO_4(aq)$, reduces the solubility of Ag_2CrO_4 by a factor of about 35 over the concentration range shown (from 0 to 0.10 M added salt). Over the same concentration range, the solubility of Ag_2CrO_4 is increased by the presence of the diverse ions from KNO_3, but only by about 25%

values are usually limited to slightly soluble (essentially insoluble) solutes, and ion molarities are used in place of activities. In addition, the K_{sp} concept has several other limitations, which are discussed in the following sections.

The Diverse Noncommon Ion Effect: The Salt Effect

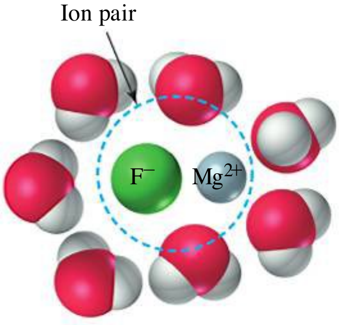
We have explored the effect of common ions on a solubility equilibrium, but what effect do ions different from those involved in the equilibrium have on solute solubilities? The effect of "noncommon" or *diverse* ions is not as striking as the common-ion effect. Moreover, diverse ions tend to increase rather than decrease solubility. As the total ionic concentration of a solution increases, interionic attractions become more important. *Activities* (effective concentrations) *become smaller* than the stoichiometric concentration. For the ions involved in the solution process, this means that higher concentrations must appear in solution before equilibrium is established—the *solubility increases*. Figure 18-2 compares the effects of common ions and diverse ions.

The diverse ion effect is more commonly called the **salt effect**. As a result of the salt effect, the numerical value of a K_{sp} based on molarities will vary depending on the ionic atmosphere. Most tabulated values of K_{sp} are based on activities rather than on molarities, thus avoiding the problem of the salt effect.

Incomplete Dissociation of Solute into Ions

In performing calculations involving K_{sp} values and solubilities, we have assumed that all the dissolved solute appears in solution as separated cations and anions. However, this assumption is often not valid. The solute might not be 100% ionic, and some of the solute might enter solution in molecular form. Alternatively, some ions in solution might join together into **ion pairs**. An ion pair is two oppositely charged ions that are held together by the electrostatic attraction between the ions. For example, in a saturated solution of magnesium fluoride, although most of the solute exists as Mg^{2+} and F^- ions, some exists as the ion pair MgF^+.

To the extent that a solution contains cations and anions of a solute as ion pairs, the concentrations of the dissociated ions are reduced from the stoichiometric expectations. Thus, although the measured solubility of MgF_2 is about 4×10^{-3} M, we cannot safely assume that $[Mg^{2+}] = 4 \times 10^{-3}$ M, and that $[F^-] = 8 \times 10^{-3}$ M, because some of the Mg^{2+} and F^- ions are involved



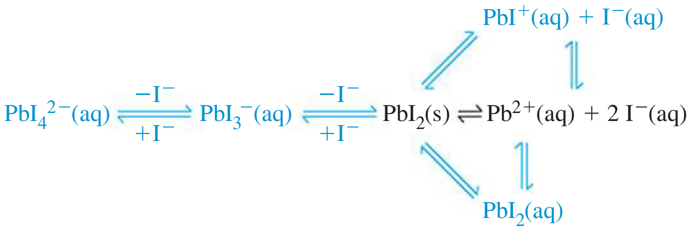
▲ An ion pair, MgF^+, in a magnesium fluoride aqueous solution. The water molecules surrounding the ion pair form what is referred to as a solvent cage.

in ion pairing. This means that additional solute must be present for the product of ion concentrations to equal K_{sp} of the solute, making the true solubility of the solute greater than otherwise expected on the basis of K_{sp}.

The degree of ion-pair formation increases as mutual electrostatic attraction of the anion and cation increases. Hence, ion-pair formation is increasingly likely when the cations or anions in solution carry multiple charges (for example, Mg^{2+} or SO_4^{2-}).

Simultaneous Equilibria

The reversible reaction between a solid solute and its ions in aqueous solution is never the sole process occurring. At the very least, the self-ionization of water also occurs, although we can generally ignore it. Other equilibrium processes that may occur include reactions between solute ions and other solution species. Two possibilities are acid–base reactions (Section 18-7) and complex-ion formation (Section 18-8). Calculations based on the K_{sp} expression may be in error if we fail to take into account other equilibrium processes that occur simultaneously with solution equilibrium. We have encountered the dissolution of $PbI_2(s)$ several times already in this chapter. However, the dissolution process is, in fact, a lot more complex than we've shown. As suggested below, there are many competing processes:



Assessing the Limitations of K_{sp}

Let's assess the importance of the effects discussed in this section, some of which apply to $CaSO_4$. Recall that in Example 18-2 we calculated K_{sp} for $CaSO_4$ on the basis of its measured solubility. Our result was $K_{sp} = 2.3 \times 10^{-4}$. This value is about 25 times larger than the value listed in Table 18.1, which is $K_{sp} = 9.1 \times 10^{-6}$.

These conflicting results for $CaSO_4$ are understandable. The K_{sp} value listed in Table 18.1 is based on ion activities, whereas the K_{sp} value calculated from the experimentally determined solubility is based on ion concentrations, assuming complete dissociation of the solute into ions and no ion-pair formation. We will continue to substitute molarities for activities of ions, and the case of $CaSO_4$ simply suggests that some of our results, although of the appropriate general magnitude (that is, within a factor of 10 or 100), may not be highly accurate. These order-of-magnitude results, however, still allow us to make some correct predictions and to apply the K_{sp} concept in useful ways.

18-5 Criteria for Precipitation and Its Completeness

Silver iodide is a light-sensitive compound used in photographic film and also in cloud seeding to produce rain. Its solubility equilibrium and K_{sp} are represented as

$$AgI(s) \rightleftharpoons Ag^+(aq) + I^-(aq)$$
$$K_{sp} = [Ag^+][I^-] = 8.5 \times 10^{-17}$$

Suppose we mix solutions of $AgNO_3(aq)$ and KI(aq) to obtain a mixed solution that has $[Ag^+] = 0.010\ M$ and $[I^-] = 0.015\ M$. Is this solution unsaturated, saturated, or supersaturated?

Recall the reaction quotient, Q, that was introduced in Chapter 15. It has the same form as an equilibrium constant expression but uses initial concentrations rather than equilibrium concentrations. Initially,

$$Q_{sp} = [Ag^+]_{init} \times [I^-]_{init} = (0.010)(0.015) = 1.5 \times 10^{-4} > K_{sp}$$

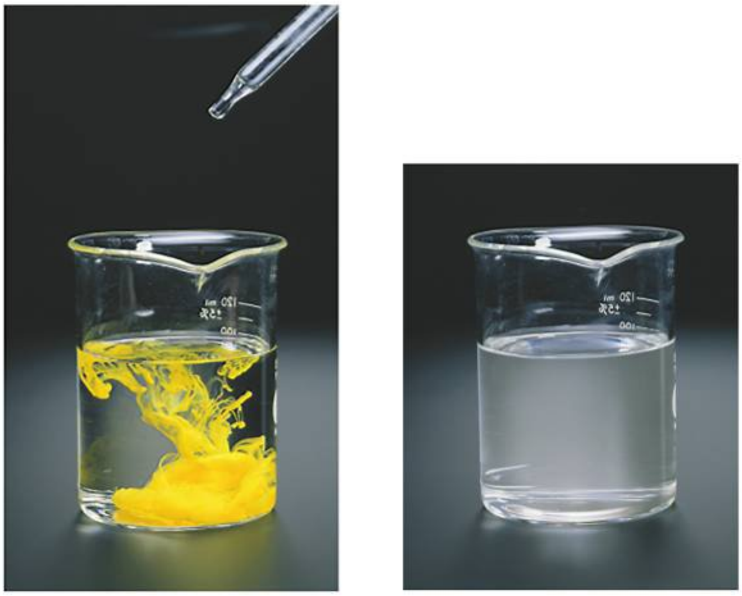
The fact that $Q_{sp} > K_{sp}$ indicates that the concentrations of Ag^+ and I^- are already higher than they would be in a saturated solution and that a net change should occur to the left. The solution is *supersaturated*. As is generally the case with supersaturated solutions, excess AgI should precipitate from solution. If we had found $Q_{sp} < K_{sp}$, the solution would have been *unsaturated*. No precipitate would form from such a solution.

When applied to solubility equilibria, $\boldsymbol{Q_{sp}}$ is generally called the **ion product** because its form is that of the product of ion concentrations raised to appropriate powers. The criteria for determining whether ions in a solution will combine to form a precipitate require us to compare the ion product with K_{sp}.

- Precipitation *should occur* if $Q_{sp} > K_{sp}$.
- Precipitation *cannot occur* if $Q_{sp} < K_{sp}$.
- A solution is just saturated if $Q_{sp} = K_{sp}$.

These criteria are illustrated in Figure 18-3 and Example 18-5. The example emphasizes the important point that *any possible dilutions must be considered before the criteria for precipitation are applied.*

Precipitation of a solute is considered to be complete only if the amount of solute remaining in solution is very small. An arbitrary rule of thumb is that



(a) (b)

▲ FIGURE 18-3

Applying the criteria for precipitation from solution—Example 18-5 illustrated

(a) When three drops of 0.20 M KI are first added to 100.0 mL of 0.010 M $Pb(NO_3)_2$, a precipitate forms because K_{sp} is exceeded in the immediate vicinity of the drops. **(b)** When the KI becomes uniformly mixed in the $Pb(NO_3)_2(aq)$, K_{sp} is no longer exceeded and the precipitate redissolves. The criteria for precipitation must be applied *after* dilution has occurred.

precipitation is complete if 99.9% or more of a particular ion has precipitated, leaving less than 0.1% of the ion in solution. In Example 18-6, we will calculate the concentration of Mg^{2+} that remains in a solution from which $Mg(OH)_2(s)$ has precipitated. We will compare this remaining $[Mg^{2+}]$ to the initial $[Mg^{2+}]$ to determine the completeness of the precipitation.

EXAMPLE 18-5 Applying the Criteria for Precipitation of a Slightly Soluble Solute

Three drops of 0.20 M KI are added to 100.0 mL of 0.010 M $Pb(NO_3)_2$. Will a precipitate of lead(II) iodide form? (Assume 1 drop = 0.05 mL.)

$$PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,I^-(aq) \qquad K_{sp} = 7.1 \times 10^{-9}$$

Analyze

We need to compare the product $[Pb^{2+}][I^-]^2$ formulated for the initial concentrations with the K_{sp} for PbI_2. For $[Pb^{2+}]$, the dilution caused by adding 3 drops (0.15 mL = 0.00015 L) to 0.100 L of solution is negligible and so we can simply use 0.010 M. For $[I^-]$, however, we must consider the great reduction in concentration that occurs when the three drops of 0.20 M KI are diluted to 100.0 mL.

Solve

Dilution Calculation:

$$\text{amount } I^- = 3\text{ drops} \times \frac{0.05\text{ mL}}{1\text{ drop}} \times \frac{1\text{ L}}{1000\text{ mL}} \times \frac{0.20\text{ mol KI}}{\text{L}} \times \frac{1\text{ mol } I^-}{1\text{ mol KI}} = 3 \times 10^{-5}\text{ mol } I^-$$

$$\text{Total volume} = 0.1000\text{ L} + \left(3\text{ drops} \times \frac{0.05\text{ mL}}{\text{drop}} \times \frac{1\text{ L}}{1000\text{ mL}}\right) = 0.1002\text{ L}$$

$$[I^-] = \frac{3 \times 10^{-5}\text{ mol } I^-}{0.1002\text{ L}} = 3 \times 10^{-4}\text{ M}$$

Applying Precipitation Criteria:

$$Q_{sp} = [Pb^{2+}][I^-]^2 = (0.010)(3 \times 10^{-4})^2 = 9 \times 10^{-10}$$

Because a Q_{sp} of 9×10^{-10} is *smaller than* a K_{sp} of 7.1×10^{-9}, we conclude that $PbI_2(s)$ should *not* precipitate.

Assess

In this calculation, as well as problems similar to this one, any possible dilutions must be considered *before* the criteria for precipitation are applied. Note that the addition of the three drops of KI(aq) does not change the value of $[Pb^{2+}]$: $0.010\text{ M} \times (0.1000\text{ L}/0.1002\text{ L}) = 0.010\text{ M}$ (two significant figures).

PRACTICE EXAMPLE A: Three drops of 0.20 M KI are added to 100.0 mL of a 0.010 M solution of $AgNO_3$. Will a precipitate of silver iodide form?

PRACTICE EXAMPLE B: We saw in Example 18-5 that a 3-drop volume of 0.20 M KI is insufficient to cause precipitation in 100.0 mL of 0.010 M $Pb(NO_3)_2$. What minimum number of drops would be required to produce the first precipitate?

EXAMPLE 18-6 Assessing the Completeness of a Precipitation Reaction

The first step in a commercial process in which magnesium is obtained from seawater involves precipitating Mg^{2+} as $Mg(OH)_2(s)$. The magnesium ion concentration in seawater is about 0.059 M. If a seawater sample is treated so that its $[OH^-]$ is maintained at 2.0×10^{-3} M, **(a)** what will be $[Mg^{2+}]$ remaining in solution when precipitation stops ($K_{sp} = 1.8 \times 10^{-11}$)? **(b)** Is the precipitation of $Mg(OH)_2(s)$ complete under these conditions?

Analyze

In part (a) of this example we compare the Q_{sp} of the solution with the known K_{sp} for $Mg(OH)_2$ to determine whether precipitation will occur. If it will, then precipitation of $Mg(OH)_2(s)$ will continue as long as the ion product exceeds K_{sp} and will stop when that product is equal to K_{sp}. At the point at which the ion product equals K_{sp}, whatever Mg^{2+} is in solution remains in solution. In part (b) we need to compare the amount of Mg^{2+} remaining after precipitation with the original amount.

Solve

(a) There is no question that precipitation will occur, because the ion product $Q_{sp} = [Mg^{2+}][OH^-]^2 = (0.059)(2.0 \times 10^{-3})^2 = 2.4 \times 10^{-7}$ exceeds K_{sp}.

$$[Mg^{2+}][OH^-]^2 = [Mg^{2+}](2.0 \times 10^{-3})^2 = 1.8 \times 10^{-11} = K_{sp}$$

$$[Mg^{2+}]_{\text{remaining}} = \frac{1.8 \times 10^{-11}}{(2.0 \times 10^{-3})^2} = 4.5 \times 10^{-6}\ \text{M}$$

(b) $[Mg^{2+}]$ in seawater is reduced from 0.059 M to 4.5×10^{-6} M as a result of the precipitation reaction. Expressed as a percentage,

$$\%[Mg^{2+}]_{\text{remaining}} = \frac{4.5 \times 10^{-6}\ \text{M}}{0.059\ \text{M}} \times 100\% = 0.0076\%$$

Because less than 0.1% of the Mg^{2+} remains, we conclude that precipitation is essentially complete.

Assess

Because $[OH^-]$ is maintained at a constant value, the calculation of $[Mg^{2+}]_{\text{remaining}}$ is straightforward. (A method of maintaining a constant $[OH^-]$ during a precipitation is to carry out the precipitation from a buffer solution.) If $[OH^-]$ was initially 2.0×10^{-3} M but with no source of OH^- to replenish it, $[Mg^{2+}]_{\text{remaining}}$ would be 0.058 M. Verify this result yourself.

PRACTICE EXAMPLE A: A typical Ca^{2+} concentration in seawater is 0.010 M. Will the precipitation of $Ca(OH)_2$ be complete from a seawater sample in which $[OH^-]$ is maintained at 0.040 M?

PRACTICE EXAMPLE B: What $[OH^-]$ should be maintained in a solution if, after precipitation of Mg^{2+} as $Mg(OH)_2(s)$, the remaining Mg^{2+} is to be at a level of 1 $\mu g\ Mg^{2+}/L$?

18-2 ARE YOU WONDERING...

What conditions favor completeness of precipitation?

The key factors in determining whether the target ion is essentially completely removed from solution in a precipitation are (1) the value of K_{sp}, (2) the initial concentration of the target ion, and (3) the concentration of the common ion. In general, completeness of precipitation is favored by

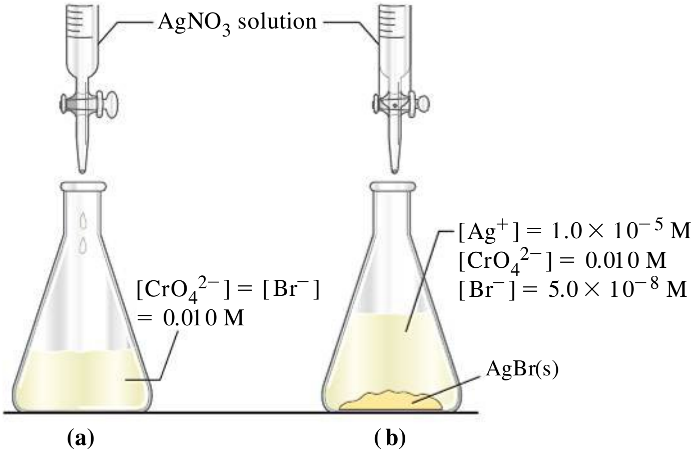
- *a very small value of K_{sp}.* (The concentration of the target ion remaining in solution will be very small.)
- *a high initial concentration of the target ion.* (The concentration of the target ion remaining in solution will be only a very small fraction of the initial value.)
- *a concentration of common ion much larger than that of the target ion.* (The common-ion concentration will remain nearly constant during the precipitation.)

18-6 Fractional Precipitation

If a large excess of $AgNO_3(s)$ is added to a solution containing the ions CrO_4^{2-} and Br^-, a mixed precipitate of $Ag_2CrO_4(s)$ and $AgBr(s)$ is obtained. There is a method of adding $AgNO_3$, however, that will cause $AgBr(s)$ to precipitate but leave CrO_4^{2-} in solution. That method is fractional precipitation.

Fractional precipitation is a technique in which two or more ions in solution, each capable of being precipitated by the same reagent, are separated by the proper use of that reagent: *One ion is precipitated, while the other(s) remains in solution.* The primary condition for a successful fractional precipitation is

◀ Fractional precipitation is also called *selective precipitation.*



▶ FIGURE 18-4
Fractional precipitation—Example 18-7 illustrated
(a) $AgNO_3(aq)$ is slowly added to a solution that is 0.010 M in Br^- and 0.010 M in CrO_4^{2-}. **(b)** Essentially all the Br^- has precipitated as pale yellow AgBr(s), with $[Br^-]$ in solution $= 5.0 \times 10^{-8}$ M. Red-brown $Ag_2CrO_4(s)$ is just about to precipitate.

that there be a significant difference in the solubilities of the substances being separated. (Usually this means a significant difference in their K_{sp} values.) The key to the technique is the slow addition of a concentrated solution of the precipitating reagent to the solution from which precipitation is to occur, as from a buret (Fig. 18-4).

Example 18-7 considers the separation of $CrO_4^{2-}(aq)$ and $Br^-(aq)$ through the use of $Ag^+(aq)$.

EXAMPLE 18-7 Separating Ions by Fractional Precipitation

$AgNO_3(aq)$ is slowly added to a solution that has $[CrO_4^{2-}] = 0.010$ M and $[Br^-] = 0.010$ M.

(a) Show that AgBr(s) should precipitate before $Ag_2CrO_4(s)$ does.
(b) When $Ag_2CrO_4(s)$ begins to precipitate, what is $[Br^-]$ remaining in solution?
(c) Is complete separation of $Br^-(aq)$ and $CrO_4^{2-}(aq)$ by fractional precipitation feasible?

Analyze

First, write equations for the solubility equilibria and look up the corresponding K_{sp} values.

$$Ag_2CrO_4(s) \rightleftharpoons 2\,Ag^+(aq) + CrO_4^{2-}(aq) \qquad K_{sp} = 1.1 \times 10^{-12}$$
$$AgBr(s) \rightleftharpoons Ag^+(aq) + Br^-(aq) \qquad K_{sp} = 5.0 \times 10^{-13}$$

Next we determine the concentration of silver ion needed to precipitate either AgBr(s) or $Ag_2CrO_4(s)$. The one that requires the least amount of silver ion will precipitate first. The formation of the first precipitate helps keep $[Ag^+]$ below that required to form the second precipitate; $[Ag^+]$ will, however, slowly increase and, eventually, the second precipitate will form. We can use the value of $[Ag^+]$ at the point at which the second precipitate starts to form to calculate $[Br^-]$ and $[CrO_4^{2-}]$ and determine whether complete separation is possible (i.e., when 99.9% of the bromide ion has precipitated).

Solve

(a) The required values of $[Ag^+]$ for precipitation to start are

AgBr ppt: $Q_{sp} = [Ag^+][Br^-] = [Ag^+](0.010) = 5.0 \times 10^{-13} = K_{sp}$

$$[Ag^+] = 5.0 \times 10^{-11}\ \text{M}$$

Ag_2CrO_4 ppt: $Q_{sp} = [Ag^+]^2[CrO_4^{2-}] = [Ag^+]^2(0.010)$

$$= 1.1 \times 10^{-12} = K_{sp}$$

$$[Ag^+]^2 = 1.1 \times 10^{-10} \quad \text{and} \quad [Ag^+] = 1.0 \times 10^{-5}\ \text{M}$$

Because the $[Ag^+]$ required to start the precipitation of AgBr(s) is much less than that for $Ag_2CrO_4(s)$, AgBr(s) precipitates first. As long as AgBr(s) is forming, the silver ion concentration can only slowly approach the value required for the precipitation of $Ag_2CrO_4(s)$.

(b) As AgBr(s) precipitates, $[\mathrm{Br^-}]$ gradually decreases, and this permits $[\mathrm{Ag^+}]$ to increase. When $[\mathrm{Ag^+}]$ reaches 1.0×10^{-5} M, precipitation of $Ag_2CrO_4(s)$ begins. To determine $[\mathrm{Br^-}]$ at the point at which $[\mathrm{Ag^+}] = 1.0 \times 10^{-5}$ M, we use K_{sp} for AgBr and solve for $[\mathrm{Br^-}]$.

$$K_{sp} = [\mathrm{Ag^+}][\mathrm{Br^-}] = (1.0 \times 10^{-5})[\mathrm{Br^-}] = 5.0 \times 10^{-13}$$

$$[\mathrm{Br^-}] = \frac{5.0 \times 10^{-13}}{1.0 \times 10^{-5}} = 5.0 \times 10^{-8}\ \mathrm{M}$$

(c) Before $Ag_2CrO_4(s)$ begins to precipitate, $[\mathrm{Br^-}]$ will have been reduced from 1.0×10^{-2} M to 5.0×10^{-8} M. Essentially, all the Br^- will have precipitated from solution as AgBr(s), whereas the CrO_4^{2-} remains in solution. Fractional precipitation is feasible for separating mixtures of Br^- and CrO_4^{2-}.

Assess

Even though the solubility products of these two compounds have similar values, we were able to separate the two ions. The concept of fractional precipitation is used to separate and identify unknown ions in solution.

PRACTICE EXAMPLE A: $AgNO_3(aq)$ is slowly added to a solution with $[\mathrm{Cl^-}] = 0.115$ M and $[\mathrm{Br^-}] = 0.264$ M. What percent of the Br^- remains unprecipitated at the point at which AgCl(s) begins to precipitate?

$$\text{AgCl:} \quad K_{sp} = 1.8 \times 10^{-10} \qquad \text{AgBr:} \quad K_{sp} = 5.0 \times 10^{-13}$$

PRACTICE EXAMPLE B: A solution has $[\mathrm{Ba^{2+}}] = [\mathrm{Sr^{2+}}] = 0.10$ M. Use data from Appendix D to choose the best precipitating agent to separate these two ions. What is the concentration of the first ion to precipitate when the second ion begins to precipitate?

18-3 CONCEPT ASSESSMENT

In the fractional precipitation pictured in Figure 18-4 and described in Example 18-7, no mention was made of the concentration of the $AgNO_3(aq)$ used. Is this concentration immaterial? Explain.

18-7 Solubility and pH

The pH of a solution can affect the solubility of a salt to a large degree. That is especially true when the anion of the salt is the conjugate base of a weak acid or the base OH^- itself. An interesting example is the highly insoluble $Mg(OH)_2(s)$, which, when suspended in water, is the popular antacid known as milk of magnesia. A **suspension** is a heterogeneous fluid containing solid particles that are sufficiently large for sedimentation and, unlike colloids, will settle. Hydroxide ions from the dissolved magnesium hydroxide react with hydronium ions (in stomach acid) to form water.

GENUINE
Phillips'
Milk of Magnesia
LAXATIVE/ANTACID

▲ Milk of magnesia, an aqueous suspension of $Mg(OH)_2(s)$.

$$Mg(OH)_2(s) \rightleftharpoons Mg^{2+}(aq) + 2\,OH^-(aq) \qquad \textbf{(18.2)}$$

$$OH^-(aq) + H_3O^+(aq) \longrightarrow 2\,H_2O(l) \qquad \textbf{(18.3)}$$

According to Le Châtelier's principle, we expect reaction (18.2) to be displaced to the right—that is, additional $Mg(OH)_2$ would dissolve to replace OH^- ions drawn off by the neutralization reaction (18.3). The overall net ionic equation can be obtained by doubling equation (18.3) and adding it to equation (18.2). At the same time, we can apply the method of combining equilibrium constants (page 664). The result is

$$\begin{array}{ll} Mg(OH)_2(s) \rightleftharpoons Mg^{2+}(aq) + \cancel{2\,OH^-(aq)} & K_{sp} = 1.8 \times 10^{-11} \\ \cancel{2\,OH^-(aq)} + 2\,H_3O^+(aq) \rightleftharpoons 4\,H_2O(l) & K' = 1/K_w^2 = 1.0 \times 10^{28} \\ \hline Mg(OH)_2(s) + 2\,H_3O^+ \rightleftharpoons Mg^{2+}(aq) + 4\,H_2O(l) & \textbf{(18.4)} \end{array}$$

$$K = K_{sp}/K_w^2 = 1.8 \times 10^{-11} \times 1.0 \times 10^{28} = 1.8 \times 10^{17}$$

▶ In general, a water-insoluble salt of a weak acid can be dissolved by acid, but not the water-insoluble salt of a strong acid.

▶ Equilibrium constant expressions can be combined. See Section 15-3.

The large value of *K* for reaction (18.4) indicates that a greater amount of $Mg(OH)_2$ will react (dissolve) in acidic solution than in pure water.

Other slightly soluble solutes having basic anions (such as $ZnCO_3$, MgF_2, and CaC_2O_4) also dissolve to a greater extent in acidic solutions. For these solutes, we can write overall net ionic equations for solubility equilibria and corresponding *K* values based on K_{sp} for the solutes and K_a for the conjugate acids of the anions.

Although $Mg(OH)_2$ dissolves in acidic solution, in moderately or strongly basic solutions it does not. In Example 18-8, we calculate $[OH^-]$ in a solution of the weak base NH_3 and then use the criteria for precipitation to see if $Mg(OH)_2(s)$ will precipitate. In Example 18-9, we determine how to adjust $[OH^-]$ to prevent precipitation of $Mg(OH)_2(s)$. This adjustment is made by adding NH_4^+ to the $NH_3(aq)$, thereby converting it to a buffer solution.

18-4 CONCEPT ASSESSMENT

Which will be affected more by the addition of a strong acid or a strong base: the solubility of CaF_2 or the solubility of $CaCl_2$? Explain.

EXAMPLE 18-8 Determining Whether a Precipitate Will Form in a Solution in Which There Is Also an Ionization Equilibrium

Should $Mg(OH)_2(s)$ precipitate from a solution that is 0.010 M $MgCl_2$ and also 0.10 M NH_3?

Analyze

The key here is in understanding that $[OH^-]$ is established by the ionization of $NH_3(aq)$.

$$NH_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq) \qquad K_b = 1.8 \times 10^{-5}$$

Solve

If we set this up in the usual way, the equilibrium values are $x = [NH_4^+] = [OH^-]$ and $[NH_3] = (0.10 - x) \approx 0.10$. Then we obtain

$$K_b = \frac{[NH_4^+][OH^-]}{[NH_3]} = \frac{x \cdot x}{0.10} = 1.8 \times 10^{-5}$$

$$x^2 = 1.8 \times 10^{-6} \qquad x = [OH^-] = 1.3 \times 10^{-3}\,M$$

Now we can rephrase the original question: Should $Mg(OH)_2(s)$ precipitate from a solution in which $[Mg^{2+}] = 1.0 \times 10^{-2}$ M and $[OH^-] = 1.3 \times 10^{-3}$ M? We must compare the ion product, Q_{sp}, with K_{sp}.

$$\begin{aligned} Q_{sp} &= [Mg^{2+}][OH^-]^2 = (1.0 \times 10^{-2})(1.3 \times 10^{-3})^2 \\ &= 1.7 \times 10^{-8} > K_{sp} = 1.8 \times 10^{-11} \end{aligned}$$

Precipitation should occur.

Assess

In this example the ionization equilibrium was easy to identify. Always look for anions and cations of salts that can establish an ionization equilibrium (e.g., through hydrolysis).

PRACTICE EXAMPLE A: Should $Mg(OH)_2(s)$ precipitate from a solution that is 0.010 M $MgCl_2(aq)$ and also 0.10 M $NaC_2H_3O_2$? $K_{sp}[Mg(OH)_2] = 1.8 \times 10^{-11}$; $K_a(HC_2H_3O_2) = 1.8 \times 10^{-5}$. [*Hint:* What equilibrium expression establishes $[OH^-]$ in the solution?]

PRACTICE EXAMPLE B: Will a precipitate of $Fe(OH)_3$ form from a solution that is 0.013 M Fe^{3+} in a buffer solution that is 0.150 M $HC_2H_3O_2$ and 0.250 M $NaC_2H_3O_2$?

EXAMPLE 18-9 Controlling an Ion Concentration, Either to Cause Precipitation or to Prevent It

What $[NH_4^+]$ must be maintained to prevent precipitation of $Mg(OH)_2(s)$ from a solution that is 0.010 M $MgCl_2$ and 0.10 M NH_3?

Analyze

The maximum value of the ion product, Q_{sp}, before precipitation occurs is 1.8×10^{-11}, the value of K_{sp} for $Mg(OH)_2$. This fact allows us to determine the maximum concentration of OH^- that can be tolerated.

Solve

$$\begin{aligned}
[Mg^{2+}][OH^-]^2 &= (1.0 \times 10^{-2})[OH^-]^2 = 1.8 \times 10^{-11} \\
[OH^-]^2 &= 1.8 \times 10^{-9} \\
[OH^-] &= 4.2 \times 10^{-5}\ M
\end{aligned}$$

Next let's determine what $[NH_4^+]$ must be present in 0.10 M NH_3 to maintain $[OH^-] = 4.2 \times 10^{-5}$ M.

$$NH_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq) \qquad K_b = 1.8 \times 10^{-5}$$

$$K_b = \frac{[NH_4^+][OH^-]}{[NH_3]} = \frac{[NH_4^+](4.2 \times 10^{-5})}{0.10} = 1.8 \times 10^{-5}$$

$$[NH_4^+] = \frac{0.10 \times 1.8 \times 10^{-5}}{4.2 \times 10^{-5}} = 0.043\ M$$

To keep the $[OH^-]$ at 4.2×10^{-5} M *or less*, and thus prevent the precipitation of $Mg(OH)_2(s)$, $[NH_4^+]$ should be maintained at 0.043 M or *greater*.

Assess

The reason for keeping $[NH_4^+]$ *greater* than 0.043 M is that at higher concentrations of NH_4^+, the equilibrium for the ionization of NH_3 shifts to the left, reducing the amount of OH^-. Practically, one would choose 0.10 M since the ratio $[NH_3]/[NH_4^+]$ would be 1.0 and the buffer capacity of the solution is at a maximum.

PRACTICE EXAMPLE A: What minimum $[NH_4^+]$ must be present to prevent precipitation of $Mn(OH)_2(s)$ from a solution that is 0.0050 M $MnCl_2$ and 0.025 M NH_3? For $Mn(OH)_2$, $K_{sp} = 1.9 \times 10^{-13}$.

PRACTICE EXAMPLE B: What is the molar solubility of $Mg(OH)_2(s)$ in a solution that is 0.250 M NH_3 and 0.100 M NH_4Cl? [*Hint:* Use equation (18.4).]

18-5 CONCEPT ASSESSMENT

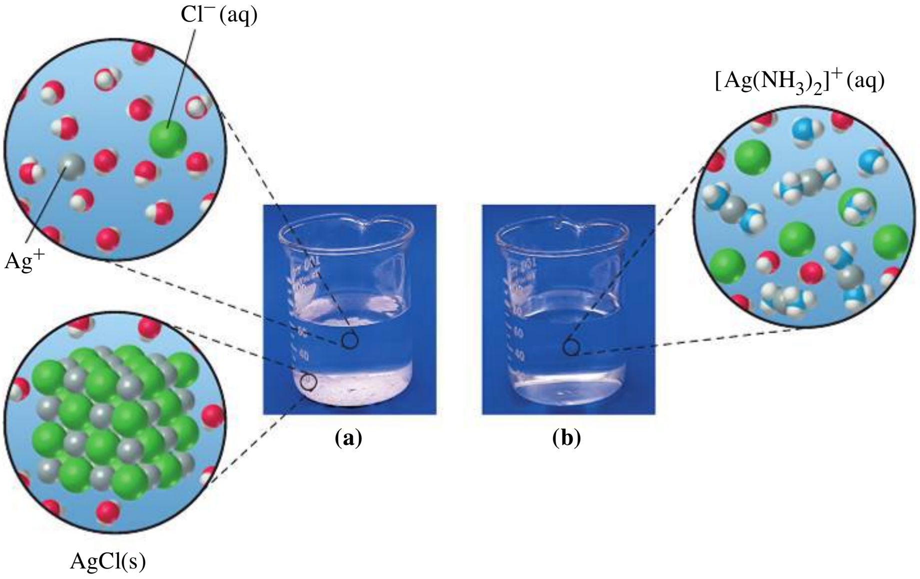
Determine $[Mg^{2+}]$ in a saturated solution of $Mg(OH)_2$ at **(a)** pH = 10.00 and **(b)** pH = 5.00. Is each of these a plausible quantity? Explain.

18-8 Equilibria Involving Complex Ions

As shown in Figure 18-5, when moderately concentrated $NH_3(aq)$ is added to a saturated solution of silver chloride in contact with undissolved $AgCl(s)$, the solid dissolves. The key to this dissolving action is that Ag^+ ions from AgCl combine with NH_3 molecules to form the ions $[Ag(NH_3)_2]^+$, which, together with Cl^- ions, remain in solution as the soluble compound $Ag(NH_3)_2Cl$.

$$AgCl(s) + 2\,NH_3(aq) \longrightarrow [Ag(NH_3)_2]^+(aq) + Cl^-(aq) \qquad \textbf{(18.5)}$$

Here $[Ag(NH_3)_2]^+$ is called a complex ion, and $Ag(NH_3)_2Cl$ is called a coordination compound. A **complex ion** is a polyatomic cation or anion composed of a central metal ion to which other groups (molecules or ions) called *ligands* are

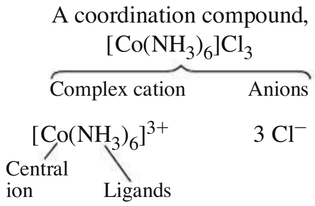


▲ FIGURE 18-5

Complex-ion formation: dissolution of AgCl(s) in NH_3(aq)

(a) A saturated solution of silver chloride in contact with excess AgCl(s). **(b)** When NH_3(aq) is added, the excess AgCl(s) dissolves through the formation of the complex ion $[Ag(NH_3)_2]^+$.

bonded. **Coordination compounds** are substances containing complex ions. It helps to think of reaction (18.5) as involving two simultaneous equilibria.



$$AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq) \qquad \textbf{(18.6)}$$
$$Ag^+(aq) + 2\,NH_3(aq) \rightleftharpoons [Ag(NH_3)_2]^+(aq) \qquad \textbf{(18.7)}$$

The equilibrium in reaction (18.7) is shifted far to the right—$[Ag(NH_3)_2]^+$ is a stable complex ion. The equilibrium concentration of $Ag^+(aq)$ in (18.7) is kept so low that the ion product $[Ag^+][Cl^-]$ fails to exceed K_{sp} and AgCl remains in solution. Let's first apply additional qualitative reasoning of this sort in Example 18-10. Then we can turn to some of the quantitative calculations that are also possible.

To describe the ionization of a weak acid, we use the ionization constant K_a. For a solubility equilibrium, we use the solubility product constant K_{sp}. The equilibrium constant that is used to deal with a complex-ion equilibrium is called the formation constant. The **formation constant, K_f,** of a complex ion is the equilibrium constant describing the formation of a complex ion from a central ion and its attached groups. For reaction (18.7) this equilibrium constant expression is

$$K_f = \frac{[[Ag(NH_3)_2]^+]}{[Ag^+][NH_3]^2} = 1.6 \times 10^7$$

Table 18.2 lists some representative formation constants, K_f.

One feature that distinguishes K_f from most other equilibrium constants previously considered is that K_f values are usually *large* numbers. This fact can affect the way we approach certain calculations. With large K values, it is sometimes convenient to solve a problem in two steps. First, assume that the forward reaction goes to completion; second, assume that a small change occurs in the reverse direction to establish the equilibrium. This approach is demonstrated in Example 18-11.

EXAMPLE 18-10 Predicting Reactions Involving Complex Ions

Predict what will happen if nitric acid is added to a solution of $[Ag(NH_3)_2]Cl$ in $NH_3(aq)$.

Analyze

We consider the equilibria represented by equations (18.6) and (18.7) and use Le Chatelier's principle to assess the effect of adding HNO_3 to the solution. An important consideration is that nitric acid will protonate the base, NH_3.

Solve

Since $HNO_3(aq)$ is a strong acid, we will represent the acid as $H_3O^+(aq)$ and write the protonation reaction as

$$H_3O^+(aq) + NH_3(aq) \longrightarrow NH_4^+(aq) + H_2O(l)$$

The formation reaction is

$$Ag^+(aq) + 2\,NH_3(aq) \rightleftharpoons [Ag(NH_3)_2]^+(aq)$$

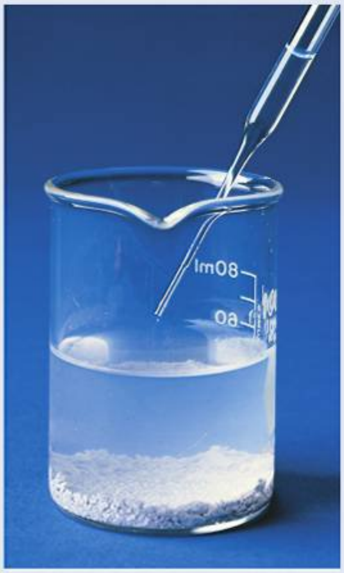
To replace free NH_3 lost in this neutralization, equilibrium in the formation reaction shifts to the *left*. As a result, $[Ag^+]$ increases. When $[Ag^+]$ increases to the point at which the ion product $[Ag^+][Cl^-]$ exceeds K_{sp}, AgCl(s) precipitates (Fig. 18-6).

Assess

The addition of any acid to a solution of $[Ag(NH_3)_2]Cl$ will result in precipitation.

PRACTICE EXAMPLE A: Copper(II) ion forms both an insoluble hydroxide and the complex ion $[Cu(NH_3)_4]^{2+}$. Write equations to represent the expected reaction when **(a)** $CuSO_4(aq)$ and NaOH(aq) are mixed; **(b)** an excess of $NH_3(aq)$ is added to the product of part (a); and **(c)** an excess of $HNO_3(aq)$ is added to the product of part (b).

PRACTICE EXAMPLE B: Zinc(II) ion forms both an insoluble hydroxide and the complex ions $[Zn(OH)_4]^{2-}$ and $[Zn(NH_3)_4]^{2+}$. Write four equations to represent the reactions of **(a)** $NH_3(aq)$ with $ZnSO_4(aq)$, followed by **(b)** enough $HNO_3(aq)$ to make the product of part (a) acidic; **(c)** enough NaOH(aq) to make the product of part (b) slightly basic; **(d)** enough NaOH(aq) to make the product of part (c) strongly basic.



▲ FIGURE 18-6
Reprecipitating AgCl(s)
The reagent being added to the solution containing $[Ag(NH_3)_2]^+$ and Cl^- is $HNO_3(aq)$. H_3O^+ from the acid reacts with $NH_3(aq)$ to form $NH_4^+(aq)$. As a result, equilibrium between $[Ag(NH_3)_2]^+$, Ag^+, and NH_3 is upset. The complex ion is destroyed, $[Ag^+]$ quickly rises to the point at which K_{sp} for AgCl is exceeded, and a precipitate forms.

TABLE 18.2 Formation Constants for Some Complex Ions[a]

Complex Ion	Equilibrium Reaction[b]	K_f
$[Co(NH_3)_6]^{3+}$	$Co^{3+} + 6\,NH_3 \rightleftharpoons [Co(NH_3)_6]^{3+}$	4.5×10^{33}
$[Cu(NH_3)_4]^{2+}$	$Cu^{2+} + 4\,NH_3 \rightleftharpoons [Cu(NH_3)_4]^{2+}$	1.1×10^{13}
$[Fe(CN)_6]^{4-}$	$Fe^{2+} + 6\,CN^- \rightleftharpoons [Fe(CN)_6]^{4-}$	1×10^{37}
$[Fe(CN)_6]^{3-}$	$Fe^{3+} + 6\,CN^- \rightleftharpoons [Fe(CN)_6]^{3-}$	1×10^{42}
$[Pb(OH)_3]^-$	$Pb^{2+} + 3\,OH^- \rightleftharpoons [Pb(OH)_3]^-$	3.8×10^{14}
$[PbCl_3]^-$	$Pb^{2+} + 3\,Cl^- \rightleftharpoons [PbCl_3]^-$	2.4×10^{1}
$[Ag(NH_3)_2]^+$	$Ag^+ + 2\,NH_3 \rightleftharpoons [Ag(NH_3)_2]^+$	1.6×10^{7}
$[Ag(CN)_2]^-$	$Ag^+ + 2\,CN^- \rightleftharpoons [Ag(CN)_2]^-$	5.6×10^{18}
$[Ag(S_2O_3)_2]^{3-}$	$Ag^+ + 2\,S_2O_3^{2-} \rightleftharpoons [Ag(S_2O_3)_2]^{3-}$	1.7×10^{13}
$[Zn(NH_3)_4]^{2+}$	$Zn^{2+} + 4\,NH_3 \rightleftharpoons [Zn(NH_3)_4]^{2+}$	4.1×10^{8}
$[Zn(CN)_4]^{2-}$	$Zn^{2+} + 4\,CN^- \rightleftharpoons [Zn(CN)_4]^{2-}$	1×10^{18}
$[Zn(OH)_4]^{2-}$	$Zn^{2+} + 4\,OH^- \rightleftharpoons [Zn(OH)_4]^{2-}$	4.6×10^{17}

[a] A more extensive tabulation is given in Appendix D.

[b] Tabulated here are *overall* formation reactions and the corresponding *overall* formation constants. In Section 24-8, we describe the formation of complex ions in a *stepwise* fashion and introduce formation constants for individual steps.

EXAMPLE 18-11 Determining Whether a Precipitate Will Form in a Solution Containing Complex Ions

A 0.10 mol sample of $AgNO_3$ is dissolved in 1.00 L of 1.00 M NH_3. If 0.010 mol NaCl is added to this solution, will AgCl(s) precipitate?

Analyze

We begin by first assuming that because the value of K_f for $[Ag(NH_3)_2]^+$ is very large, the formation reaction goes to completion. Then we use those results to perform an equilibrium calculation. Finally, from the equilibrium calculation we can determine a Q_{sp} for the reaction and determine whether precipitation will occur.

Solve

Assuming the formation reaction goes to completion, we obtain

	$Ag^+(aq)$ +	$2\,NH_3(aq)$ $\longrightarrow$	$[Ag(NH_3)_2]^+(aq)$
initial concns, M:	0.10	1.00	
changes, M:	-0.10	-0.20	$+0.10$
after reaction, M:	≈ 0	0.80	0.10

However, the concentration of uncomplexed silver ion, though very small, is not zero. To determine the value of $[Ag^+]$, let's start with $[[Ag(NH_3)_2]^+]$ and $[NH_3]$ in solution and establish $[Ag^+]$ at equilibrium.

	Ag^+ +	$2\,NH_3$ $\rightleftharpoons$	$[Ag(NH_3)_2]^+$
initial concns, M:	0	0.80	0.10
changes, M:	$+x$	$+2x$	$-x$
equil concns, M:	x	$0.80 + 2x$	$0.10 - x$

When substituting into the following expression, we make the assumption that $x \ll 0.10$, which we will find to be the case.

$$\frac{[[Ag(NH_3)_2]^+]}{[Ag^+][NH_3]^2} = \frac{0.10 - x}{x(0.80 + 2x)^2} \approx \frac{0.10}{x(0.80)^2} = 1.6 \times 10^7$$

$$x = [Ag^+] = \frac{0.10}{(1.6 \times 10^7)(0.80)^2} = 9.8 \times 10^{-9}\ M$$

Finally, we must compare $Q_{sp} = [Ag^+][Cl^-]$ with K_{sp} for AgCl (that is, 1.8×10^{-10}). $[Ag^+]$ is the value of x that we just calculated. Because the solution contains 0.010 mol NaCl/L, $[Cl^-] = 0.010\ M = 1.0 \times 10^{-2}\ M$, and

$$Q_{sp} = (9.8 \times 10^{-9})(1.0 \times 10^{-2}) = 9.8 \times 10^{-11} < 1.8 \times 10^{-10}$$

AgCl will not precipitate.

Assess

The formation reaction goes almost to completion, with only a small amount of silver ion remaining in solution. Our initial assumption that the formation reaction goes to completion was valid. The amount of silver ion remaining is not enough to cause precipitation.

PRACTICE EXAMPLE A: Will AgCl(s) precipitate from 1.50 L of a solution that is 0.100 M $AgNO_3$ and 0.225 M NH_3 if 1.00 mL of 3.50 M NaCl is added? [*Hint:* What are $[Ag^+]$ and $[Cl^-]$ immediately after the addition of the 1.00 mL of 3.50 M NaCl? Take into account the dilution of the NaCl(aq), but assume the total volume remains at 1.50 L.]

PRACTICE EXAMPLE B: A solution is prepared that is 0.100 M in $Pb(NO_3)_2$ and 0.250 M in the ethylenediaminetetraacetate anion, $EDTA^{4-}$. Together, Pb^{2+} and $EDTA^{4-}$ form the complex ion $[PbEDTA]^{2-}$. If the solution is also made 0.10 M in I^-, will $PbI_2(s)$ precipitate? For PbI_2, $K_{sp} = 7.1 \times 10^{-9}$; for $[PbEDTA]^{2-}$, $K_f = 2 \times 10^{18}$.

Just as some precipitation reactions can be controlled by using a buffer solution (Example 18-9), precipitation from a solution of complex ions can be controlled by fixing the concentration of the complexing agent. Such a case is demonstrated for AgCl in Example 18-12.

EXAMPLE 18-12 Controlling a Concentration to Cause or Prevent Precipitation from a Solution of Complex Ions

What is the *minimum* concentration of NH_3 needed to prevent AgCl(s) from precipitating from 1.00 L of a solution containing 0.10 mol $AgNO_3$ and 0.010 mol NaCl?

Analyze

To prevent AgCl(s) from precipitating, we must ensure that the solubility product for AgCl is not exceeded. We are given a fixed amount of chloride ion in solution, and so that means we need to determine the maximum concentration of silver ion that can exist without precipitation occurring. Finally, we can solve for the amount of NH_3 necessary to complex all the silver ion.

Solve

Solve for the amount of silver ion that can be in solution without precipitation in a solution containing 1.0×10^{-2} M Cl^-. That is, $[Ag^+][Cl^-] \leq K_{sp}$.

$$[Ag^+](1.0 \times 10^{-2}) \leq K_{sp} = 1.8 \times 10^{-10} \qquad [Ag^+] \leq 1.8 \times 10^{-8}\ \text{M}$$

Thus, the maximum concentration of *uncomplexed* Ag^+ in solution is 1.8×10^{-8} M. This means that essentially all the Ag^+ (0.10 mol/L) must be tied up (complexed) in the complex ion $[Ag(NH_3)_2]^+$. We need to solve the expression at the right for $[NH_3]$.

$$K_f = \frac{[[Ag(NH_3)_2]^+]}{[Ag^+][NH_3]^2} = \frac{1.0 \times 10^{-1}}{1.8 \times 10^{-8}[NH_3]^2} = 1.6 \times 10^7$$

$$[NH_3]^2 = \frac{1.0 \times 10^{-1}}{1.8 \times 10^{-8} \times 1.6 \times 10^7} = 0.35 \qquad [NH_3] = 0.59\ \text{M}$$

The concentration just calculated is that of *free*, *uncomplexed* NH_3. Considering as well the 0.20 mol NH_3/L complexed in the 0.10 M $[Ag(NH_3)_2]^+$, we see that the total concentration of $NH_3(aq)$ required is

$$[NH_3]_{tot} = 0.59\ \text{M} + 0.20\ \text{M} = 0.79\ \text{M}$$

Assess

In this example the precipitation from a solution is controlled by using a sufficiently large concentration of a complexing agent (i.e., NH_3).

PRACTICE EXAMPLE A: What $[NH_3]_{tot}$ is necessary to keep AgCl from precipitating from a solution that is 0.13 M $AgNO_3$ and 0.0075 M NaCl?

PRACTICE EXAMPLE B: What minimum concentration of thiosulfate ion, $S_2O_3{}^{2-}$, should be present in 0.10 M $AgNO_3(aq)$ so that AgCl(s) does not precipitate when the solution is also made 0.010 M in Cl^-? For AgCl, $K_{sp} = 1.8 \times 10^{-10}$; for $[Ag(S_2O_3)_2]^{3-}$, $K_f = 1.7 \times 10^{13}$.

On page 799, there is a qualitative description of how the solubility of AgCl increases in the presence of $NH_3(aq)$. Example 18-13 shows how to calculate the actual solubility of AgCl in $NH_3(aq)$.

18-6 CONCEPT ASSESSMENT

(1) The measured molar solubility of AgCl in water is 1.3×10^{-5} M. In the presence of $Cl^-(aq)$ as a common ion at different concentrations, the measured solubilities of AgCl are as listed below.

$[Cl^-]$, M:	0.0039	0.036	0.35	1.4	2.9	3.8
Solubility of AgCl, M:	7.2×10^{-7}	1.9×10^{-6}	1.7×10^{-5}	1.8×10^{-4}	1.0×10^{-2}	2.5×10^{-2}

Give a plausible explanation for the trends in the molar solubilities of the AgCl.

(2) When we add sodium hydroxide to a lead(II) chloride solution, what species are formed?

EXAMPLE 18-13 Determining the Solubility of a Solute When Complex Ions Form

What is the molar solubility of AgCl in 0.100 M $NH_3(aq)$?

Analyze

We need to have the equilibrium constant for the reaction that forms $[Ag(NH_3)_2]^+$ from AgCl(s) and $NH_3(aq)$. We can determine the equilibrium constant from the product of K_{sp} for AgCl(s) and K_f for the formation of $[Ag(NH_3)_2]^+$. By using that equilibrium constant, we can then determine the molar solubility.

Solve

As we have already seen, equation (18.5) describes the solubility equilibrium.

$$AgCl(s) + 2\,NH_3(aq) \rightleftharpoons [Ag(NH_3)_2]^+(aq) + Cl^-(aq) \qquad \textbf{(18.5)}$$

Let's base our calculation on the equilibrium constant K for reaction (18.5). There are two ways to obtain this value. By one method, equation (18.5) is written as the sum of equations (18.6) and (18.7) on page 800. Then its K value is obtained as the product of a K_{sp} and a K_f.

$$\begin{array}{rll}
AgCl(s) \rightleftharpoons \cancel{Ag^+(aq)} + Cl^-(aq) & & K_{sp} = 1.8 \times 10^{-10} \\
\cancel{Ag^+(aq)} + 2\,NH_3(aq) \rightleftharpoons [Ag(NH_3)_2{}^+](aq) & & K_f = 1.6 \times 10^{7} \\
\hline
AgCl(s) + 2\,NH_3(aq) \rightleftharpoons [Ag(NH_3)_2{}^+](aq) + Cl^-(aq) & &
\end{array}$$

$$K = K_{sp} \times K_f = 1.8 \times 10^{-10} \times 1.6 \times 10^{7} = 2.9 \times 10^{-3}$$

By a second method, the equilibrium constant expression for reaction (18.5) is written first, and then the numerator and denominator are multiplied by $[Ag^+]$.

$$K = \frac{[Ag(NH_3)_2{}^+][Cl^-]}{[NH_3]^2} = \frac{[Ag(NH_3)_2{}^+][Cl^-][Ag^+]}{[NH_3]^2[Ag^+]} = K_f \times K_{sp} = 2.9 \times 10^{-3}$$

The expression printed in red is K_f for $[Ag(NH_3)_2]^+$; the one in blue is K_{sp} for AgCl. The K value for reaction (18.5) is the product of the two.

According to equation (18.5), if s mol AgCl/L dissolves (the molar solubility), the expected concentrations of $[Ag(NH_3)_2]^+$ and Cl^- are also equal to s.

$$K = \frac{[[Ag(NH_3)_2]^+][Cl^-]}{[NH_3]^2} = \frac{s \cdot s}{(0.100 - 2s)^2} = \left(\frac{s}{0.100 - 2s}\right)^2 = 2.9 \times 10^{-3}$$

We can solve this equation by taking the square root of both sides.

$$\frac{s}{0.100 - 2s} = \sqrt{2.9 \times 10^{-3}} = 5.4 \times 10^{-2}$$

The molar solubility of AgCl(s) in 0.100 M $NH_3(aq)$ is 4.9×10^{-3} M.

$$\begin{aligned}
s &= 5.4 \times 10^{-3} - 0.11s \\
1.11s &= 5.4 \times 10^{-3} \\
s &= 4.9 \times 10^{-3}
\end{aligned}$$

Assess

The usual simplifying assumption, that is, $(0.100 - 2s) \approx 0.100$, would not have worked well in this calculation. If the simplifying assumption had been made, the value of s obtained would have been 5.4×10^{-3} M and $2s$ would have been 10.8% of 0.100. That is, $0.100 - (2 \times 0.0054) \neq 0.100$. Also, the molar solubility is actually the *total* concentration of silver in solution: $[Ag^+] + [[Ag(NH_3)_2]^+]$. Only when K_f is large and the concentration of complexing agent sufficiently high can we ignore the concentration of uncomplexed metal ion, as was the case here.

PRACTICE EXAMPLE A: What is the molar solubility of $Fe(OH)_3$ in a solution containing 0.100 M $C_2O_4{}^{2-}$? For $[Fe(C_2O_4)_3]^{3-}$, $K_f = 2 \times 10^{20}$.

PRACTICE EXAMPLE B: *Without doing detailed calculations*, show that the order of *decreasing* solubility in 0.100 M $NH_3(aq)$ should be AgCl > AgBr > AgI.

18-9 Qualitative Cation Analysis

In *qualitative analysis*, we determine what substances are present in a mixture but *not* their quantities. An analysis that aims at identifying the cations present in a mixture is called **qualitative cation analysis**. Qualitative cation analysis provides us with many examples of precipitation (and dissolution) equilibria, acid–base equilibria, and oxidation–reduction reactions. Also, in the general chemistry laboratory it offers the challenge of unraveling a mystery—solving a qualitative analysis "unknown."

In the scheme in Figure 18-7, about 25 common cations are divided into five groups, depending on differing solubilities of their compounds. The first cations separated, Pb^{2+}, Hg_2^{2+}, and Ag^+, are those with insoluble *chlorides*. The reagent used is HCl(aq). All other cations remain in solution because their chlorides are soluble. After the chloride group precipitate is removed, the remaining solution is treated with H_2S in an acidic medium. Under these conditions, a group of sulfides precipitates. They are known as the hydrogen sulfide group. Next, the solution containing the remaining cations is treated with H_2S in a buffer mixture of ammonia and ammonium ion, yielding a mixture of insoluble hydroxides and sulfides.

◀ In the Hg_2^{2+} ion, a covalent bond links a Hg atom to a Hg^{2+} ion.

This group is called the ammonium sulfide group. The sulfide of aluminum(III) and chromium(III) are unstable, reacting with water to form the hydroxides.

Treatment of the ammonium sulfide group filtrate with CO_3^{2-} yields the fourth group precipitate, which consists of the carbonates of Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+}. It is called the carbonate group because the aqueous carbonate anion is the key reagent. At the end of this series of precipitations, the resulting

Various aspects of this scheme are described in the text. A sample containing all 25 cations can be separated into five groups by the indicated reagents.

solution contains only Na^+, K^+, and NH_4^+, all of whose common salts are water soluble.

In this section, we will discuss the chemistry of the chloride and sulfide groups. The chemistry of metal carbonates is discussed in Chapter 21.

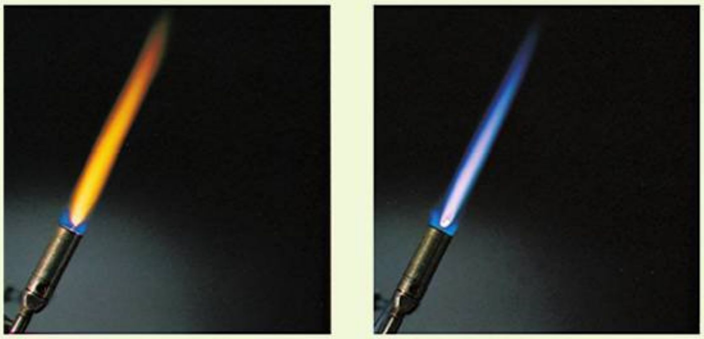
18-3 ARE YOU WONDERING...

How to test for the presence of Na^+, K^+, and NH_4^+ cations?

Tests by precipitation are difficult because the salts of these cations exhibit near-universal solubility. Both Na^+ and K^+ ions are most easily detected with a flame test. When a solution containing sodium ions is brought into contact with a flame, the characteristic orange-yellow color of the emission spectrum of sodium atoms is observed. For potassium atoms, a pale violet color results. To detect the presence of NH_4^+, we use the fact that the ammonium ion is the conjugate acid of the weak volatile base ammonia. Heating some of the original solution (not the final solution, which contains NH_4^+ ions added in the fractional precipitation scheme) with excess strong base will liberate ammonia.

$$NH_4^+(aq) + OH^- \longrightarrow NH_3(g) + H_2O(l)$$

The NH_3 is detected by its characteristic odor and its effect on the color of an acid–base indicator such as litmus.



(a) **(b)**

▲ Flame colors of **(a)** sodium and **(b)** potassium.

▶ The mechanism of light emission in flame tests is presented on page 921.

Cation Group 1: The Chloride Group

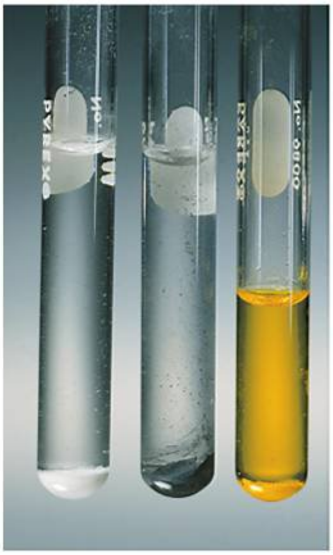
If a precipitate forms when a solution is treated with HCl(aq), one or more of the following cations must be present: Pb^{2+}, Hg_2^{2+}, Ag^+. To establish the presence or absence of each of these three cations, the chloride group precipitate is filtered off and subjected to further testing.

Of the three chlorides in the group precipitate, $PbCl_2(s)$ is the most soluble; its K_{sp} is much larger than those of AgCl and Hg_2Cl_2. When the precipitate is washed with hot water, a sufficient quantity of $PbCl_2$ dissolves to permit a test for Pb^{2+} in the solution. In this test, a lead compound less soluble than $PbCl_2$, such as lead(II) chromate, precipitates (Fig. 18-8).

$$Pb^{2+}(aq) + CrO_4^{2-}(aq) \longrightarrow PbCrO_4(s)$$

The portion of the chloride group precipitate that is insoluble in hot water is then treated with $NH_3(aq)$. Two things happen. One is that any AgCl(s) present dissolves and forms the complex ion $[Ag(NH_3)_2^+]$, as described by equation (18.5).

$$AgCl(s) + 2\,NH_3(aq) \longrightarrow [Ag(NH_3)_2]^+(aq) + Cl^-(aq)$$



(a) **(b)** **(c)**

▲ FIGURE 18-8
Chloride group precipitates
(a) Group 1 precipitate: a mixture of $PbCl_2$ (white), Hg_2Cl_2 (white), and AgCl (white). **(b)** Test for Hg_2^{2+}: a mixture of Hg (black) and $HgNH_2Cl$ (white). **(c)** Test for Pb^{2+}: a yellow precipitate of $PbCrO_4(s)$.

At the same time, any $Hg_2Cl_2(s)$ present undergoes an oxidation–reduction reaction. One of the products of the reaction is finely divided black mercury. A black color is common for finely divided metals.

$$Hg_2Cl_2(s) + 2\,NH_3(aq) \longrightarrow \underbrace{Hg(l) + HgNH_2Cl(s)}_{\text{Dark gray}} + NH_4^+(aq) + Cl^-(aq)$$

The appearance of a dark gray mixture of black mercury and white $HgNH_2Cl$ [mercury(II) amidochloride] is the qualitative analysis confirmation of mercury(I) ion (see Figure 18-8).

When the solution from reaction (18.5) is acidified with $HNO_3(aq)$, any silver ion present precipitates as $AgCl(s)$. This is the reaction predicted in Example 18-10 and pictured in Figure 18-6.

18-7 CONCEPT ASSESSMENT

A qualitative analysis chloride group unknown forms a white precipitate with HCl(aq). The precipitate is treated with hot water, yielding a solution that gives a yellow precipitate with $K_2CrO_4(aq)$. There is no change in color when the undissolved portion of the precipitate is treated with $NH_3(aq)$. Indicate for each chloride group cation whether it is present or absent, or about which there is some doubt.

Cation Groups 2 and 3: Equilibria Involving Hydrogen Sulfide

Figure 18-7 suggests that aqueous hydrogen sulfide (hydrosulfuric acid) is the key reagent in the analysis of cation groups 2 and 3. In aqueous solution, H_2S is a *weak diprotic acid.*

$$\begin{aligned} H_2S(aq) + H_2O(l) &\rightleftharpoons H_3O^+(aq) + HS^-(aq) \qquad K_{a_1} = 1.0 \times 10^{-7} \\ HS^-(aq) + H_2O(l) &\rightleftharpoons H_3O^+(aq) + S^{2-}(aq) \qquad K_{a_2} = 1 \times 10^{-19} \end{aligned}$$

The extremely small value of K_{a_2} suggests that sulfide ion is a very strong base, as seen in the following hydrolysis reaction and K_b value.

$$S^{2-} + H_2O \rightleftharpoons HS^- + OH^- \qquad K_b = K_w/K_{a_2}$$
$$= (1.0 \times 10^{-14})/(1 \times 10^{-19}) = 1 \times 10^5$$

◀ $H_2S(g)$ has a familiar rotten egg odor, especially noticeable in volcanic areas and near sulfur hot springs. Because of the smell, any gas containing a significant amount of H_2S (4 ppm or more) is called "sour gas."

The hydrolysis of S^{2-} should go nearly to completion, which means that very little S^{2-} can exist in an aqueous solution and that sulfide ion is probably not the precipitating agent for sulfides.

One way to handle the precipitation and dissolution of sulfide precipitates is to restrict the discussion to acidic solutions. Then we can write an equilibrium constant expression in which the concentration terms for HS^- and S^{2-} are eliminated. This approach is reasonable because most sulfide separations are carried out in acidic solution.

Consider (1) the solubility equilibrium equation for PbS written to reflect hydrolysis of S^{2-}, (2) an equation written for the reverse of the first ionization of H_2S, and (3) an equation that is the reverse of the self-ionization of water. These three equations can be combined into an overall equation that shows the dissolving of PbS(s) in an acidic solution. The equilibrium constant for this overall equation is generally referred to as K_{spa}.*

$$\begin{array}{lrcll} (1) & PbS(s) + \cancel{H_2O(l)} & \rightleftharpoons & Pb^{2+}(aq) + \cancel{HS^-(aq)} + \cancel{OH^-(aq)} & K_{sp} = 3 \times 10^{-28} \\ (2) & H_3O^+(aq) + \cancel{HS^-(aq)} & \rightleftharpoons & H_2S(aq) + H_2O(l) & 1/K_{a_1} = 1/1.0 \times 10^{-7} \\ (3) & H_3O^+(aq) + \cancel{OH^-(aq)} & \rightleftharpoons & H_2O(l) + H_2O(l) & 1/K_w = 1/1.0 \times 10^{-14} \\ \hline \textit{Overall:} & PbS(s) + 2\,H_3O^+(aq) & \rightleftharpoons & Pb^{2+}(aq) + H_2S(aq) + 2\,H_2O(l) & K_{spa} = ? \end{array}$$

---

*See Myers, R. J. *J. Chem. Educ.* **63,** 687 (1986).

$$K_{spa} = \frac{K_{sp}}{K_{a_1} \times K_w} = \frac{3 \times 10^{-28}}{(1.0 \times 10^{-7})(1.0 \times 10^{-14})} = 3 \times 10^{-7}$$

Example 18-14 illustrates the use of K_{spa} in the type of calculation needed to sort the sulfides into two qualitative analysis groups. Pb^{2+} is in qualitative analysis cation group 2, and Fe^{2+} is in group 3. The conditions cited in the example are those generally used.

▶ $PbCl_2$ is sufficiently soluble that enough Pb^{2+} ions from cation group 1 remain in solution to precipitate again as PbS(s) in cation group 2.

18-8 CONCEPT ASSESSMENT

The dissolution of PbS(s) in water is given by

$$PbS(s) + H_2O(l) = Pb^{2+}(aq) + HS^- = OH^-(aq)$$

In an apparent violation of Le Châtelier's principle, the addition of NaOH to the solution leads more PbS to dissolve. Explain.

EXAMPLE 18-14 Separating Metal Ions by Selective Precipitation of Metal Sulfides

Show that PbS(s) will precipitate but FeS(s) will not precipitate from a solution that is 0.010 M in Pb^{2+}, 0.010 M in Fe^{2+}, saturated in H_2S (0.10 M H_2S), and maintained with $[H_3O^+] = 0.30$ M. For PbS, $K_{spa} = 3 \times 10^{-7}$; for FeS, $K_{spa} = 6 \times 10^2$.

Analyze

We must determine whether, for the stated conditions, equilibrium is displaced in the forward or reverse direction in reactions of the type

$$MS(s) + 2\,H_3O^+(aq) \rightleftharpoons M^{2+}(aq) + H_2S(aq) + 2\,H_2O(l) \qquad \textbf{(18.8)}$$

where M represents either Pb or Fe. In each case, we can compare the Q_{spa} expression to the appropriate K_{spa} value for reaction (18.8). If $Q_{spa} > K_{spa}$, a net change will occur to the *left* and MS(s) will precipitate. If $Q_{spa} < K_{spa}$, a net change will occur to the *right*.

Solve

Calculating Q_{spa} we have

$$Q_{spa} = \frac{[M^{2+}][H_2S]}{[H_3O^+]^2} = \frac{0.010 \times 0.10}{(0.30)^2} = 1.1 \times 10^{-2}$$

For PbS: Q_{spa} of $1.1 \times 10^{-2} > K_{spa}$ of 3×10^{-7}. PbS(s) will precipitate.

For FeS: Q_{spa} of $1.1 \times 10^{-2} < K_{spa}$ of 6×10^2. FeS(s) will not precipitate.

Assess

The results here show that using hydrogen sulfide in an acidic medium is a good way to separate cations of groups 2 and 3. You may be wondering how the value for the K_{spa} for FeS was determined. The value of K_{spa} of FeS can be derived from K_{sp} of FeS (6×10^{-19}) by the method outlined for PbS.

PRACTICE EXAMPLE A: Show that $Ag_2S(s)$ ($K_{spa} = 6 \times 10^{-30}$) should precipitate and that FeS(s) ($K_{spa} = 6 \times 10^2$) should not precipitate from a solution that is 0.010 M Ag^+ and 0.020 M Fe^{2+}, but otherwise under the same conditions as in Example 18-14.

PRACTICE EXAMPLE B: What is the minimum pH of a solution that is 0.015 M Fe^{2+} and saturated in H_2S (0.10 M) from which FeS(s) ($K_{spa} = 6 \times 10^2$) can be precipitated?

18-9 CONCEPT ASSESSMENT

Both Cu^{2+} and Ag^+ are present in the same aqueous solution. Explain which of the following reagents would work best in separating these ions, precipitating one and leaving the other in solution: $(NH_4)_2CO_3(aq)$, $HNO_3(aq)$, $H_2S(aq)$, HCl(aq), $NH_3(aq)$, or NaOH(aq).

Dissolving Metal Sulfides

In the qualitative cation analysis, it is necessary to both precipitate and redissolve sulfides. Here, we look at several methods of dissolving metal sulfides. One way to increase the solubility of any sulfide is to allow it to react with an acid, as equation (18.8) suggests. According to Le Châtelier's principle, the solubility increases as the solution is made more acidic—equilibrium is shifted to the right. As a result, some water-insoluble sulfides, such as FeS, are readily soluble in strongly acidic solutions. Others, such as PbS and HgS, cannot be dissolved in acidic solutions because their K_{sp} values are too low. In these cases, $[H_3O^+]$ cannot be made high enough to force reaction (18.8) very far to the right.

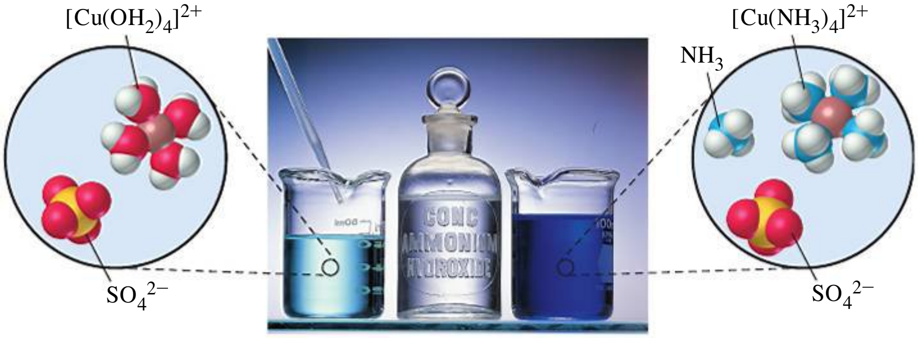
Another way to promote the dissolving of metal sulfides is to use an *oxidizing* acid such as $HNO_3(aq)$. In this case, sulfide ion is oxidized to elemental sulfur and the free metal ion appears in solution, as in the dissolving of CuS(s).

$$3\,CuS(s) + 8\,H^+(aq) + 2\,NO_3^-(aq) \longrightarrow 3\,Cu^{2+}(aq) + 3\,S(s) + 2\,NO(g) + 4\,H_2O(l) \qquad \textbf{(18.9)}$$

To render the $Cu^{2+}(aq)$ more visible, it is converted to the deeply colored complex ion $[Cu(NH_3)_4]^{2+}(aq)$ in a reaction in which NH_3 molecules replace H_2O molecules in a complex ion (Fig. 18-9).

$$\underset{\text{Pale blue}}{[(Cu(H_2O)_4]^{2+}(aq)} + 4\,NH_3(aq) \longrightarrow \underset{\text{Deep violet}}{[Cu(NH_3)_4]^{2+}(aq)} + 4\,H_2O(l)$$

A few metal sulfides dissolve in a basic solution with a high concentration of HS^-, just as acidic oxides dissolve in solutions with a high concentration of OH^-. This property is used to advantage in separating the eight sulfides of cation group 2, the hydrogen sulfide group, into two subgroups. The subgroup consisting of HgS, PbS, CuS, CdS, and Bi_2S_3 remains unchanged after treatment with an alkaline solution with an excess of HS^-, but As_2S_3, SnS_2, and Sb_2S_3 dissolve.



▲ FIGURE 18-9
Complex-ion formation: A test for $Cu^{2+}(aq)$
Dilute $CuSO_4(aq)$ (left) derives its pale blue color from the complex ions $[Cu(H_2O)_4]^{2+}$. When $NH_3(aq)$ is added (here labeled "conc ammonium hydroxide"), the color changes to a deep violet, signaling the presence of $[Cu(NH_3)_4]^{2+}$ (right). The deep violet color is detectable at much lower concentrations than the pale blue; the formation of $[Cu(NH_3)_4]^{2+}$ is a sensitive test for the presence of Cu^{2+}.

KEEP IN MIND

that $Cu^{2+}(aq)$ means that the copper (II) ion will be coordinated to several water molecules (see page 733).

MasteringCHEMISTRY **www.masteringchemistry.com**

The formation of some of the Earth's minerals has been by chemical precipitation. Biological precipitation is responsible for the formation of certain marine shells. The Focus On feature for Chapter 18, Shells, Teeth, and Fossils, on the MasteringChemistry site describes the relationship between shells, teeth, and fossils.

Summary

18-1 Solubility Product Constant, K_{sp}—The equilibrium constant for the equilibrium between a solid ionic solute and its ions in a saturated aqueous solution is expressed through the **solubility product constant, K_{sp}** (expression 18.1, Table 18.1).

18-2 Relationship Between Solubility and K_{sp}—A solute's molarity in a saturated aqueous solution is known as its molar solubility. Molar solubility and K_{sp} are related to each other in a way that makes it possible to calculate one when the other is known.

18-3 Common-Ion Effect in Solubility Equilibria—The solubility of a slightly soluble ionic solute is greatly reduced in an aqueous solution containing an ion in common with the solubility equilibrium—a common ion.

18-4 Limitations of the K_{sp} Concept—The solubility product concept is most useful for slightly soluble ionic solutes, and especially in cases where activities can be replaced by molar concentrations. Moderately or highly soluble ionic compounds require the use of activities. The presence of common ions reduces the solubility of a slightly soluble ionic solute, generally to a significant degree.

Other factors also affect solute solubility. The presence of noncommon or diverse ions generally increases solute solubility, an effect called the **salt effect**. Solute activities, and hence solute solubilities, are strongly influenced by interionic attractions, which become especially significant at higher concentrations and for highly charged ions. Dissociation of ionic solutes may not be 100% complete, leading to the formation of **ion pairs** which act as single units, such as MgF^+ in $MgF_2(aq)$.

18-5 Criteria for Precipitation and Its Completeness—To determine whether a slightly soluble solute will precipitate from a solution, the **ion product, Q_{sp}**, is compared with the solubility product constant, K_{sp}. Q_{sp} is based on the initial ion concentrations in a solution. K_{sp}, on the other hand, is based on the equilibrium ion concentrations in a saturated solution. If $Q_{sp} > K_{sp}$, precipitation will occur; if $Q_{sp} < K_{sp}$, the solution will remain unsaturated. When $Q_{sp} = K_{sp}$, the solution is just saturated.

18-6 Fractional Precipitation—A comparison of K_{sp} values is a factor in determining the feasibility of **fractional precipitation**, a process in which one ionic species is removed by precipitation while others remain in solution.

18-7 Solubility and pH—The solubility of a slightly soluble solute is affected by pH if the anion is OH^- or derived from a weak acid. The solubility increases as the pH is lowered or decreases as the pH is raised. This can be illustrated through Le Châtelier's principle. Also, an equilibrium constant for the dissolution reaction can be obtained by combining the solubility equilibrium equation and the ionization equilibrium equation of the weak electrolyte. Some slightly soluble solutions form **suspensions**, which are heterogeneous fluids containing solid particles that will eventually settle.

18-8 Equilibria Involving Complex Ions—A **complex ion** is a polyatomic ion composed of a central metal ion bonded to two or more molecules or ions called ligands. The formation of a complex ion is an equilibrium process with an equilibrium constant called the **formation constant, K_f**. In general, if the formation constant is large, the concentration of uncomplexed metal ion in equilibrium with the complex ion is very small. Complex-ion formation can render certain insoluble materials quite soluble in appropriate aqueous solutions, such as AgCl in $NH_3(aq)$. A complex ion is either a cation or an anion depending upon the particular central metal ion and the particular ligands. When a complex ion and an oppositely charged ion combine they form a **coordination compound**.

18-9 Qualitative Cation Analysis—Precipitation, acid–base, oxidation–reduction, and complex-ion formation reactions are all used extensively in **qualitative cation analysis**. Such an analysis can provide a rapid means of determining the presence or absence of certain cations in an unknown material.

Integrative Example

Lime (quicklime), CaO, is obtained from the high-temperature decomposition of limestone ($CaCO_3$). Quicklime is the cheapest source of basic substances, but it is water insoluble. It does react with water, however, producing $Ca(OH)_2$ (slaked lime). Unfortunately, $Ca(OH)_2(s)$ has limited solubility, so it cannot be used to prepare aqueous solutions of high pH.

$$Ca(OH)_2(s) \rightleftharpoons Ca^{2+}(aq) + 2\,OH^-(aq) \qquad K_{sp} = 5.5 \times 10^{-6}$$

When $Ca(OH)_2(s)$ reacts with a *soluble* carbonate, such as $Na_2CO_3(aq)$, however, the solution produced has a much higher pH. Equilibrium is displaced to the right in reaction (18.10) because $CaCO_3$ is much less soluble than $Ca(OH)_2$.

$$Ca(OH)_2(s) + CO_3{}^{2-}(aq) \rightleftharpoons CaCO_3(s) + 2\,OH^-(aq) \tag{18.10}$$

Assume an initial $[CO_3{}^{2-}] = 1.0\text{ M}$ in reaction (18.10), and show that the equilibrium pH should indeed be higher than that in saturated $Ca(OH)_2(aq)$.

Analyze

(1) Determine the pH of the saturated $Ca(OH)_2(aq)$. (2) Find the equilibrium constant, K, for reaction (18.10). (3) Calculate the equilibrium $[OH^-]$ in reaction (18.10). (4) Convert $[OH^-]$ to pOH and then to pH. Compare the pH in steps (1) and (4).

Solve

Write the K_{sp} expression for $Ca(OH)_2$. Let s be the molar solubility, so the $[OH^-] = 2s$.

$$K_{sp} = [Ca^{2+}][OH^-]^2 = (s)(2s)^2 = 4s^3 = 5.5 \times 10^{-6}$$
$$s = (5.5 \times 10^{-6}/4)^{1/3} = 0.011\ M$$
$$[OH^-] = 2s = 0.022\ M$$

Calculate the pOH.

$$pOH = -\log[OH^-] = -\log 0.022$$

Determine the pH from the pOH by subtracting pOH from 14.00.

$$pOH = 1.66 \quad pH = 14.00 - pOH = 14.00 - 1.66 = 12.34$$

Combine solubility equilibrium equations for $Ca(OH)_2$ and $CaCO_3$ to obtain the net ionic equation (18.10).

$$Ca(OH)_2(s) \rightleftharpoons Ca^{2+}(aq) + 2\,OH^-(aq) \qquad K_{sp} = 5.5 \times 10^{-6}$$
$$Ca^{2+}(aq) + CO_3{}^{2-}(aq) \rightleftharpoons CaCO_3(s) \qquad 1/K_{sp} = 1/(2.8 \times 10^{-9})$$
$$Ca(OH)_2(s) + CO_3{}^{2-}(aq) \rightleftharpoons CaCO_3(s) + 2\,OH^-(aq) \qquad \textbf{(18.10)}$$

Use the K_{sp} values of $Ca(OH)_2$ and $CaCO_3$ to obtain the overall K.

$$K = \frac{K_{sp}[Ca(OH)_2]}{K_{sp}[CaCO_3]}$$
$$K = 5.5 \times 10^{-6}/2.8 \times 10^{-9} = 2.0 \times 10^3$$

Next, calculate the equilibrium $[OH^-]$ in reaction (18.10), starting with $[CO_3{}^{2-}] = 1.0$ M, and proceeding in the familiar fashion to obtain a quadratic equation. The solution, to two significant figures, is

	$Ca(OH)_2(s)$ +	$CO_3{}^{2-}(aq)$	$\rightleftharpoons$ $CaCO_3(s)$ +	$2\,OH^-(aq)$
initial concns, M:		1.0		≈0
changes, M:		$-x$		$+2x$
equil concns, M:		$1.0 - x$		$2x$

$$K = \frac{[OH^-]^2}{[CO_3{}^{2-}]} = \frac{(2x)^2}{(1.0 - x)} = 2.0 \times 10^3$$
$$4x^2 + (2.0 \times 10^3)x - 2.0 \times 10^3 = 0$$
$$x = 1.0\ M$$

From the value of x, obtain $[OH^-]$, pOH, and pH.

$$[OH^-] = 2x = 2.0\ M$$
$$pOH = -\log[OH^-] = -\log 2.0 = -0.30$$
$$pH = 14.00 - pOH = 14.00 + 0.30 = 14.30$$

Assess

We have succeeded in showing that the solution produced by reaction (18.10) has a higher pH than that found in saturated $Ca(OH)_2(aq)$, that is, a pH of 14.30 compared with 12.34. An interesting aspect of this calculation concerns solution of the quadratic equation $4x^2 + (2.0 \times 10^3)x - 2.0 \times 10^3 = 0$. By using the quadratic formula with no rounding of intermediate results, the value of $x = 0.998$, which rounds off to 1.0. Alternatively, note that by assuming that $x = 1.0$, the second and third terms of the equation cancel, yielding the result $4(1.0^2) + (2.0 \times 10^3)(1.0) - 2.0 \times 10^3 = 4.0$. We conclude that x must be very slightly less than 1.0. A value of $x = 0.998$ on the left side of the equation yields the result -0.016, very close to the 0 required for an exact solution.

PRACTICE EXAMPLE A: Heavy fertilizer use can lead to phosphate pollution in lakes, causing an explosion of plant growth, particularly algae. Excess algae deplete the lake of the oxygen necessary for other plant growth and animal life. A lake in the middle of a large farm was found to contain the phosphate ion in the concentration of 5.13×10^{-4} M. The lake measured 300 m × 150 m × 5 m. One method to neutralize $PO_4{}^{3-}$ is to add a calcium salt. What mass of $Ca(NO_3)_2$ must be added to lower the phosphate ion concentration to 1.00×10^{-12} M? $K_{sp} = 1.30 \times 10^{-32}$ for $Ca_3(PO_4)_2$.

PRACTICE EXAMPLE B: In a laboratory procedure you are instructed to mix 350.0 mL of 0.200 M $AgNO_3(aq)$ and 250.0 mL of 0.240 M $Na_2SO_4(aq)$. What is the precipitate that you observe? To this mixture you add 400.0 mL of 0.500 M $Na_2S_2O_3$, causing the precipitate to dissolve. What is the mass of the remaining precipitate?

MasteringCHEMISTRY

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

Exercises

(Use data from Chapters 16 and 18 and Appendix D, as needed.)

K_{sp} and Solubility

1. Write K_{sp} expressions for the following equilibria. For example, for the reaction $AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq)$, $K_{sp} = [Ag^+][Cl^-]$.
   - **(a)** $Ag_2SO_4(s) \rightleftharpoons 2\,Ag^+(aq) + SO_4^{2-}(aq)$
   - **(b)** $Ra(IO_3)_2(s) \rightleftharpoons Ra^{2+}(aq) + 2\,IO_3^-(aq)$
   - **(c)** $Ni_3(PO_4)_2(s) \rightleftharpoons 3\,Ni^{2+}(aq) + 2\,PO_4^{3-}(aq)$
   - **(d)** $PuO_2CO_3(s) \rightleftharpoons PuO_2^{2+}(aq) + CO_3^{2-}(aq)$

2. Write solubility equilibrium equations that are described by the following K_{sp} expressions. For example, $K_{sp} = [Ag^+][Cl^-]$ represents $AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq)$.
   - **(a)** $K_{sp} = [Fe^{3+}][OH^-]^3$
   - **(b)** $K_{sp} = [BiO^+][OH^-]$
   - **(c)** $K_{sp} = [Hg_2^{2+}][I^-]^2$
   - **(d)** $K_{sp} = [Pb^{2+}]^3[AsO_4^{3-}]^2$

3. The following K_{sp} values are found in a handbook. Write the solubility product expression to which each one applies. For example, $K_{sp}(AgCl) = [Ag^+][Cl^-] = 1.8 \times 10^{-10}$.
   - **(a)** $K_{sp}(CrF_3) = 6.6 \times 10^{-11}$
   - **(b)** $K_{sp}[Au_2(C_2O_4)_3] = 1 \times 10^{-10}$
   - **(c)** $K_{sp}[Cd_3(PO_4)_2] = 2.1 \times 10^{-33}$
   - **(d)** $K_{sp}(SrF_2) = 2.5 \times 10^{-9}$

4. Calculate the aqueous solubility, in moles per liter, of each of the following.
   - **(a)** $BaCrO_4$, $K_{sp} = 1.2 \times 10^{-10}$
   - **(b)** $PbBr_2$, $K_{sp} = 4.0 \times 10^{-5}$
   - **(c)** CeF_3, $K_{sp} = 8 \times 10^{-16}$
   - **(d)** $Mg_3(AsO_4)_2$, $K_{sp} = 2.1 \times 10^{-20}$

5. Arrange the following solutes in order of increasing molar solubility in water: AgCN, $AgIO_3$, AgI, $AgNO_2$, Ag_2SO_4. Explain your reasoning.

6. Which of the following saturated aqueous solutions would have the highest $[Mg^{2+}]$: **(a)** $MgCO_3$; **(b)** MgF_2; **(c)** $Mg_3(PO_4)_2$? Explain.

7. Fluoridated drinking water contains about 1 part per million (ppm) of F^-. Is CaF_2 sufficiently soluble in water to be used as the source of fluoride ion for the fluoridation of drinking water? Explain. [*Hint:* Think of 1 ppm as signifying 1 g F^- per 10^6 g solution.]

8. In the qualitative cation analysis procedure, Bi^{3+} is detected by the appearance of a white precipitate of bismuthyl hydroxide, BiOOH(s):

$$BiOOH(s) \rightleftharpoons BiO^+(aq) + OH^-(aq) \qquad K_{sp} = 4 \times 10^{-10}$$

Calculate the pH of a saturated aqueous solution of BiOOH.

9. A solution is saturated with magnesium palmitate $[Mg(C_{16}H_{31}O_2)_2$, a component of bathtub ring] at 50 °C. How many milligrams of magnesium palmitate will precipitate from 965 mL of this solution when it is cooled to 25 °C? For $Mg(C_{16}H_{31}O_2)_2$, $K_{sp} = 4.8 \times 10^{-12}$ at 50 °C and 3.3×10^{-12} at 25 °C.

10. A 725 mL sample of a saturated aqueous solution of calcium oxalate, CaC_2O_4, at 95 °C is cooled to 13 °C. How many milligrams of calcium oxalate will precipitate? For CaC_2O_4, $K_{sp} = 1.2 \times 10^{-8}$ at 95 °C and 2.7×10^{-9} at 13 °C.

11. A 25.00 mL sample of a clear *saturated* solution of PbI_2 requires 13.3 mL of a certain $AgNO_3(aq)$ for its titration. What is the molarity of this $AgNO_3(aq)$?

$$I^-(\text{satd } PbI_2) + Ag^+(\text{from } AgNO_3) \longrightarrow AgI(s)$$

12. A 250 mL sample of saturated $CaC_2O_4(aq)$ requires 4.8 mL of 0.00134 M $KMnO_4(aq)$ for its titration in an acidic solution. What is the value of K_{sp} for CaC_2O_4 obtained with these data? In the titration reaction, $C_2O_4^{2-}$ is oxidized to CO_2 and MnO_4^- is reduced to Mn^{2+}.

13. To precipitate as $Ag_2S(s)$, all the Ag^+ present in 338 mL of a saturated solution of $AgBrO_3$ requires 30.4 mL of $H_2S(g)$ measured at 23 °C and 748 mmHg. What is K_{sp} for $AgBrO_3$?

14. Excess $Ca(OH)_2(s)$ is shaken with water to produce a saturated solution. A 50.00 mL sample of the clear saturated solution is withdrawn and requires 10.7 mL of 0.1032 M HCl for its titration. What is K_{sp} for $Ca(OH)_2$?

The Common-Ion Effect

15. Calculate the molar solubility of $Mg(OH)_2$ ($K_{sp} = 1.8 \times 10^{-11}$) in **(a)** pure water; **(b)** 0.0862 M $MgCl_2$; **(c)** 0.0355 M KOH(aq).

16. How would you expect the presence of each of the following solutes to affect the molar solubility of $CaCO_3$ in water: **(a)** Na_2CO_3; **(b)** HCl; **(c)** $NaHSO_4$? Explain.

17. Describe the effects of the salts KI and $AgNO_3$ on the solubility of AgI in water.

18. Describe the effect of the salt KNO_3 on the solubility of AgI in water, and explain why it is different from the effects noted in Exercise 17.

19. A 0.150 M Na_2SO_4 solution that is saturated with Ag_2SO_4 has $[Ag^+] = 9.7 \times 10^{-3}$ M. What is the value of K_{sp} for Ag_2SO_4 obtained with these data?

20. If 100.0 mL of 0.0025 M $Na_2SO_4(aq)$ is saturated with $CaSO_4$, how many grams of $CaSO_4$ would be present in the solution? [*Hint:* Does the usual simplifying assumption hold?]

21. What $[Pb^{2+}]$ should be maintained in $Pb(NO_3)_2(aq)$ to produce a solubility of 1.5×10^{-4} mol PbI_2/L when $PbI_2(s)$ is added?

22. What $[I^-]$ should be maintained in KI(aq) to produce a solubility of 1.5×10^{-5} mol PbI_2/L when $PbI_2(s)$ is added?

23. Can the solubility of Ag_2CrO_4 be lowered to 5.0×10^{-8} mol Ag_2CrO_4/L by using $CrO_4{}^{2-}$ as the common ion? by using Ag^+? Explain.

24. A handbook lists the K_{sp} values 1.1×10^{-10} for $BaSO_4$ and 5.1×10^{-9} for $BaCO_3$. When saturated $BaSO_4(aq)$ is also made with 0.50 M $Na_2CO_3(aq)$, a precipitate of $BaCO_3(s)$ forms. How do you account for this fact, given that $BaCO_3$ has a larger K_{sp} than does $BaSO_4$?

25. A particular water sample that is saturated in CaF_2 has a Ca^{2+} content of 115 ppm (that is, 115 g Ca^{2+} per 10^6 g of water sample). What is the F^- ion content of the water in ppm?

26. Assume that, to be visible to the unaided eye, a precipitate must weigh more than 1 mg. If you add 1.0 mL of 1.0 M NaCl(aq) to 100.0 mL of a clear saturated aqueous AgCl solution, will you be able to see AgCl(s) precipitated as a result of the common-ion effect? Explain.

Criteria for Precipitation from Solution

27. Will precipitation of $MgF_2(s)$ occur if a 22.5 mg sample of $MgCl_2 \cdot 6\,H_2O$ is added to 325 mL of 0.035 M KF?

28. Will $PbCl_2(s)$ precipitate when 155 mL of 0.016 M KCl(aq) are added to 245 mL of 0.175 M $Pb(NO_3)_2(aq)$?

29. What is the minimum pH at which $Cd(OH)_2(s)$ will precipitate from a solution that is 0.0055 M in $Cd^{2+}(aq)$?

30. What is the minimum pH at which $Cr(OH)_3(s)$ will precipitate from a solution that is 0.086 M in $Cr^{3+}(aq)$?

31. Will precipitation occur in the following cases?

(a) 0.10 mg NaCl is added to 1.0 L of 0.10 M $AgNO_3(aq)$.

(b) One drop (0.05 mL) of 0.10 M KBr is added to 250 mL of a saturated solution of AgCl.

(c) One drop (0.05 mL) of 0.0150 M NaOH(aq) is added to 3.0 L of a solution with 2.0 mg Mg^{2+} per liter.

32. The electrolysis of $MgCl_2(aq)$ can be represented as

$$Mg^{2+}(aq) + 2\,Cl^-(aq) + 2\,H_2O(l) \longrightarrow Mg^{2+}(aq) + 2\,OH^-(aq) + H_2(g) + Cl_2(g)$$

The electrolysis of a 315 mL sample of 0.185 M $MgCl_2$ is continued until 0.652 L $H_2(g)$ at 22 °C and 752 mmHg has been collected. Will $Mg(OH)_2(s)$ precipitate when electrolysis is carried to this point? [*Hint:* Notice that $[Mg^{2+}]$ remains constant throughout the electrolysis, but $[OH^-]$ *increases*.]

33. Determine whether 1.50 g $H_2C_2O_4$ (oxalic acid: $K_{a_1} = 5.2 \times 10^{-2}$, $K_{a_2} = 5.4 \times 10^{-5}$) can be dissolved in 0.200 L of 0.150 M $CaCl_2$ without the formation of $CaC_2O_4(s)$ ($K_{sp} = 1.3 \times 10^{-9}$).

34. If 100.0 mL of a clear saturated solution of Ag_2SO_4 is added to 250.0 mL of a clear saturated solution of $PbCrO_4$, will any precipitate form? [*Hint:* Take into account the dilutions that occur. What are the possible precipitates?]

Completeness of Precipitation

35. When 200.0 mL of 0.350 M $K_2CrO_4(aq)$ are added to 200.0 mL of 0.0100 M $AgNO_3(aq)$, what percentage of the Ag^+ is left *unprecipitated*?

36. What percentage of the original Ag^+ remains in solution when 175 mL 0.0208 M $AgNO_3$ is added to 250 mL 0.0380 M K_2CrO_4?

37. If a constant $[Cl^-] = 0.100$ M is maintained in a solution in which the initial $[Pb^{2+}] = 0.065$ M, what percentage of the Pb^{2+} will remain in solution after $PbCl_2(s)$ precipitates? What $[Cl^-]$ should be maintained to ensure that only 1.0% of the Pb^{2+} remains unprecipitated?

38. The ancient Romans added calcium sulfate to wine to clarify it and to remove dissolved lead. What is the maximum $[Pb^{2+}]$ that might be present in wine to which calcium sulfate has been added?

Fractional Precipitation

39. Assume that the seawater sample described in Example 18-6 contains approximately 440 g Ca^{2+} per metric ton (1 metric ton = 10^3 kg; density of seawater = 1.03 g/mL).

(a) Should $Ca(OH)_2(s)$ precipitate from seawater under the stated conditions, that is, with $[OH^-] = 2.0 \times 10^{-3}$ M?

(b) Is the separation of Ca^{2+} from Mg^{2+} in seawater feasible?

40. Which one of the following solutions can be used to separate the cations in an aqueous solution in which $[Ba^{2+}] = [Ca^{2+}] = 0.050$ M: 0.10 M NaCl(aq), 0.05 M $Na_2SO_4(aq)$, 0.001 M NaOH(aq), or 0.50 M $Na_2CO_3(aq)$? Explain why.

41. KI(aq) is slowly added to a solution with $[Pb^{2+}] = [Ag^+] = 0.10$ M. For PbI_2, $K_{sp} = 7.1 \times 10^{-9}$; for AgI, $K_{sp} = 8.5 \times 10^{-17}$.
(a) Which precipitate should form first, PbI_2 or AgI?
(b) What $[I^-]$ is required for the *second* cation to begin to precipitate?
(c) What concentration of the first cation to precipitate remains in solution at the point at which the second cation begins to precipitate?
(d) Can $Pb^{2+}(aq)$ and $Ag^+(aq)$ be effectively separated by fractional precipitation of their iodides?

42. A solution is 0.010 M in both $CrO_4{}^{2-}$ and $SO_4{}^{2-}$. To this solution, 0.50 M $Pb(NO_3)_2(aq)$ is slowly added.
(a) Which anion will precipitate first from solution?
(b) What is $[Pb^{2+}]$ at the point at which the second anion begins to precipitate?
(c) Are the two anions effectively separated by this fractional precipitation?

43. An aqueous solution that 2.00 M in $AgNO_3$ is slowly added from a buret to an aqueous solution that is 0.0100 M in Cl^- and 0.250 M in I^-.
(a) Which ion, Cl^- or I^-, is the first to precipitate?
(b) When the second ion begins to precipitate, what is the remaining concentration of the first ion?
(c) Is the separation of Cl^- and I^- feasible by fractional precipitation in this solution?

44. $AgNO_3(aq)$ is slowly added to a solution that is 0.250 M NaCl and also 0.0022 M KBr.
(a) Which anion will precipitate first, Cl^- or Br^-?
(b) What is $[Ag^+]$ at the point at which the second anion begins to precipitate?
(c) Can the Cl^- and Br^- be separated effectively by this fractional precipitation?

Solubility and pH

45. Which of the following solids is (are) more soluble in an acidic solution than in pure water: KCl, $MgCO_3$, FeS, $Ca(OH)_2$, or C_6H_5COOH? Explain.

46. Which of the following solids is (are) more soluble in a basic solution than in pure water: $BaSO_4$, $H_2C_2O_4$, $Fe(OH)_3$, $NaNO_3$, or MnS? Explain.

47. The solubility of $Mg(OH)_2$ in a particular buffer solution is 0.65 g/L. What must be the pH of the buffer solution?

48. To 0.350 L of 0.150 M NH_3 is added 0.150 L of 0.100 M $MgCl_2$. How many grams of $(NH_4)_2SO_4$ should be present to prevent precipitation of $Mg(OH)_2(s)$?

49. For the equilibrium

$$Al(OH)_3(s) \rightleftharpoons Al^{3+}(aq) + 3\,OH^-(aq) \qquad K_{sp} = 1.3 \times 10^{-33}$$

(a) What is the *minimum pH* at which $Al(OH)_3(s)$ will precipitate from a solution that is 0.075 M in Al^{3+}?
(b) A solution has $[Al^{3+}] = 0.075$ M and $[CH_3COOH] = 1.00$ M. What is the maximum quantity of $NaCH_3COO$ that can be added to 250.0 mL of this solution before precipitation of $Al(OH)_3(s)$ begins?

50. Will the following precipitates form under the given conditions?
(a) $PbI_2(s)$, from a solution that is 1.05×10^{-3} M HI, 1.05×10^{-3} M NaI, and 1.1×10^{-3} M $Pb(NO_3)_2$.
(b) $Mg(OH)_2(s)$, from 2.50 L of 0.0150 M $Mg(NO_3)_2$ to which is added 1 drop (0.05 mL) of 6.00 M NH_3.
(c) $Al(OH)_3(s)$ from a solution that is 0.010 M in Al^{3+}, 0.010 M CH_3COOH, and 0.010 M $NaCH_3COO$.

Complex-Ion Equilibria

51. $PbCl_2(s)$ is considerably more soluble in HCl(aq) than in pure water, but its solubility in $HNO_3(aq)$ is not much different from what it is in water. Explain this difference in behavior.

52. Which of the following would be most effective, and which would be least effective, in reducing the concentration of the complex ion $[Zn(NH_3)_4]^{2+}$ in a solution: HCl, NH_3, or NH_4Cl? Explain your choices.

53. In a solution that is 0.0500 M in $[Cu(CN)_4]^{3-}$ and 0.80 M in free CN^-, the concentration of Cu^+ is 6.1×10^{-32} M. Calculate K_f of $[Cu(CN)_4]^{3-}$.

$$Cu^+(aq) + 4\,CN^-(aq) \rightleftharpoons [Cu(CN)_4]^{3-}(aq) \qquad K_f = ?$$

54. Calculate $[Cu^{2+}]$ in a 0.10 M $CuSO_4(aq)$ solution that is also 6.0 M in free NH_3.

$$Cu^{2+}(aq) + 4\,NH_3(aq) \rightleftharpoons [Cu(NH_3)_4]^{2+}(aq) \qquad K_f = 1.1 \times 10^{13}$$

55. Can the following ion concentrations be maintained in the same solution without a precipitate forming: $[[Ag(S_2O_3)_2]^{3-}] = 0.048$ M, $[S_2O_3{}^{2-}] = 0.76$ M, and $[I^-] = 2.0$ M?

56. A solution is 0.10 M in *free* NH_3, 0.10 M in NH_4Cl, and 0.015 M in $[Cu(NH_3)_4]^{2+}$. Will $Cu(OH)_2(s)$ precipitate from this solution? K_{sp} of $Cu(OH)_2$ is 2.2×10^{-20}.

57. A 0.10 mol sample of $AgNO_3(s)$ is dissolved in 1.00 L of 1.00 M NH_3. How many grams of KI can be dissolved in this solution without a precipitate of AgI(s) forming?

58. A solution is prepared that has $[NH_3] = 1.00$ M and $[Cl^-] = 0.100$ M. How many grams of $AgNO_3$ can be dissolved in 1.00 L of this solution without a precipitate of AgCl(s) forming?

Precipitation and Solubilities of Metal Sulfides

59. Can Fe^{2+} and Mn^{2+} be separated by precipitating FeS(s) and not MnS(s)? Assume $[Fe^{2+}] = [Mn^{2+}] = [H_2S] = 0.10$ M. Choose a $[H_3O^+]$ that ensures maximum precipitation of FeS(s) but not MnS(s). Will the separation be complete? For FeS, $K_{spa} = 6 \times 10^2$; for MnS, $K_{spa} = 3 \times 10^7$.

60. A solution is 0.05 M in Cu^{2+}, in Hg^{2+}, and in Mn^{2+}. Which sulfides will precipitate if the solution is made to be 0.10 M $H_2S(aq)$ and 0.010 M HCl(aq)? For CuS, $K_{spa} = 6 \times 10^{-16}$; for HgS, $K_{spa} = 2 \times 10^{-32}$; for MnS, $K_{spa} = 3 \times 10^7$.

61. A buffer solution is 0.25 M CH_3COOH–0.15 M $NaCH_3COO$, saturated in H_2S (0.10 M), and with $[Mn^{2+}] = 0.15$ M.

(a) Show that MnS will *not* precipitate from this solution (for MnS, $K_{spa} = 3 \times 10^7$).

(b) Which buffer component would you increase in concentration, and to what minimum value, to ensure that precipitation of MnS(s) begins? Assume that the concentration of the other buffer component is held constant. [*Hint:* Recall equation (18.8).]

62. The following expressions pertain to the precipitation or dissolving of metal sulfides. Use information about the qualitative cation analysis scheme to predict whether a reaction proceeds to a significant extent in the forward direction and what the products are in each case.

(a) $Cu^{2+}(aq) + H_2S(\text{satd aq}) \longrightarrow$

(b) $Mg^{2+}(aq) + H_2S(\text{satd aq}) \xrightarrow{0.3\text{ M HCl}}$

(c) $PbS(s) + HCl(0.3\text{ M}) \longrightarrow$

(d) $ZnS(s) + HNO_3(aq) \longrightarrow$

Qualitative Cation Analysis

63. Suppose you did a group 1 qualitative cation analysis and treated the chloride precipitate with $NH_3(aq)$ without first treating it with hot water. What might you observe, and what valid conclusions could you reach about cations present, cations absent, and cations in doubt?

64. Show that in qualitative cation analysis group 1, if you obtain 1.00 mL of saturated $PbCl_2(aq)$ at 25 °C, sufficient Pb^{2+} should be present to produce a precipitate of $PbCrO_4(s)$. Assume that you use 1 drop (0.05 mL) of 1.0 M K_2CrO_4 for the test.

65. The addition of HCl(aq) to a solution containing several different cations produces a white precipitate. The filtrate is removed and treated with $H_2S(aq)$ in 0.3 M HCl. No precipitate forms. Which of the following conclusions is (are) valid? Explain.

(a) Ag^+ or Hg_2^{2+} (or both) is probably present.

(b) Mg^{2+} is probably not present.

(c) Pb^{2+} is probably not present.

(d) Fe^{2+} is probably not present.

66. Write net ionic equations for the following qualitative cation analysis procedures.

(a) precipitation of $PbCl_2(s)$ from a solution containing Pb^{2+}

(b) dissolution of $Zn(OH)_2(s)$ in a solution of NaOH(aq)

(c) dissolution of $Fe(OH)_3(s)$ in HCl(aq)

(d) precipitation of CuS(s) from an acidic solution of Cu^{2+} and H_2S

Integrative and Advanced Exercises

(Use data from Chapters 16 and 18 and Appendix D as needed.)

67. A particular water sample has 131 ppm of $CaSO_4$ (131 g $CaSO_4$ per 10^6 g water). If this water is boiled in a teakettle, approximately what fraction of the water must be evaporated before $CaSO_4(s)$ begins to precipitate? Assume that the solubility of $CaSO_4(s)$ does not change much in the temperature range 0 to 100 °C.

68. A handbook lists the solubility of $CaHPO_4$ as 0.32 g $CaHPO_4 \cdot 2\,H_2O$/L and lists K_{sp} as 1×10^{-7}.

$$CaHPO_4(s) \rightleftharpoons Ca^{2+}(aq) + HPO_4^{\,2-}(aq)$$

(a) Are these data consistent? (That is, are the molar solubilities the same when derived in two different ways?)

(b) If there is a discrepancy, how do you account for it?

69. A 50.0 mL sample of 0.0152 M $Na_2SO_4(aq)$ is added to 50.0 mL of 0.0125 M $Ca(NO_3)_2(aq)$. What percentage of the Ca^{2+} remains unprecipitated?

70. What percentage of the Ba^{2+} in solution is precipitated as $BaCO_3(s)$ if equal volumes of 0.0020 M $Na_2CO_3(aq)$ and 0.0010 M $BaCl_2(aq)$ are mixed?

71. Determine the molar solubility of lead(II) azide, $Pb(N_3)_2$, in a buffer solution with pH = 3.00, given that

$$Pb(N_3)_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,N_3^{\,-}(aq) \qquad K_{sp} = 2.5 \times 10^{-9}$$

$$HN_3(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + N_3^{\,-}(aq) \qquad K_a = 1.9 \times 10^{-5}$$

72. Calculate the molar solubility of $Mg(OH)_2$ in 1.00 M $NH_4Cl(aq)$.

73. The chief compound in marble is $CaCO_3$. Marble has been widely used for statues and ornamental work on buildings. However, marble is readily attacked by acids. Determine the solubility of marble (that is, $[Ca^{2+}]$ in a saturated solution) in **(a)** normal rainwater of pH = 5.6; **(b)** acid rainwater of pH = 4.20. Assume that the overall reaction that occurs is

$$CaCO_3(s) + H_3O^+(aq) \rightleftharpoons Ca^{2+}(aq) + HCO_3^-(aq) + H_2O(l)$$

74. What is the solubility of MnS, in grams per liter, in a buffer solution that is 0.100 M CH_3COOH − 0.500 M $NaCH_3COO$? For MnS, $K_{spa} = 3 \times 10^7$.

75. Write net ionic equations for each of the following observations.
(a) When concentrated $CaCl_2(aq)$ is added to $Na_2HPO_4(aq)$, a white precipitate forms that is 38.7% Ca by mass.
(b) When a piece of dry ice, $CO_2(s)$, is placed in a clear dilute solution of limewater $[Ca(OH)_2(aq)]$, bubbles of gas evolve. At first, a white precipitate forms, but then it redissolves.

76. Concerning the reactions described in Exercise 75(b),
(a) Will the same observations be made if $Ca(OH)_2(aq)$ is replaced by $CaCl_2(aq)$? Explain.
(b) Show that the white precipitate will redissolve if the $Ca(OH)_2(aq)$ is about 0.005 M, but not if the solution is saturated.

77. Reaction (18.10), described in the Integrative Example, is called a *carbonate transposition.* In such a reaction, anions of a slightly soluble compound (for example, hydroxides and sulfates) are obtained in a sufficient concentration in aqueous solution that they can be identified by qualitative analysis tests. Suppose that 3 M Na_2CO_3 is used and that an anion concentration of 0.050 M is sufficient for its detection. Predict whether carbonate transposition will be effective for detecting **(a)** SO_4^{2-} from $BaSO_4(s)$; **(b)** Cl^- from AgCl(s); **(c)** F^- from $MgF_2(s)$.

78. For the titration in Example 18-7, verify the assertion that $[Ag^+]$ increases very rapidly between the point at which AgBr has finished precipitating and Ag_2CrO_4 is about to begin.

79. Aluminum compounds are soluble in acidic solution, where aluminum(III) exists as the complex ion $[Al(H_2O)_6]^{3+}$, which is generally represented simply as $Al^{3+}(aq)$. They are also soluble in basic solutions, where the aluminum(III) is present as the complex ion $[Al(OH)_4]^-$. At certain intermediate pH values, the concentration of aluminum(III) that can exist in solution is at a minimum. Thus, a plot of the total concentration of aluminum(III) in solution as a function of pH yields a U-shaped curve. Demonstrate that this is the case with a few calculations.

80. The solubility of AgCN(s) in 0.200 M $NH_3(aq)$ is 8.8×10^{-6} mol/L. Calculate K_{sp} for AgCN.

81. The solubility of $CdCO_3(s)$ in 1.00 M KI(aq) is 1.2×10^{-3} mol/L. Given that K_{sp} of $CdCO_3$ is 5.2×10^{-12}, what is K_f for $[CdI_4]^{2-}$?

82. Use K_{sp} for $PbCl_2$ and K_f for $[PbCl_3]^-$ to determine the molar solubility of $PbCl_2$ in 0.10 M HCl(aq). [*Hint:* What is the total concentration of lead species in solution?]

83. A mixture of $PbSO_4(s)$ and $PbS_2O_3(s)$ is shaken with pure water until a saturated solution is formed. Both solids remain in excess. What is $[Pb^{2+}]$ in the saturated solution? For $PbSO_4$, $K_{sp} = 1.6 \times 10^{-8}$; for PbS_2O_3, $K_{sp} = 4.0 \times 10^{-7}$.

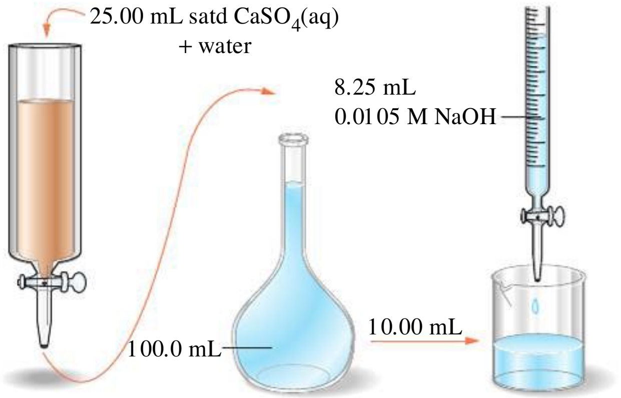
84. Use the method of Exercise 83 to determine $[Pb^{2+}]$ in a saturated solution in contact with a mixture of $PbCl_2(s)$ and $PbBr_2(s)$.

85. A 2.50 g sample of $Ag_2SO_4(s)$ is added to a beaker containing 0.150 L of 0.025 M $BaCl_2$.
(a) Write an equation for any reaction that occurs.
(b) Describe the final contents of the beaker—that is, the masses of any precipitates present and the concentrations of the ions in solution.

86. How many moles of solid sodium fluoride should be added to 1.0 L of a saturated solution of barium fluoride, BaF_2, at 25 °C to raise the fluoride concentration to 0.030 mol/L? What mass of BaF_2 precipitates? You may ignore the hydrolysis of fluoride ion. [*Hint*: This first part of this problem is most easily solved by first writing down an electroneutrality condition. See pages 721–722.]

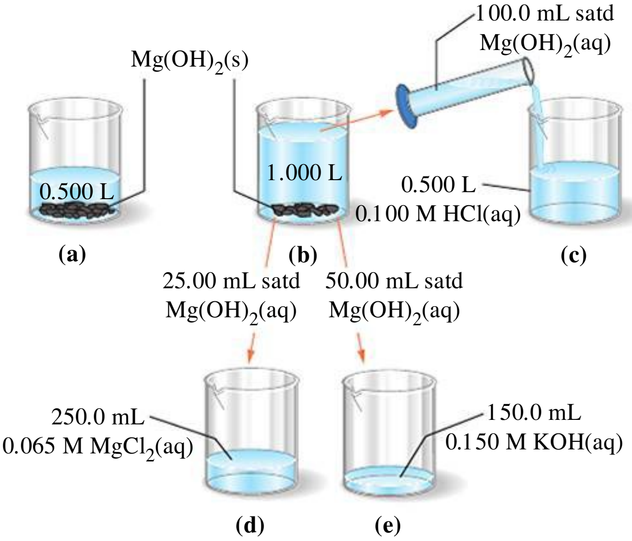
Feature Problems

87. In an experiment to measure K_{sp} of $CaSO_4$ [D. Masterman, *J. Chem. Educ.*, **64**, 409 (1987)], a saturated solution of $CaSO_4(aq)$ is poured into the ion-exchange column pictured (and described in Chapter 21). As the solution passes through the column, Ca^{2+} is retained by the ion-exchange medium and H_3O^+ is released; two H_3O^+ ions appear in the effluent solution for every Ca^{2+} ion. As the drawing suggests, a 25.00 mL sample is added to the column, and the effluent is collected and diluted to 100.0 mL in a volumetric flask. A 10.00 mL portion of the diluted solution requires 8.25 mL of 0.0105 M NaOH for its titration. Use these data to obtain a value of K_{sp} for $CaSO_4$.



88. In the *Mohr titration*, $Cl^-(aq)$ is titrated with $AgNO_3(aq)$ in solutions that are at about pH = 7. Thus, it is suitable for determining the chloride ion content of drinking water. The indicator used in the titration is $K_2CrO_4(aq)$. A red-brown precipitate of $Ag_2CrO_4(s)$ forms after all the Cl^- has precipitated. The titration reaction is $Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$. At the equivalence point of the titration, the titration mixture consists of AgCl(s) and a solution having neither Ag^+ nor Cl^- in excess. Also, no $Ag_2CrO_4(s)$ is present, but it forms immediately after the equivalence point.
(a) How many milliliters of 0.01000 M $AgNO_3(aq)$ are required to titrate 100.0 mL of a municipal water sample having 29.5 mg Cl^-/L?
(b) What is $[Ag^+]$ at the equivalence point of the Mohr titration?
(c) What is $[CrO_4^{2-}]$ in the titration mixture to meet the requirement of no precipitation of $Ag_2CrO_4(s)$ until immediately after the equivalence point?
(d) Describe the effect on the results of the titration if $[CrO_4^{2-}]$ were (1) greater than that calculated in part (c) or (2) less than that calculated?
(e) Do you think the Mohr titration would work if the reactants were exchanged—that is, with $Cl^-(aq)$ as the titrant and $Ag^+(aq)$ in the sample being analyzed? Explain.

89. The accompanying drawing suggests a series of manipulations starting with saturated $Mg(OH)_2(aq)$. Calculate $[Mg^{2+}(aq)]$ at each of the lettered stages.
(a) 0.500 L of saturated $Mg(OH)_2(aq)$ is in contact with $Mg(OH)_2(s)$.
(b) 0.500 L of H_2O is added to the 0.500 L of solution in part (a), and the solution is vigorously stirred. Undissolved $Mg(OH)_2(s)$ remains.
(c) 100.0 mL of the clear solution in part (b) is removed and added to 0.500 L of 0.100 M HCl(aq).
(d) 25.00 mL of the clear solution in part (b) is removed and added to 250.0 mL of 0.065 M $MgCl_2(aq)$.
(e) 50.00 mL of the clear solution in part (b) is removed and added to 150.0 mL of 0.150 M KOH(aq).



Self-Assessment Exercises

90. In your own words, define the following terms or symbols: **(a)** K_{sp}; **(b)** K_f; **(c)** Q_{sp}; **(d)** complex ion.

91. Briefly describe each of the following ideas, methods, or phenomena: **(a)** common-ion effect in solubility equilibrium; **(b)** fractional precipitation; **(c)** ion-pair formation; **(d)** qualitative cation analysis.

92. Explain the important distinction between each pair of terms: **(a)** solubility and solubility product constant; **(b)** common-ion effect and salt effect; **(c)** ion pair and ion product.

93. Pure water is saturated with slightly soluble PbI_2. Which of the following is a correct statement concerning the lead ion concentration in the solution, and what is wrong with the others? **(a)** $[Pb^{2+}] = [I^-]$; **(b)** $[Pb^{2+}] = K_{sp}$ of PbI_2; **(c)** $[Pb^{2+}] = \sqrt{K_{sp}}$ of PbI_2; **(d)** $[Pb^{2+}] = 0.5[I^-]$.

94. Adding 1.85 g Na_2SO_4 to 500.0 mL of saturated aqueous $BaSO_4$: **(a)** reduces $[Ba^{2+}]$; **(b)** reduces $[SO_4^{2-}]$; **(c)** increases the solubility of $BaSO_4$; **(d)** has no effect.

95. The slightly soluble solute Ag_2CrO_4 is *most* soluble in **(a)** pure water; **(b)** 0.10 M K_2CrO_4; **(c)** 0.25 M KNO_3; **(d)** 0.40 M $AgNO_3$.

96. Cu^{2+} and Pb^{2+} are both present in an aqueous solution. To precipitate one of the ions and leave the other in solution, add **(a)** $H_2S(aq)$; **(b)** $H_2SO_4(aq)$; **(c)** $HNO_3(aq)$; **(d)** $NH_4NO_3(aq)$.

97. All but two of the following solutions yield a precipitate when the solution is also made 2.00 M in NH_3. Those two are **(a)** $MgCl_2(aq)$; **(b)** $FeCl_3(aq)$; **(c)** $(NH_4)_2SO_4(aq)$; **(d)** $Cu(NO_3)_2(aq)$; **(e)** $Al_2(SO_4)_3(aq)$.

98. To increase the molar solubility of $CaCO_3(s)$ in a saturated aqueous solution, add **(a)** ammonium chloride; **(b)** sodium carbonate; **(c)** ammonia; **(d)** more water.

99. The best way to ensure complete precipitation from saturated $H_2S(aq)$ of a metal ion, M^{2+}, as its sulfide, MS(s), is to **(a)** add an acid; **(b)** increase $[H_2S]$ in the solution; **(c)** raise the pH; **(d)** heat the solution.

100. Which of the following solids are likely to be more soluble in acidic solution and which in basic solution? Which are likely to have a solubility that is independent of pH? Explain. **(a)** $H_2C_2O_4$; **(b)** $MgCO_3$; **(c)** CdS; **(d)** KCl; **(e)** $NaNO_3$; **(f)** $Ca(OH)_2$.

101. Both Mg^{2+} and Cu^{2+} are present in the same aqueous solution. Which of the following reagents would work best in separating these ions, precipitating one and leaving the other in solution: NaOH(aq), HCl(aq), $NH_4Cl(aq)$, or $NH_3(aq)$? Explain your choice.

102. Will $Al(OH)_3(s)$ precipitate from a buffer solution that is 0.45 M CH_3COOH and 0.35 M $NaCH_3COO$ and also 0.275 M in $Al^{3+}(aq)$? For $Al(OH)_3$, $K_{sp} = 1.3 \times 10^{-33}$; for CH_3COOH, $K_a = 1.8 \times 10^{-5}$.

103. Saturated solutions of sodium phosphate, copper(II) chloride, and ammonium acetate are mixed together. The precipitate is **(a)** copper(II) acetate; **(b)** copper(II) phosphate; **(c)** sodium chloride; **(d)** ammonium phosphate; **(e)** nothing precipitates.

104. Which of the following has the highest molar solubility? **(a)** MgF_2, $K_{sp} = 3.7 \times 10^{-8}$; **(b)** $MgCO_3$, $K_{sp} = 3.5 \times 10^{-8}$; **(c)** $Mg_3(PO_4)_2$, $K_{sp} = 1 \times 10^{-25}$; **(d)** Li_3PO_4, $K_{sp} = 3.2 \times 10^{-9}$.

105. Lead(II) chloride is most soluble in **(a)** 0.100 M NaCl; **(b)** 0.100 $Na_2S_2O_3$; **(c)** 0.100 M $Pb(NO_3)_2$; **(d)** 0.100 M $NaNO_3$; **(e)** 0.100 $MnSO_4$.

106. Given the following ions in solution, Hg^{2+}, I^-, Ag^+, and NO_3^-, does the formation of a complex ion increase or decrease the amount of precipitate?

107. Will AgI(s) precipitate from a solution with $[[Ag(CN)_2]^-] = 0.012$ M, $[CN^-] = 1.05$ M, and $[I^-] = 2.0$ M? For AgI, $K_{sp} = 8.5 \times 10^{-17}$; for $[Ag(CN)_2]^-$, $K_f = 5.6 \times 10^{18}$.

108. Without performing detailed calculations, indicate whether either of the following compounds is appreciably soluble in $NH_3(aq)$: **(a)** CuS, $K_{sp} = 6.3 \times 10^{-36}$; **(b)** $CuCO_3$, $K_{sp} = 1.4 \times 10^{-10}$. Also use the fact that K_f for $[Cu(NH_3)_4]^{2+}$ is 1.1×10^{13}.

109. Appendix E describes a useful study aid known as concept mapping. Using the methods presented in Appendix E, construct a concept map that links the various factors affecting the solubility of slightly soluble solutes.

19

Spontaneous Change: Entropy and Gibbs Energy

Thermodynamics originated in the early nineteenth century with attempts to improve the efficiency of steam engines. However, the laws of thermodynamics are widely useful throughout the field of chemistry and in biology as well, as we discover in this chapter.

CONTENTS

19-1 Spontaneity: The Meaning of Spontaneous Change
19-2 The Concept of Entropy
19-3 Evaluating Entropy and Entropy Changes
19-4 Criteria for Spontaneous Change: The Second Law of Thermodynamics
19-5 Standard Gibbs Energy Change, ΔG°
19-6 Gibbs Energy Change and Equilibrium
19-7 ΔG° and K as Functions of Temperature
19-8 Coupled Reactions

In Chapter 15, we noted that the reaction of nitrogen and oxygen gases, which does not occur appreciably in the forward direction at room temperature, produces significant equilibrium amounts of NO(g) at *high* temperatures.

$$N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g)$$

Another reaction involving oxides of nitrogen is the conversion of NO(g) to $NO_2(g)$:

$$2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$$

This reaction, unlike the first, yields its greatest equilibrium amounts of $NO_2(g)$ at *low* temperatures.

What is there about these two reactions that causes the forward reaction of one to be favored at high temperatures but the forward reaction of the other to be favored at low temperatures? Our primary objective in this chapter is to develop concepts to help us answer questions like this. This chapter, taken together with ideas from Chapter 7, shows the great power of thermodynamics to provide explanations of many chemical phenomena.

◀ Throughout the text we have adopted the IUPAC recommended name of "Gibbs energy" to replace the terms *free energy* or *Gibbs free energy*.

19-1 Spontaneity: The Meaning of Spontaneous Change

Most of us have played with spring-wound toys, whether a toy automobile, top, or music box. In every case, once the wound-up toy is released, it keeps running until the stored energy in the spring has been released; then the toy stops. The toy never rewinds itself. Human intervention is necessary (winding by hand). The running down of a wound-up spring is an example of a *spontaneous* process. The rewinding of the spring is a *nonspontaneous* process. Let's explore the scientific meaning of these two terms.

▲ When the spring powering this mechanical toy unwinds, the toy stops moving. The spring cannot spontaneously rewind.

A **spontaneous process** is a process that occurs in a system left to itself; once started, no action from outside the system (external action) is necessary to make the process continue. Conversely, a **nonspontaneous process** will not occur *unless* some external action is continuously applied. Consider the rusting of an iron pipe exposed to the atmosphere. Although the process occurs slowly, it does so continuously. As a result, the amount of iron decreases and the amount of rust increases until a final state of equilibrium is reached in which essentially all the iron has been converted to iron(III) oxide. We say that the reaction

$$4\,\mathrm{Fe(s)} + 3\,\mathrm{O_2(g)} \longrightarrow 2\,\mathrm{Fe_2O_3(s)}$$

is *spontaneous*. Now consider the reverse situation: the extraction of pure iron from iron(III) oxide. We should not say that the process is impossible, but it is certainly *nonspontaneous*. In fact, this nonspontaneous reverse process is involved in the manufacture of iron from iron ore.

▶ Spontaneous: "proceeding from natural feeling or native tendency without external constraint . . . ; developing without apparent external influence, force, cause, or treatment." *Merriam-Webster's Collegiate Dictionary*, online, 2000.

We will consider specific quantitative criteria for spontaneous change later in the chapter, but even now we can identify some spontaneous processes intuitively. For example, in the neutralization of NaOH(aq) with HCl(aq), the net change that occurs is

$$\mathrm{H_3O^+(aq)} + \mathrm{OH^-(aq)} \longrightarrow 2\,\mathrm{H_2O(l)}$$

There is very little tendency for the reverse reaction (self-ionization) to occur, so the neutralization reaction is a spontaneous reaction. The melting of ice, however, is spontaneous at temperatures above 0 °C but nonspontaneous below 0 °C.

From our discussion of spontaneity to this point, we can reach these conclusions at ambient pressures.

- If a process is spontaneous, the reverse process is nonspontaneous.
- Both spontaneous and nonspontaneous processes are possible, but only spontaneous processes will occur *without intervention*. Nonspontaneous processes require the system to be acted on by an external agent.
- Some spontaneous processes occur very slowly and others occur rather rapidly. For example, the melting of an ice cube that has been dropped into cold water at 1 °C is a spontaneous process that occurs slowly. The melting of an ice cube that has been dropped into hot water at 99 °C is a spontaneous process that occurs rapidly. The main point is that spontaneous does not mean fast.

▲ The melting of an ice cube occurs spontaneously at temperatures above 0 °C.

We would like to do more, however. We want to be able to predict whether the forward or the reverse direction is the direction of spontaneous change in a process, so we need a criterion for spontaneous change. To begin, let's look to mechanical systems for a clue. A ball rolls downhill, and water flows to a lower level. A common feature of these processes is that *potential energy decreases*.

For chemical systems, the property analogous to the potential energy of a mechanical system is the internal energy (U) or the closely related property enthalpy (H). In the 1870s, P. Berthelot and J. Thomsen proposed that the direction of spontaneous change is the direction in which the enthalpy of a system decreases. In a system in which enthalpy decreases, heat is given off by the system to the surroundings. Bertholet and Thomsen concluded that exothermic reactions should be spontaneous. In fact, many exothermic processes are spontaneous, but some are not. Also, some endothermic reactions *are* spontaneous. Thus, we cannot predict whether a process is spontaneous from its enthalpy change alone. Here are three examples of spontaneous, *endothermic* processes:

- the melting of ice at room temperature
- the evaporation of liquid diethyl ether from an open beaker
- the dissolving of ammonium nitrate in water

We will have to look to thermodynamic functions other than enthalpy change (ΔH) as criteria for spontaneous change.

19-1 CONCEPT ASSESSMENT

Is it correct to say that a spontaneous process is a fast process and a nonspontaneous process is a very slow one? Explain.

19-2 The Concept of Entropy

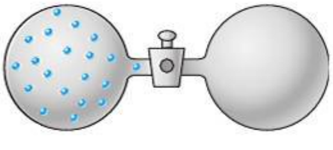
To continue our search for criteria for spontaneous change, consider Figure 19-1, which depicts two identical glass bulbs joined by a stopcock. Initially, the bulb on the left contains an ideal gas at 1.00 atm pressure, and the bulb on the right is evacuated. When the valve is opened, the gas immediately expands into the evacuated bulb. After this expansion, the molecules are dispersed throughout the apparatus, with essentially equal numbers of molecules in both bulbs and a pressure of 0.50 atm. What causes this spontaneous expansion of the gas at a constant temperature?

One of the characteristics of an ideal gas is that its internal energy (U) does not depend on the gas pressure, but only on the temperature. Therefore, in this expansion $\Delta U = 0$. Also, the enthalpy change is zero: $\Delta H = 0$. This means that the expansion is not caused by the system dropping to a lower energy state. A convenient mental image to "explain" the expansion is that the gas molecules tend to spread out into the larger volume available to them at the reduced pressure. A more fundamental description of the underlying cause is that, for the same total energy, in the expanded volume there are more available translational energy levels among which the gas molecules can be distributed. The tendency is for the energy of the system to spread out over a larger number of energy levels.

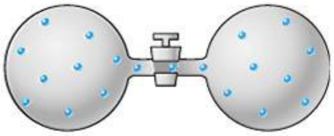
A similar situation—the mixing of ideal gases—is depicted in Figure 19-2. In this case, the two bulbs initially are filled with different ideal gases at 1.00 atm. When the stopcock is opened, the gases mix. The resulting change is essentially that of the expansion of the ideal gas pictured in Figure 19-1, but twice over. That is, each gas expands into the new volume available to it, without regard for the other gas (recall Dalton's law of partial pressures, page 213). Again, each expanded gas has more translational energy levels available to its molecules—the energy of the system has spread out. And again, the internal energy and enthalpy of the system are not changed by the expansion.

Entropy

The thermodynamic property related to the way in which the energy of a system is distributed among the available microscopic energy levels is called **entropy**.



(a) Initial condition



(b) After expansion into vacuum

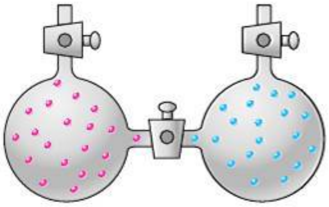
▲ FIGURE 19-1

Expansion of an ideal gas into a vacuum

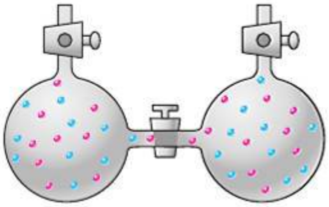
(a) Initially, an ideal gas is confined to the bulb on the left at 1.00 atm pressure. **(b)** When the stopcock is opened, the gas expands into the identical bulb on the right. The final condition is one in which the gas is equally distributed between the two bulbs at a pressure of 0.50 atm.

KEEP IN MIND

that U and H are related as follows: $H = U + PV$, and $\Delta H = \Delta U + \Delta(PV)$. For a fixed amount of an ideal gas at a constant temperature, PV = constant, $\Delta(PV) = 0$, and $\Delta H = \Delta U$.



(a) Before mixing



(b) After mixing

▲ FIGURE 19-2
The mixing of ideal gasses
The total volume of the system and the total gas pressure remain fixed. The net change is that **(a)** before mixing, each gas is confined to half the total volume (a single bulb) at a pressure of 1.00 atm, and **(b)** after mixing, each gas has expanded into the total volume (both bulbs) and exerts a partial pressure of 0.50 atm.

> The greater the number of arrangements (i.e., microstates) of the microscopic particles (atoms, ions, molecules) among the energy levels in a particular state of a system, the greater the entropy of the system.

Entropy is denoted by the symbol S. Like internal energy and enthalpy, entropy is a function of state (see page 256). It has a unique value for a system whose temperature, pressure, and composition are specified. The **entropy change, ΔS,** is the difference in entropy between two states of a system, and it also has a unique value.

In the gas expansion of Figure 19-1, the entropy of the gas *increases* and $\Delta S > 0$. In the mixing of gases as carried out in Figure 19-2, entropy also increases, a fact that we can represent symbolically.

$$\mathrm{A(g)} + \mathrm{B(g)} \longrightarrow \text{mixture of A(g) and B(g)}$$
$$\Delta S = S_{\text{mix of gases}} - [S_{\mathrm{A(g)}} + S_{\mathrm{B(g)}}] > 0$$

Because both of these expansions occur spontaneously and neither is accompanied by a change in internal energy or enthalpy, it seems possible that *increases in entropy underlie spontaneous processes*. This is a proposition that we will have to examine more closely later, but let's accept it for now.

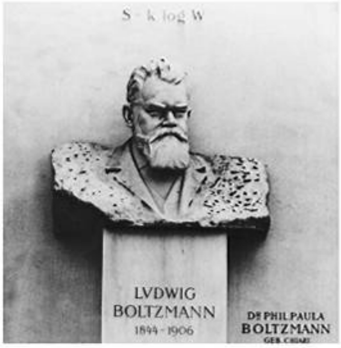
The Boltzmann Equation for Entropy

The connection between macroscopic changes, such as the mixing of gases, and the microscopic nature of matter was enunciated by Ludwig Boltzmann. The conceptual breakthrough that Boltzmann made was to associate the number of energy levels in the system with the number of ways of arranging the particles (atoms, ions, or molecules) in these energy levels. The microscopic energy levels are also called *states*, and the particular way a number of particles is distributed among these states is called a *microstate*. The more states a given number of particles can occupy, the more microstates the system has. The more microstates that exist, the greater the entropy. Boltzmann derived the relationship

$$S = k \ln W \tag{19.1}$$

where S is the entropy, k is the Boltzmann constant, and W is the number of microstates. We can think of the Boltzmann constant as the gas constant per molecule; that is, $k = R/N_A$. [Although we didn't specifically introduce k in the discussion of kinetic-molecular theory, R/N_A appears in equation (6.21).] The number of microstates, W, is the number of ways that the atoms or molecules can be positioned in the states available and still give rise to the same total energy. Each permissible arrangement of the particles constitutes one of the microstates, so W is the total number of microstates that correspond to the same energy.

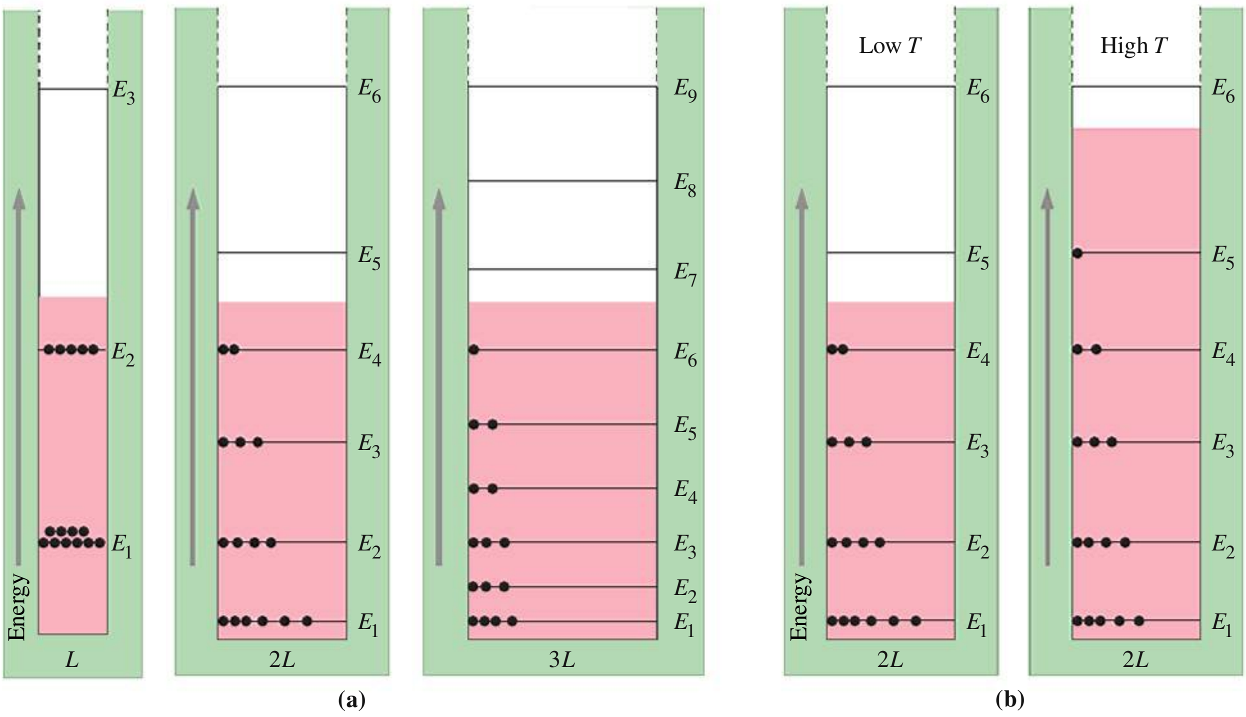
Let us explore the connection between the number of microstates (W) and entropy (S) a little further by using a small one-dimensional crystal of four nitrous oxide molecules, NO. At $T = 0$ K, the four NO molecules are aligned as NO $\cdots$ NO $\cdots$ NO $\cdots$ NO, which is the only microstate possible. Therefore, $W = 1$ and $S = 0$. Now consider what happens when the temperature is raised just enough to allow a single NO to rotate. Such an increase in temperature corresponds to an increase in the internal energy of the system. Now four microstates are possible, NO $\cdots$ NO $\cdots$ NO $\cdots$ ON; NO $\cdots$ NO $\cdots$ ON $\cdots$ NO; NO $\cdots$ ON $\cdots$ NO $\cdots$ NO; and ON $\cdots$ NO $\cdots$ NO $\cdots$ NO; W equals 4. By using Boltzmann's equation, we find that $S = k \ln 4 = (1.3807 \times 10^{-23}\ \mathrm{J\,K^{-1}}) \ln 4 = 1.9141 \times 10^{-23}\ \mathrm{J\,K^{-1}}$. As the energy of the system increases, the number of microstates increases; therefore, entropy of the system will increase.



▲ **A bust marking Ludwig Boltzmann's tomb in Vienna**
Boltzmann's famous equation is inscribed on the tomb. At the time of Boltzmann's death, the term *log* was used for both natural logarithms and logarithms to the base ten; the symbol "ln" had not yet been adopted.

How can we use Boltzmann's equation to think about the distribution of microscopic particles among the energy levels of a system? Let's consider again the particle-in-a-box model for a matter wave (page 318). Specifically, we can use the equation $E = n^2h^2/8mL^2$ to calculate a few energy levels for a matter wave in a one-dimensional box. Representative energy levels are shown in the energy-level diagrams in Figure 19-3(a) for a particle in boxes of lengths L, $2L$, and $3L$. We see the following relationship between the length of the box and the number of levels: L, *three* levels; $2L$, *six* levels; and $3L$, *nine* levels. As the boundaries of the box are expanded, the separation between the energy levels decreases resulting in an increase of accessible energy levels. Extending this model to three-dimensional space and large numbers of gas molecules, we find less crowding of molecules into a limited number of energy levels when the pressure of the gas drops and the molecules expand into a larger volume. Thus, there is a greater spreading of the energy, and the entropy increases.

We can use the same particle-in-a-box model to understand the effect of raising the temperature of a substance on the entropy of the system. We will consider a gas, but our conclusions are equally valid for a liquid or solid. At low temperatures, the molecules have a low energy, and the gas molecules can occupy only a few of the energy levels; the value of W is small, and the entropy is low. As the temperature is raised, the energy of the molecules increases and the molecules have access to a larger number of energy levels. Thus the number of accessible microstates (W) increases and the entropy rises (Fig. 19-3(b)).



▲ FIGURE 19-3

Energy levels for a particle in a one-dimensional box

(a) The energy levels of a particle in a box become more numerous and closer together as the length of the box increases. The range of thermally accessible levels is indicated by the tinted band. The solid circles signify a system consisting of 15 particles. Each drawing represents a single microstate of the system. Can you see that as the box length increases there are many more microstates available to the particles for a given amount of thermal energy? As the number of possible microstates for a given total energy increases, so does the entropy. **(b)** More energy levels become accessible in a box of fixed length as the temperature is raised. Because the average energy of the particles also increases, the internal energy and entropy both increase as the temperature is raised.

In summary, the state of a thermodynamic system can be described in two ways: the macroscopic description, in terms of state functions P, V, and T; and the microscopic description, requiring a knowledge of the position and velocity of every particle (atom or molecule) in the system. Boltzmann's equation provides the connection between the two.

Entropy Change

▶ The number of accessible states, W, is determined by the properties of a system. When a process takes place, the coupling must make the system larger; hence W must increase as the system spontaneously moves to a different equilibrium.

An entropy change is based on two measurable quantities: heat (q) and temperature (T). Both of these factors affect the availability of energy levels to the microscopic particles of a system. The following equation relates these factors to an entropy change,

$$\Delta S = \frac{q_{\text{rev}}}{T} \qquad \textbf{(19.2)}$$

where T is the Kelvin temperature. Notice that ΔS is directly proportional to the quantity of heat because the more energy added to a system (as heat), the greater the number of energy levels available to the microscopic particles. Raising the temperature also increases the availability of energy levels, but for a given quantity of heat the proportional increase in number of energy levels is greatest at low temperatures. That is why ΔS is inversely proportional to the Kelvin temperature.

Equation (19.2) appears simple, but it is not. If S is to be a function of state, ΔS for a system must be independent of the path by which heat is lost or

19-1 ARE YOU WONDERING...

If there is a natural way to incorporate the notion of infinitesimal changes in deriving equation (19.2)?

The infinitesimal change in entropy, dS, that accompanies an infinitesimal reversible heat flow, dq_{rev}, is $dS = dq_{\text{rev}}/T$. Now imagine the change in a system from state 1 to state 2 is carried out in a series of such infinitesimal reversible steps. Summation of all these infinitesimal quantities through the calculus technique of integration yields ΔS.

$$\Delta S = \int \frac{dq_{\text{rev}}}{T}$$

If the change of state is isothermal (carried out at constant temperature), we can write

$$\Delta S = \int \frac{dq_{\text{rev}}}{T} = \frac{1}{T}\int dq_{\text{rev}} = \frac{q_{\text{rev}}}{T}$$

and we have recovered the definition of entropy change in (19.2.)

Starting with equivalent expressions for dq_{rev}, ΔS can be related to other system properties. For the isothermal, reversible expansion of an ideal gas, $dq_{\text{rev}} = -dw_{\text{rev}}$, leading to equation (19.10) on page 839, which describes ΔS in terms of gas volumes. For a reversible change in temperature, $dq_{\text{rev}} = C_p\,dT$, which leads to the entropy change for a change in temperature (see Exercise 86).

gained. Conversely, because the value of q ordinarily depends on the path chosen (recall page 260), equation (19.2) holds only for a carefully defined path. The path must be *reversible*, that is, $q = q_{\text{rev}}$. As we learned in Chapter 7, a reversible process can be made to reverse its direction when just an infinitesimal change in the opposite direction is made in a system property (review Figure 7-12). Because q has the unit J and $1/T$ has the unit K^{-1}, the unit of entropy change, ΔS, is J/K, or J K^{-1}.

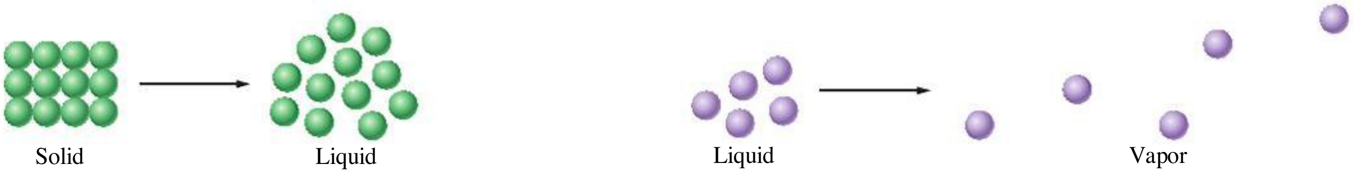
In some instances, it is difficult to construct mental pictures to assess how the entropy of a system changes during a process. However, in many cases, an increase or a decrease in the accessibility of energy levels for the microscopic particles of a system parallels an increase or decrease in the *number* of microscopic particles and the *space* available to them. As a consequence, we can often make qualitative predictions about entropy change by focusing on those two factors. Let's test this idea by considering again the three spontaneous, endothermic processes listed at the conclusion of Section 19-1 and illustrated in Figure 19-4.

In the melting of ice, a crystalline solid is replaced by a less structured liquid. Molecules that were relatively fixed in position in the solid, being limited to vibrational motion, are now free to move about a bit. The molecules have gained some translational and rotational motion. The number of accessible microscopic energy levels has increased, and so has the entropy.

In the vaporization process, a liquid is replaced by the even less structured gas. Molecules in the gaseous state, because they can move within a large free volume, have many more accessible energy levels than do those in the liquid state. In the gas, energy can be spread over a much greater number of microscopic energy levels than in the liquid. The entropy of the gaseous state is much higher than that of the liquid state.

In the dissolving of ammonium nitrate in water, for example, a crystalline solid and a pure liquid are replaced by a mixture of ions and water molecules in the liquid (solution) state. This situation is somewhat more involved than the first two because some decrease in entropy is associated with the clustering of water molecules around the ions because of ion–dipole forces. The increase in entropy that accompanies the destruction of the solid's crystalline lattice predominates, however, and for the overall dissolution process, $\Delta S > 0$.

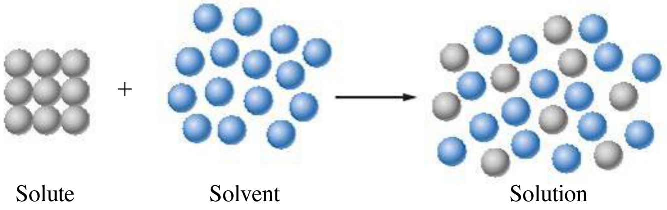
In each of the three spontaneous, endothermic processes discussed here, the increase in entropy ($\Delta S > 0$) outweighs the fact that heat must be absorbed ($\Delta H > 0$), and each process is spontaneous.



(a) Melting: $S_{\text{liquid}} > S_{\text{solid}}$

(b) Vaporization: $S_{\text{vapor}} > S_{\text{liquid}}$

▲ FIGURE 19-4
Three processes in which entropy increases
Each of the processes pictured—**(a)** the melting of a solid, **(b)** the evaporation of a liquid, and **(c)** the dissolving of a solute—results in an increase in entropy. For part (c), the generalization works best for nonelectrolyte solutions, in which ion–dipole forces do not exist.



(c) Dissolving: $S_{\text{soln}} > (S_{\text{solvent}} + S_{\text{solute}})$

In summary, four situations generally produce an *increase* in entropy:

- Pure liquids or liquid solutions are formed from solids.
- Gases are formed from either solids or liquids.
- The number of molecules of gas increases as a result of a chemical reaction.
- The temperature of a substance increases. (Increased temperature means an increased number of accessible energy levels for the increased molecular motion, whether it be vibrational motion of atoms or ions in a solid, or translational and rotational motion of molecules in a liquid or gas.)

We apply these generalizations in Example 19-1.

EXAMPLE 19-1 Making Qualitative Predictions of Entropy Changes in Physical and Chemical Processes

Predict whether each of the following processes involves an increase or a decrease in entropy or whether the outcome is uncertain.

(a) The decomposition of ammonium nitrate (a fertilizer and a highly explosive compound): $2\,NH_4NO_3(s) \longrightarrow 2\,N_2(g) + 4\,H_2O(g) + O_2(g)$.

(b) The conversion of SO_2 to SO_3 (a key step in the manufacture of sulfuric acid): $2\,SO_2(g) + O_2(g) \longrightarrow 2\,SO_3(g)$.

(c) The extraction of sucrose from cane sugar juice: $C_{12}H_{22}O_{11}(aq) \longrightarrow C_{12}H_{22}O_{11}(s)$.

(d) The "water gas shift" reaction (involved in the gasification of coal): $CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$.

Analyze

Apply the generalizations summarized above. Three of the processes are chemical reactions, and for those processes, we should first consider whether the number of molecules of gas increases or decreases.

Solve

(a) Here, a solid yields a large quantity of gas. Entropy increases.

(b) Three moles of gaseous reactants produce two moles of gaseous products. The loss of one mole of gas indicates a loss of volume available to a smaller number of gas molecules. This loss reduces the number of possible configurations for the molecules in the system and the number of accessible microscopic energy levels. Entropy decreases.

(c) The sucrose molecules are reduced in mobility and in the number of forms in which their energy can be stored when they leave the solution and arrange themselves into a crystalline state. Entropy decreases.

(d) The entropies of the four gases are likely to be different because their molecular structures are different. The number of moles of gases is the same on both sides of the equation, however, so the entropy change is likely to be small if the temperature is constant. On the basis of just the generalizations listed above, we cannot determine whether entropy increases or decreases.

Assess

As we shall soon see, the ability to predict increases or decreases in entropy will help us to understand when a process will proceed spontaneously in the forward direction.

PRACTICE EXAMPLE A: Predict whether entropy increases or decreases in each of the following reactions. **(a)** The Claus process for removing H_2S from natural gas: $2\,H_2S(g) + SO_2(g) \longrightarrow 3\,S(s) + 2\,H_2O(g)$; **(b)** the decomposition of mercury(II) oxide: $2\,HgO(s) \longrightarrow 2\,Hg(l) + O_2(g)$.

PRACTICE EXAMPLE B: Predict whether entropy increases or decreases or whether the outcome is uncertain in each of the following reactions. **(a)** $Zn(s) + Ag_2O(s) \longrightarrow ZnO(s) + 2\,Ag(s)$; **(b)** the chlor-alkali process, $2\,Cl^-(aq) + 2\,H_2O(l) \xrightarrow{\text{electrolysis}} 2\,OH^-(aq) + H_2(g) + Cl_2(g)$.

19-2 CONCEPT ASSESSMENT

Figure 19-1 illustrates a spontaneous process through the expansion of an ideal gas into an evacuated bulb. Use the one-dimensional particle-in-a-box model to represent the initial condition of Figure 19-1. Use a second particle-in-a-box model to represent the system after expansion into the vacuum. Use these models to explain on a microscopic basis why this expansion is spontaneous. [*Hint:* Assume that the volume of the bulbs is analogous to the length of the box.]

19-3 Evaluating Entropy and Entropy Changes

The difficulty of calculating an entropy change with equation (19.2) was mentioned on page 824. The emphasis then shifted to making qualitative predictions about entropy changes. In this section we will see that in a few instances a simple direct calculation of ΔS is possible. Also, we will find that, unlike the case with internal energy and enthalpy, it is possible to determine *absolute* entropy values.

Phase Transitions

In the equilibrium between two phases, the exchange of heat can be carried out reversibly, and the quantity of heat proves to be equal to the enthalpy change for the transition, ΔH_{tr}. In this case, equation (19.2) can be written as

$$\Delta S_{\text{tr}} = \frac{\Delta H_{\text{tr}}}{T_{\text{tr}}} \tag{19.3}$$

Rather than use the general symbol “tr” to represent a transition, we can be more specific about just which phases are involved, such as “fus” for the melting of a solid and “vap” for the vaporization of a liquid. If the transitions involve standard state conditions (1 bar ≈ 1 atm pressure), we also use the degree sign (°). Thus for the melting (fusion) of ice at its normal melting point,

$$\text{H}_2\text{O(s, 1 atm)} \rightleftharpoons \text{H}_2\text{O(l, 1 atm)} \qquad \Delta H^\circ_{\text{fus}} = 6.02\ \text{kJ mol}^{-1} \text{ at } 273.15\ \text{K}$$

the standard entropy change is

$$\Delta S^\circ_{\text{fus}} = \frac{\Delta H^\circ_{\text{fus}}}{T_{\text{mp}}} = \frac{6.02\ \text{kJ mol}^{-1}}{273.15\ \text{K}} = 2.20 \times 10^{-2}\ \text{kJ mol}^{-1}\ \text{K}^{-1}$$
$$= 22.0\ \text{J mol}^{-1}\ \text{K}^{-1}$$

Entropy changes depend on the quantities of substances involved and are usually expressed on a per-mole basis.

KEEP IN MIND

that the normal melting point and normal boiling point are determined at 1 atm pressure. The difference between 1 atm and the standard state pressure of 1 bar is so small that we can usually ignore it.

A useful generalization known as **Trouton's rule** states that for many liquids at their normal boiling points, the standard molar *entropy of vaporization* has a value of about 87 J mol^{-1} K^{-1}.

$$\Delta S^\circ_{\text{vap}} = \frac{\Delta H^\circ_{\text{vap}}}{T_{\text{bp}}} \approx 87\ \text{J mol}^{-1}\ \text{K}^{-1} \tag{19.4}$$

For instance, the values of $\Delta S^\circ_{\text{vap}}$ for benzene (C_6H_6) and octane (C_8H_{18}) are 87.1 and 86.2 J mol^{-1} K^{-1}, respectively. If the increased accessibility of microscopic energy levels produced in transferring one mole of molecules from liquid

19-2 ARE YOU WONDERING...

If the thermodynamic entropy (equation 19.2), $\Delta S = q_{rev}/T$, can be derived from the statistical entropy (equation 19.1), $S = k \ln W$?

It can, but a rigorous derivation is very complex. However, by using a system of evenly spaced energy levels for the surroundings, a simplified derivation can be shown. Consider just two energy levels from the numerous energy levels representing the surroundings. Now, as suggested in Figure 19-5, construct two states, **A** and **B**, which are the most probable initial state (state **A**) and final state (state **B**) after the addition of an infinitesimal amount of heat (q_{rev}).

The temperature of **B** is slightly higher than the temperature of **A**. The amount of heat (q) used is just the energy difference ($\Delta\varepsilon$) between the two levels and therefore a single particle jumps from level i to level j. The number of **A** microstates, W_A, is almost exactly the same as the number of **B** microstates, W_B. The entropy change for the surroundings is

$$\Delta S_{sur} = k \ln\left(\frac{W_B}{W_A}\right)$$

However, the ratio of probabilities is related to the population of each state as shown in the following relationship:

$$\frac{W_B}{W_A} = \frac{n_i}{n_j + 1} \approx \frac{n_i}{n_j}$$

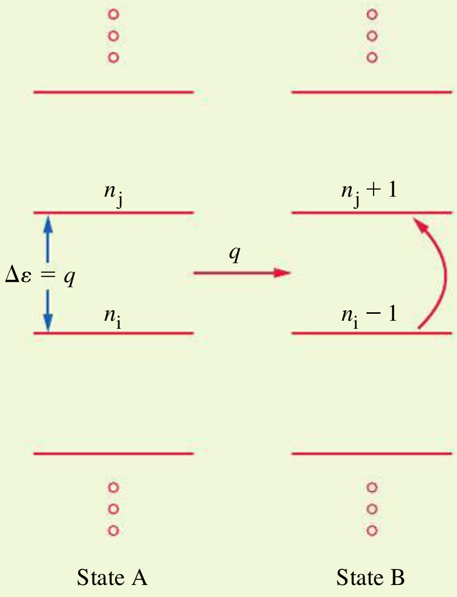
Boltzmann derived the following distribution law

$$\frac{n_j}{n_i} = e^{-\Delta\varepsilon/kT}$$

which relates the population of level i to that of level j. We use this to determine the entropy change of the surroundings along with the substitution of q_{rev} for $\Delta\varepsilon$.

$$\Delta S_{sur} = k \ln\left(\frac{W_B}{W_A}\right) = k \ln\left(e^{q_{rev}/kT}\right) = k\frac{q_{rev}}{kT} = \frac{q_{rev}}{T}$$

We have shown the relationship of the statistical entropy (equation 19.1) to the thermodynamic entropy (equation 19.2) to be true for the entropy change of the surroundings; however, this can be shown to hold for the system as well.



▶ FIGURE 19-5
Energy levels and populations representing the initial state of the surroundings (State A) and the state of the surroundings (State B) upon the addition of a quantity of heat (q). The spacing between the energy levels is $\Delta\varepsilon$. The populations of the energy levels are indicated by n_i and n_j.

EXAMPLE 19-2 Determining the Entropy Change for a Phase Transition

What is the standard molar entropy for the vaporization of water at 373 K given that the standard molar enthalpy of vaporization is 40.7 kJ mol^{-1}?

Analyze

This is an example of a phase transition, which means we can make use of $\Delta S° = \dfrac{\Delta H°_{\text{transition}}}{T_{\text{transition}}}$.

Solve

Although a chemical equation is not necessary, writing one can help us see the process we use to find the value of $\Delta S°_{\text{vap}}$.

$$H_2O(l, 1\ \text{atm}) \rightleftharpoons H_2O(g, 1\ \text{atm}) \qquad \begin{aligned}\Delta H°_{\text{vap}} &= 40.7\ \text{kJ/mol}\ H_2O \\ \Delta S°_{\text{vap}} &= ?\end{aligned}$$

$$\begin{aligned}\Delta S°_{\text{vap}} &= \frac{\Delta H°_{\text{vap}}}{T_{\text{bp}}} = \frac{40.7\ \text{kJ mol}^{-1}}{373\ \text{K}} = 0.109\ \text{kJ mol}^{-1}\ \text{K}^{-1} \\ &= 109\ \text{J mol}^{-1}\ \text{K}\end{aligned}$$

Assess

When solving this type of problem, we should check the sign of ΔS. Here, we expect an increase in entropy (ΔS is positive) because, as discussed on page 825, the entropy of a gas is much higher than that of a liquid.

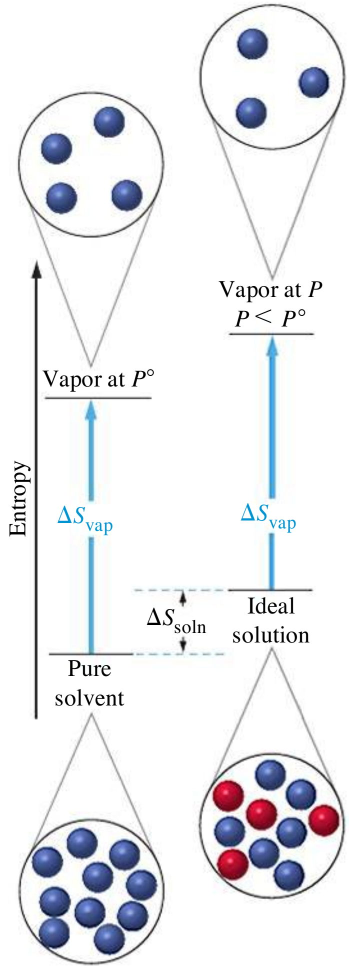
PRACTICE EXAMPLE A: What is the standard molar entropy of vaporization, $\Delta S°_{\text{vap}}$, for CCl_2F_2, a chlorofluorocarbon that once was heavily used in refrigeration systems? Its normal boiling point is −29.79 °C, and $\Delta H°_{\text{vap}} = 20.2\ \text{kJ mol}^{-1}$.

PRACTICE EXAMPLE B: The entropy change for the transition from solid rhombic sulfur to solid monoclinic sulfur at 95.5 °C is $\Delta S°_{\text{tr}} = 1.09\ \text{J mol}^{-1}\ \text{K}^{-1}$. What is the standard molar enthalpy change, $\Delta H°_{\text{tr}}$, for this transition?

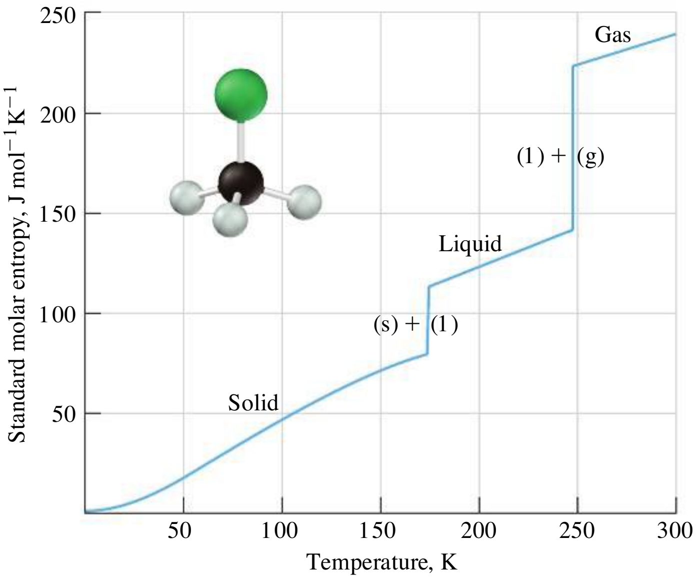
to vapor at 1 atm pressure is roughly comparable for different liquids, then we should expect similar values of $\Delta S°_{\text{vap}}$.

Instances in which Trouton's rule fails are also understandable. In water and in ethanol, for example, hydrogen bonding among molecules produces a lower entropy than would otherwise be expected in the liquid state. Consequently, the entropy increase in the vaporization process is greater than normal, and so $\Delta S°_{\text{vap}} > 87\ \text{J mol}^{-1}\ \text{K}^{-1}$.

The entropy concept helps explain Raoult's law (Section 13-6). Recall that for an ideal solution, $\Delta H_{\text{soln}} = 0$ and intermolecular forces of attraction are the same as in the pure liquid solvent (page 564). Thus, we expect the molar ΔH_{vap} to be the same whether vaporization of solvent occurs from an ideal solution or from the pure solvent at the same temperature. So, too, should ΔS_{vap} be the same because $\Delta S_{\text{vap}} = \Delta H_{\text{vap}}/T$. When one mole of solvent is transferred from liquid to vapor at the equilibrium vapor pressure $P°$, entropy increases by the amount ΔS_{vap}. As shown in Figure 19-6, because the entropy of the ideal solution is greater than that of the pure solvent, the entropy of the vapor produced by the vaporization of solvent from the ideal solution is also greater than the entropy of the vapor obtained from the pure solvent. For the vapor above the solution to have the higher entropy, its molecules must have a greater number of accessible microscopic energy levels. In turn, the vapor must be present in a larger volume and, hence, must be at a lower pressure than the vapor coming from the pure solvent. This relationship corresponds to Raoult's law: $P_A = x_A P°_A$.



▲ FIGURE 19-6
An entropy-based rationale of Raoult's law
If ΔS_{vap} has the same value for vaporization from the pure solvent and from an ideal solution, the equilibrium vapor pressure is lower above the solution: $P < P°$.



▲ FIGURE 19-7
Molar entropy as a function of temperature
The standard molar entropy of methyl chloride, CH_3Cl, is plotted at various temperatures from 0 to 300 K, with the phases noted. The vertical segment between the solid and liquid phases corresponds to ΔS_{fus}; the other vertical segment, to ΔS_{vap}. By the third law of thermodynamics, an entropy of *zero* is expected at 0 K. Experimental methods cannot be carried to that temperature, however, so an extrapolation is required.

Absolute Entropies

To establish an *absolute* value of the entropy of a substance, we look for a condition in which the substance is in its lowest possible energy state, called the *zero-point energy*. The entropy of this state is taken to be zero. Then we evaluate entropy changes as the substance is brought to other conditions of temperature and pressure. We add together these entropy changes and obtain a numerical value of the absolute entropy. The principle that permits this procedure is the **third law of thermodynamics,** which can be stated as follows:

> The entropy of a pure perfect crystal at 0 K is zero.

Figure 19-7 illustrates the method outlined in the preceding paragraph for determining absolute entropy as a function of temperature. Where phase transitions occur, equation (19.3) is used to evaluate the corresponding entropy changes. Over temperature ranges in which there are no transitions, $\Delta S°$ values are obtained from measurements of specific heats as a function of temperature.

The absolute entropy of one mole of a substance in its standard state is called the **standard molar entropy, $S°$**. Standard molar entropies of a number of substances at 25 °C are tabulated in Appendix D. To use these values to calculate the entropy change of a reaction, we use an equation with a familiar form (recall equation 7.21).

$$\Delta S° = \left[\sum \nu_p S°(\text{products}) - \sum \nu_r S°(\text{reactants})\right] \qquad \textbf{(19.5)}$$

The symbol $\sum$ means "the sum of," and the terms added are the products of the standard molar entropies and the corresponding stoichiometric coefficients, ν. Example 19-3 shows how to use this equation.

KEEP IN MIND

that there are no units of the stoichiometric coefficient, ν.

EXAMPLE 19-3 Calculating Entropy Changes from Standard Molar Entropies

Use data from Appendix D to calculate the standard molar entropy change for the conversion of nitrogen monoxide to nitrogen dioxide (a step in the manufacture of nitric acid).

$$2\,\mathrm{NO(g)} + \mathrm{O_2(g)} \longrightarrow 2\,\mathrm{NO_2(g)} \qquad \Delta S^\circ_{298\,\mathrm{K}} = ?$$

Analyze

In this example we are applying equation (19.5).

Solve

Equation (19.5) takes the form

$$\begin{aligned}\Delta S^\circ &= 2S^\circ_{\mathrm{NO_2(g)}} - 2S^\circ_{\mathrm{NO(g)}} - S^\circ_{\mathrm{O_2(g)}}\\ &= (2 \times 240.1) - (2 \times 210.8) - 205.1 = -146.5\ \mathrm{J\,K^{-1}}\end{aligned}$$

Assess

Some qualitative reasoning can be applied as a useful check on this calculation. Because three moles of gaseous reactants produce only two moles of gaseous products, the entropy should decrease; that is, ΔS° should be negative.

PRACTICE EXAMPLE A: Use data from Appendix D to calculate the standard molar entropy change for the synthesis of ammonia from its elements.

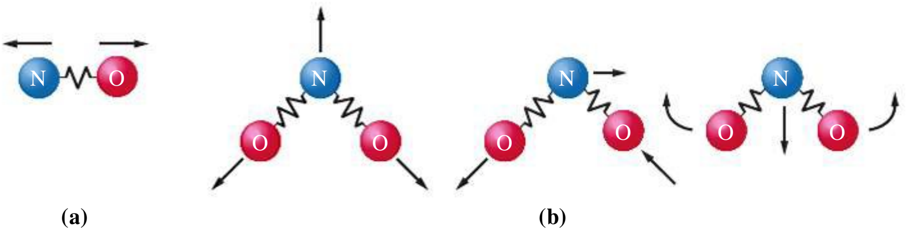
$$\mathrm{N_2(g)} + 3\,\mathrm{H_2(g)} \longrightarrow 2\,\mathrm{NH_3(g)} \qquad \Delta S^\circ_{298\,\mathrm{K}} = ?$$

PRACTICE EXAMPLE B: N_2O_3 is an unstable oxide that readily decomposes. The decomposition of 1.00 mol of N_2O_3 to nitrogen monoxide and nitrogen dioxide at 25 °C is accompanied by the entropy change $\Delta S^\circ = 138.5\ \mathrm{J\,K^{-1}}$. What is the standard molar entropy of $N_2O_3(g)$ at 25 °C?

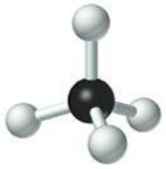
Example 19-3 used the standard molar entropies of $NO_2(g)$ and NO(g). Why is the value for $NO_2(g)$, 240.1 $\mathrm{J\,mol^{-1}\,K^{-1}}$, greater than that of NO(g), 210.8 $\mathrm{J\,mol^{-1}\,K^{-1}}$? Entropy increases when a substance absorbs heat (recall that $\Delta S = q_{\mathrm{rev}}/T$), and some of this heat goes into raising the average translational kinetic energies of molecules. But there are other ways for heat energy to be used. One possibility, pictured in Figure 19-8, is that the vibrational energies of molecules can be increased. In the *diatomic* molecule NO(g), only one type of vibration is possible; in the *triatomic* molecule $NO_2(g)$, *three* types are possible. Because there are more possible ways of distributing energy among NO_2 molecules than among NO molecules, $NO_2(g)$ has a higher molar entropy than does NO(g) at the same temperature. Thus the following statement should be added to the generalizations about entropy on page 826.

In general, as seen on page 832, more complex molecules (e.g., with more atoms per molecule) produce greater molar entropies.

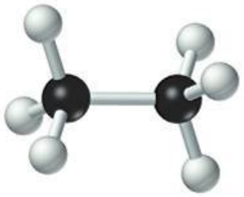
◀ In general, at low temperatures, because the quanta of energy are so small, translational energies are most important in establishing the entropy of gaseous molecules. As the temperature increases and the quanta of energy become larger, first rotational energies become important, and finally, at still higher temperatures, vibrational modes of motion start to contribute to the entropy.



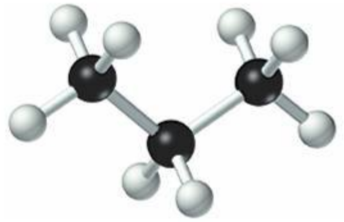
▲ FIGURE 19-8
Vibrational energy and entropy
The movement of atoms is suggested by the arrows. **(a)** The NO molecule has only one type of vibrational motion, whereas **(b)** the NO_2 molecule has three. This difference helps account for the fact that the molar entropy of $NO_2(g)$ is greater than that of NO(g).



Methane, CH_4
$S° = 186.3\ \text{J mol}^{-1}\ \text{K}^{-1}$



Ethane, C_2H_6
$S° = 229.6\ \text{J mol}^{-1}\ \text{K}^{-1}$



Propane, C_3H_8
$S° = 270.3\ \text{J mol}^{-1}\ \text{K}^{-1}$

19-3 ARE YOU WONDERING...

Whether there is a correlation between standard entropy and enthalpy?

The answer to this question is yes, at least for solids heated to 298.15 K at 1 bar. To see why this is so we begin with the temperature variation of entropy and enthalpy written as

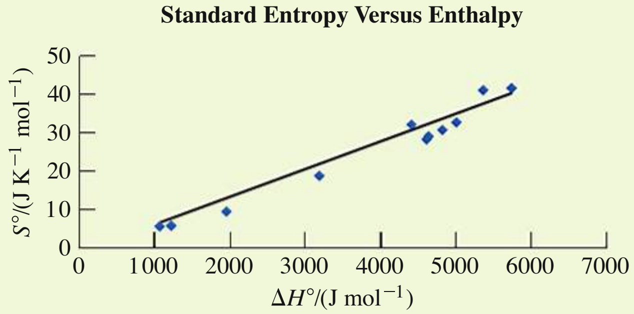
$$S° = \int_0^{298.15} \frac{C_p(T)}{T}\, dT$$

$$\Delta H° = \int_0^{298.15} C_p(T)\, dT$$

If we assume that the constant pressure heat capacity, C_p, of a solid is a linear function of temperature, $C_p = AT$, then the ratio of the entropy to enthalpy is

$$\frac{S°}{\Delta H°} = \frac{\displaystyle\int_{0\,\text{K}}^{298.15\,\text{K}} \frac{C_p(T)}{T}\, dT}{\displaystyle\int_{0\,\text{K}}^{298.15\,\text{K}} T\frac{C_p(T)}{T}\, dT} \approx \frac{\displaystyle\int_{0\,\text{K}}^{298.15\,\text{K}} A dT}{\displaystyle\int_{0\,\text{K}}^{298.15\,\text{K}} TA dT} = \frac{1}{149.075\ \text{K}} = 0.0067\ \text{K}^{-1}$$

This result suggests that a simple (linear) correlation exists between entropy and enthalpy. Do experimental facts support this conclusion? The following figure is a plot of standard entropy versus standard enthalpy change at 298.15 K and 1 bar for several monatomic solids.



The slope of the line is equal to the predicted ratio $(0.0067\ \text{K}^{-1})$. Notice that the points lie close to this line. So what does this mean? As we heat the solid from nearly absolute zero to 298.15 K, the solid gains energy, represented here as a standard enthalpy change. This energy is dispersed throughout the various energy levels of the solid. The standard entropy value, $S°$, of the solid at 298.15 K and 1 bar is proportional to the quantity of energy stored in the solid at that temperature with the proportionality constant of $0.0067\ \text{K}^{-1}$.

19-4 Criteria for Spontaneous Change: The Second Law of Thermodynamics

In Section 19-2, we came to the tentative conclusion that processes in which the entropy of a system increases should be spontaneous and that processes in which entropy decreases should be nonspontaneous. But this statement can present difficulties, for example, of how to explain the spontaneous freezing of water at −10 °C. Because crystalline ice has a lower molar entropy than does liquid water, the freezing of water is a process for which entropy *decreases*. The way out of this dilemma is to recognize that *two* entropy changes must always be considered simultaneously—the entropy change of the system itself and the entropy change of the surroundings. The criteria for spontaneous change must be based on the sum of the two, called the entropy change of the "universe":

$$\Delta S_{\text{total}} = \Delta S_{\text{universe}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}} \qquad \textbf{(19.6)}$$

Although it is beyond the scope of this discussion to verify the following expression, the expression provides the basic criterion for spontaneous change. In a spontaneous change,

$$\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} > 0 \qquad \textbf{(19.7)}$$

Equation (19.7) is one way of stating the **second law of thermodynamics**. Another way is through the following statement.

All spontaneous processes produce an increase in the entropy of the universe.

According to expression (19.7), if a process produces positive entropy changes in both the system and its surroundings, the process is surely spontaneous. And if both these entropy changes are negative, the process is just as surely nonspontaneous. If one of the entropy changes is positive, and the other negative, whether the sum of the two is positive or negative depends on the relative magnitudes of the two changes. The freezing of water produces a negative entropy change in the system, but in the surroundings, which absorb heat, the entropy change is positive. As long as the temperature is below 0 °C, the entropy of the surroundings increases more than the entropy of the system decreases. Because the *total* entropy change is positive, the freezing of water below 0 °C is indeed spontaneous.

Gibbs Energy and Gibbs Energy Change

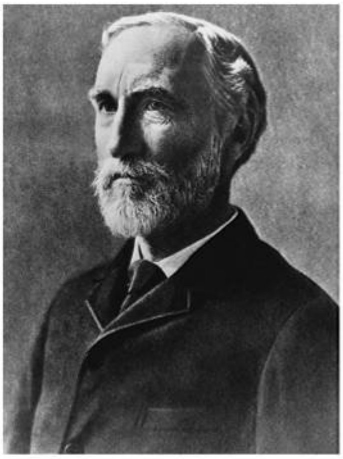
We could use expression (19.7) as the basic criterion for spontaneity (spontaneous change), but it would be very difficult to apply. To evaluate a total entropy change (ΔS_{univ}), we always have to evaluate ΔS for the surroundings. At best, this process is tedious, and in many cases it is not even possible, because we cannot figure out all the interactions between a system and its surroundings. Surely it is preferable to have a criterion that can be applied to *the system itself*, without having to worry about changes in the surroundings.

To develop this new criterion, let us explore a hypothetical process conducted at constant temperature and pressure and with work limited to pressure–volume work. This process is accompanied by a heat effect, q_{p}, which is equal to ΔH for the system (ΔH_{sys}) as seen in Section 7-6. The heat effect experienced by the surroundings is the *negative* of that for the system: $q_{\text{surr}} = -q_{\text{p}} = -\Delta H_{\text{sys}}$. Furthermore, if the hypothetical surroundings are large enough, the path by which heat enters or leaves the surroundings can be made *reversible*. That is, the quantity of heat can be made to produce only an infinitesimal change in the temperature of the surroundings. In this case, according to equation (19.2), the entropy change in the surroundings is $\Delta S_{\text{surr}} = -\Delta H_{\text{sys}}/T$.* Now substitute this value of ΔS_{surr} into equation (19.6), then multiply by T to obtain

$$T\,\Delta S_{\text{univ}} = T\,\Delta S_{\text{sys}} - \Delta H_{\text{sys}} = -(\Delta H_{\text{sys}} - T\,\Delta S_{\text{sys}})$$

---

*We cannot similarly substitute $\Delta H_{\text{sys}}/T$ for ΔS_{sys}. A process that occurs spontaneously is generally far removed from an equilibrium condition and is therefore *irreversible*. We cannot substitute q for an irreversible process into equation (19.2).



▲ **J. Willard Gibbs (1839–1903)—a great "unknown" scientist**
Gibbs, a Yale University professor of mathematical physics, spent most of his career without recognition, partly because his work was abstract and partly because his important publications were in little-read journals. Yet today, Gibbs's ideas serve as the basis of most of chemical thermodynamics.

Finally, multiply by −1 (change signs).

$$-T\,\Delta S_{\text{univ}} = \Delta H_{\text{sys}} - T\,\Delta S_{\text{sys}} \qquad \textbf{(19.8)}$$

This is the significance of equation (19.8). The right side of this equation has terms involving *only the system*. On the left side appears the term ΔS_{univ}, which embodies the criterion for spontaneous change, that for a spontaneous process, $\Delta S_{\text{univ}} > 0$.

Equation (19.8) is generally cast in a somewhat different form that requires a new thermodynamic function, called the **Gibbs energy**, G. The Gibbs energy for a system is defined by the equation

$$G = H - TS$$

The **Gibbs energy change, ΔG**, for a process at constant T is

$$\Delta G = \Delta H - T\,\Delta S \qquad \textbf{(19.9)}$$

In equation (19.9), all the terms apply to measurements *on the system*. All reference to the surroundings has been eliminated. Also, when we compare equations (19.8) and (19.9), we get

$$\Delta G = -T\,\Delta S_{\text{univ}}$$

Now, by noting that ΔG is *negative* when ΔS_{univ} is *positive*, we have our final criterion for spontaneous change based on properties of only the system itself.

For a process occurring at constant T and P, these statements hold true.

- If $\Delta G < 0$ (*negative*), the process is *spontaneous*.
- If $\Delta G > 0$ (*positive*), the process is *nonspontaneous*.
- If $\Delta G = 0$ (*zero*), the process is *at equilibrium*.

Evaluation of the units in equation (19.9) shows that Gibbs energy is indeed an energy term. ΔH has the unit joules per mole (J mol^{-1}), and the product $T\,\Delta S$ has the units $\text{K} \times \text{J mol}^{-1}\,\text{K}^{-1} = \text{J mol}^{-1}$. ΔG is the difference in two quantities with units of energy.

Applying the Gibbs Energy Criteria for Spontaneous Change

▶ Sometimes the term "$T\,\Delta S$" is referred to as "organizational energy," because ΔS is related to the way the energy of a system is distributed among the available energy levels.

Later, we will look at quantitative applications of equation (19.9), but for now we can use the equation to make some qualitative predictions. Altogether there are four possibilities for ΔG on the basis of the signs of ΔH and ΔS. These possibilities are outlined in Table 19.1 and demonstrated in Example 19-4.

If ΔH is *negative* and ΔS is *positive*, the expression $\Delta G = \Delta H - T\,\Delta S$ is negative at all temperatures. The process is spontaneous at all temperatures. This corresponds to the situation noted previously in which both ΔS_{sys} and ΔS_{surr} are positive and ΔS_{univ} is also positive.

Unquestionably, if a process is accompanied by an *increase* in enthalpy (heat is absorbed) and a *decrease* in entropy, ΔG is positive at all temperatures

TABLE 19.1 Criteria for Spontaneous Change: $\Delta G - \Delta H - T\Delta S$

Case	ΔH	ΔS	ΔG	Result	Example
1.	−	+	−	spontaneous at all temp.	$2\,N_2O(g) \longrightarrow 2\,N_2(g) + O_2(g)$
2.	−	−	− +	spontaneous at low temp. nonspontaneous at high temp.	$H_2O(l) \longrightarrow H_2O(s)$
3.	+	+	+ −	nonspontaneous at low temp. spontaneous at high temp.	$2\,NH_3(g) \longrightarrow N_2(g) + 3\,H_2(g)$
4.	+	−	+	nonspontaneous at all temp.	$3\,O_2(g) \longrightarrow 2\,O_3(g)$

and the process is nonspontaneous. This corresponds to a situation in which both ΔS_{sys} and ΔS_{surr} are negative and ΔS_{univ} is also negative.

The questionable cases are those in which the entropy and enthalpy factors work in opposition—that is, with ΔH and ΔS *both* negative or *both* positive. In these cases, whether a reaction is spontaneous or not (that is, whether ΔG is negative or positive) depends on temperature. In general, if a reaction has negative values for both ΔH and ΔS, it is spontaneous at *lower* temperatures, whereas if ΔH and ΔS are both positive, the reaction is spontaneous at *higher* temperatures.

◀ For cases 2 and 3, there is a particular temperature at which a process switches from being spontaneous to being nonspontaneous. Section 19-6 explains how to determine such a temperature.

EXAMPLE 19-4 Using Enthalpy and Entropy Changes to Predict the Direction of Spontaneous Change

Under what temperature conditions would the following reactions occur spontaneously?

(a) $2\,NH_4NO_3(s) \longrightarrow 2\,N_2(g) + 4\,H_2O(g) + O_2(g) \qquad \Delta H^\circ = -236.0\ kJ\,mol^{-1}$

(b) $I_2(g) \longrightarrow 2\,I(g)$

Analyze

(a) The reaction is exothermic, and in Example 19-1(a) we concluded that $\Delta S > 0$ because large quantities of gases are produced.

(b) Because one mole of gaseous reactant produces two moles of gaseous product, we expect entropy to increase. But what is the sign of ΔH? We could calculate ΔH from enthalpy of formation data, but there is no need to. In the reaction, covalent bonds in $I_2(g)$ are broken and no new bonds are formed. Because energy is absorbed to break bonds, ΔH must be positive. With $\Delta H > 0$ and $\Delta S > 0$, case 3 in Table 19.1 applies.

Solve

(a) With $\Delta H < 0$ and $\Delta S > 0$, this reaction should be spontaneous at all temperatures (case 1 in Table 19.1). $NH_4NO_3(s)$ exists only because the decomposition has very high activation energy.

(b) ΔH is larger than $T\,\Delta S$ at low temperatures, and the reaction is nonspontaneous. At high temperatures, the $T\,\Delta S$ term becomes larger than ΔH, ΔG becomes negative, and the reaction is spontaneous.

Assess

We observe that reaction spontaneity depends on a balance of enthalpy, entropy, and temperature. Table 19.1 is a good summary of the conditions in which reactions will be spontaneous or nonspontaneous.

PRACTICE EXAMPLE A: Which of the four cases in Table 19.1 would apply to each of the following reactions:

(a) $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g), \qquad \Delta H^\circ = -92.22\ kJ;$

(b) $2\,C(graphite) + 2\,H_2(g) \longrightarrow C_2H_4(g), \qquad \Delta H^\circ = 52.26\ kJ?$

PRACTICE EXAMPLE B: Under what temperature conditions would the following reactions occur spontaneously? **(a)** The decomposition of calcium carbonate into calcium oxide and carbon dioxide. **(b)** The "roasting" of zinc sulfide in oxygen to form zinc oxide and sulfur dioxide. This exothermic reaction releases 439.1 kJ for every mole of zinc sulfide that reacts.

▲ Only because of the high activation energy for the $NH_4NO_3(s)$ decomposition reaction does $NH_4NO_3(s)$ exist at all.

Example 19-4(b) illustrates why there is an upper temperature limit for the stabilities of chemical compounds. No matter how positive the value of ΔH for dissociation of a molecule into its atoms, the term $T\,\Delta S$ will eventually exceed ΔH in magnitude as the temperature increases. Known temperatures range from near absolute zero to the interior temperatures of stars (about 3×10^7 K). Molecules exist only at limited temperatures (up to about 1×10^4 K or about 0.03% of this total temperature range).

◀ A related observation is that only a small fraction of the mass of the universe is in molecular form.

The method of Example 19-4 is adequate for making predictions about the sign of ΔG, but we will also want to use equation (19.9) to calculate numerical values. We will do that in Section 19-5.

Gibbs Energy Change and Work

We might think that the quantity of energy available to do work in the surroundings as a result of a chemical process is $-\Delta H$. This would be the same as the quantity of heat that an exothermic reaction releases to the surroundings. (In thinking along those lines, we would say that an endothermic reaction is incapable of doing work.) However, that quantity of heat must be adjusted for the heat requirement in producing the entropy change in the system ($q_{\text{rev}} = T\,\Delta S$). If an exothermic reaction is accompanied by an *increase* in entropy, the amount of energy available to do work in the surroundings is *greater* than $-\Delta H$. If entropy *decreases* in the exothermic reaction, the amount of energy available to do work is *less* than $-\Delta H$. But notice that in either case, this amount of energy is equal to $-\Delta G$. Thus, the amount of work that can be extracted from a chemical process is $-\Delta G$. Because $-\Delta G$ represents the energy freely available for doing work, G was once called *Gibbs free energy*, or *simply free energy*, by most chemists. Notice also that this interpretation of Gibbs energy allows for the possibility of work being done in an endothermic process if $T\,\Delta S$ exceeds ΔH. In Chapter 20, we will see how the Gibbs energy change of a reaction can be converted to electrical work. In any case, do not think of Gibbs energy as being free. Costs are always involved in tapping an energy source.

19-5 Standard Gibbs Energy Change, $\Delta G°$

Because Gibbs energy is related to enthalpy ($G = H - TS$), we cannot establish absolute values of G any more than we can for H. We must work with Gibbs energy changes, ΔG. We will find a special use for the Gibbs energy change corresponding to reactants and products in their standard states—the **standard Gibbs energy change, $\Delta G°$**. The standard state conventions were introduced and applied to enthalpy change in Chapter 7.

KEEP IN MIND

that a pressure of 1 bar is very nearly the same as 1 atm. The differences in these two pressures on the values of properties is generally so small that we can use the two pressure units almost interchangeably.

The **standard Gibbs energy of formation**, ΔG_f°, is the Gibbs energy change for a reaction in which a substance in its standard state is formed from its elements in their reference forms in their standard states. And, as was the case when we established enthalpies of formation in Section 7-8, this definition leads to values of *zero* for the Gibbs energies of formation of the elements in their reference forms at a pressure of 1 bar. Other Gibbs energies of formation are related to this condition of zero and are generally tabulated per mole of substance (see Appendix D).

▶ Many substances do not exist at the standard conditions that define their Gibbs energy. This does not matter since we can calculate the standard Gibbs energy from nonstandard conditions. Dealing with nonstandard conditions is discussed on page 839. Gibbs energies are listed under standard conditions for ease and conciseness.

Some additional relationships involving Gibbs energy changes are similar to those presented for enthalpy in Section 7-7: (1) ΔG changes sign when a process is reversed; and (2) ΔG for an overall process can be obtained by summing the ΔG values for the individual steps. The two expressions that follow are useful in calculating $\Delta G°$ values, depending on the data available. We can use the first expression at any temperature for which $\Delta H°$ and $\Delta S°$ values are known. We can use the second expression only at temperatures at which ΔG_f° values are known. The only temperature at which tabulated data are commonly given is 298.15 K. The first expression is applied in Example 19-5 and Practice Example 19-5A, and the second expression in Practice Example 19-5B.

$$\Delta G° = \Delta H° - T\Delta S°$$

$$\Delta G° = \left[\sum \nu_p\,\Delta G_f^\circ(\text{products}) - \sum \nu_r \Delta G_f^\circ(\text{reactants})\right]$$

EXAMPLE 19-5 Calculating $\Delta G°$ for a Reaction

Determine $\Delta G°$ at 298.15 K for the reaction

$$2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g) \quad (\text{at } 298.15\text{ K}) \qquad \begin{aligned}\Delta H° &= -114.1\text{ kJ}\\ \Delta S° &= -146.5\text{ J K}^{-1}\end{aligned}$$

Analyze

Because we have values of $\Delta H°$ and $\Delta S°$, the most direct method of calculating $\Delta G°$ is to use the expression $\Delta G° = \Delta H° - T\,\Delta S°$.

Solve

First we must convert all the data to a common energy unit (for instance, kJ).

$$\begin{aligned}\Delta G° &= -114.1\text{ kJ} - (298.15\text{ K} \times -0.1465\text{ kJ K}^{-1})\\ &= -114.1\text{ kJ} + 43.68\text{ kJ}\\ &= -70.4\text{ kJ}\end{aligned}$$

Assess

In this type of problem, one of the most common mistakes is not keeping the units straight. Note that the unit for the standard molar enthalpy is kJ mol^{-1}, and for the standard molar entropy it is J $\text{mol}^{-1}\text{ K}^{-1}$. This example says that all the reactants and products are maintained at 25 °C and 1 bar pressure. Under these conditions, the Gibbs energy change is −70.4 kJ for oxidizing two moles of NO to two moles of NO_2. To do this, it is necessary to replenish the NO so as to maintain the standard conditions.

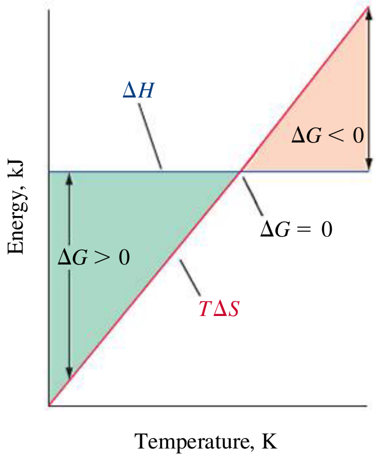
PRACTICE EXAMPLE A: Determine $\Delta G°$ at 298.15 K for the reaction $4\,Fe(s) + 3O_2(g) \longrightarrow 2\,Fe_2O_3(s)$. $\Delta H° = -1648$ kJ and $\Delta S° = -549.3\text{ J K}^{-1}$.

PRACTICE EXAMPLE B: Determine $\Delta G°$ for the reaction in Example 19-5 by using data from Appendix D. Compare the two results.

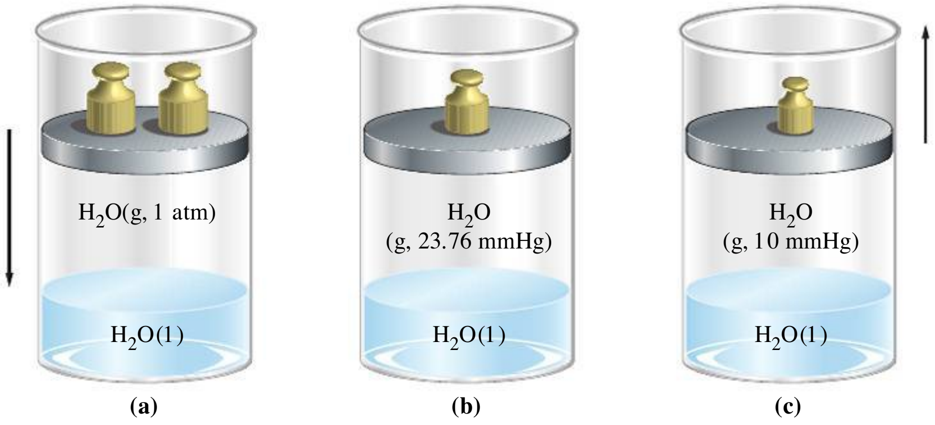
19-6 Gibbs Energy Change and Equilibrium

We have seen that $\Delta G < 0$ for spontaneous processes and that $\Delta G > 0$ for nonspontaneous processes. If $\Delta G = 0$, the forward and reverse processes show an equal tendency to occur, and the system is at *equilibrium*. At this point, even an infinitesimal change in one of the system variables (such as temperature or pressure) will cause a net change to occur. But if a system at equilibrium is left undisturbed, no net change occurs with time.

Figure 19-9 illustrates a hypothetical process in which ΔH and ΔS are independent of temperature, and both are positive. This corresponds to case 3



◀ FIGURE 19-9
Gibbs energy change as a function of temperature
The green shaded region corresponds to ΔG at temperatures in which the process is *nonspontaneous*. The orange shaded region corresponds to ΔG at temperatures in which the process is *spontaneous*.



▲ FIGURE 19-10
Liquid–vapor equilibrium and the direction of spontaneous change
(a) For the vaporization of water at 298.15 K and 1 atm, $H_2O(l, 1\ atm) \longrightarrow H_2O(g, 1\ atm)$, $\Delta G° = 8.590$ kJ. The direction of spontaneous change is the *condensation* of $H_2O(g)$. **(b)** At 298.15 K and 23.76 mmHg, the liquid and vapor are in equilibrium and $\Delta G° = 0$. **(c)** At 298.15 K and 10 mmHg, the vaporization of $H_2O(l)$ occurs spontaneously: $H_2O(l, 10\ mmHg) \longrightarrow H_2O(g, 10\ mmHg)$, and $\Delta G < 0$.

in Table 19.1. If we start at the left side of the figure (i.e., at a relatively low temperature), we see that the magnitude of ΔH exceeds the magnitude of $T\ \Delta S$ and that $\Delta H - T\ \Delta S$, which was defined as ΔG, is positive; the process is *nonspontaneous*. As the temperature increases, the magnitude of ΔG decreases. At the right side of the figure (i.e., at a relatively high temperature), the magnitude of $T\ \Delta S$ exceeds the magnitude of ΔH; therefore, ΔG is negative; the process is *spontaneous*. The temperature at which the two lines (ΔH and $T\ \Delta S$) intersect, $\Delta G = 0$, and the system is at equilibrium.

For the vaporization of water, *with both liquid and vapor in their standard states* (which means that $\Delta G = \Delta G°$), the intersection of the two lines in Figure 19-9 is at $T = 373.15$ K (100.00 °C). That is, for the vaporization of water at 1 atm,

$$H_2O(l, 1\ atm) \rightleftharpoons H_2O(g, 1\ atm) \qquad \Delta G° = 0 \text{ at } 373.15\ K$$

At 25 °C, the $\Delta H°$ line lies above the $T\ \Delta S$ line in Figure 19-9. This means that $\Delta G° > 0$.

$$H_2O(l, 1\ atm) \longrightarrow H_2O(g, 1\ atm) \qquad \Delta G° = +8.590\ kJ \text{ at } 298.15\ K$$

The positive value of $\Delta G°$ does not mean that vaporization of water will not occur. From common experience, we know that water spontaneously evaporates at room temperature. What the positive value means is that liquid water will not spontaneously produce $H_2O(g)$ at 1 atm pressure at 25 °C. Instead, $H_2O(g)$ is produced with a vapor pressure that is less than 1 atm pressure. The equilibrium vapor pressure of water at 25 °C is 23.76 mmHg = 0.03126 atm; that is,

$$H_2O(l, 0.03126\ atm) \rightleftharpoons H_2O(g, 0.03126\ atm) \qquad \Delta G = 0$$

Figure 19-10 offers a schematic summary of ideas concerning the transition between liquid and gaseous water at 25 °C.

▶ Here, we have used a standard state pressure of 1 atm. See Feature Problem 93 for an appraisal of this matter using a standard state pressure of 1 bar.

▶ The liquid–vapor equilibrium represented here is out of contact with the atmosphere. In the presence of the atmosphere, the pressure on the liquid would be barometric pressure, whereas that of the vapor would remain essentially unchanged at 0.03126 atm.

19-3 CONCEPT ASSESSMENT

Redraw Figure 19-9 for case 2 in Table 19.1. How does your drawing compare with Figure 19-9? State the similarities and differences.

Relationship of ΔG° To ΔG for Nonstandard Conditions

If you think about the situation just described for the vaporization of water, there is not much value in describing equilibrium in a process in terms of its ΔG° value. At only one temperature are the reactants in their standard states in equilibrium with products in their standard states; that is, at only one temperature does $\Delta G^\circ = 0$. We want to be able to describe equilibrium for a variety of conditions, typically *nonstandard* conditions. Many reactions, such as processes occurring under physiological conditions, take place under nonstandard conditions. How, under such circumstances, can a biochemist decide which processes are spontaneous? For this we need to work with ΔG, not ΔG°.

To obtain the relationship between ΔG and ΔG°, we will consider a reaction between ideal gas molecules. We assume this is the case in the reaction of nitrogen with hydrogen to produce ammonia.

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$$

The expressions for ΔG and ΔG° are $\Delta G = \Delta H - T\,\Delta S$ and $\Delta G^\circ = \Delta H^\circ - T\,\Delta S^\circ$, respectively. First consider how the enthalpy terms ΔH and ΔH° are related for an ideal gas. The enthalpy of an ideal gas is a function of temperature only; it is independent of pressure. Thus, under any mixing conditions for an ideal gas, $\Delta H = \Delta H^\circ$. We can write

$$\Delta G = \Delta H^\circ - T\,\Delta S \qquad \textit{(ideal gas)}$$

We now need to obtain a relationship between ΔS and ΔS°. To do so, we consider the isothermal expansion of an ideal gas for which $q = -w$ and $\Delta U = 0$. If the expansion occurs reversibly (recall Figure 7-12), the work of expansion for one mole of an ideal gas is given by an equation derived in Feature Problem 125 in Chapter 7.

$$w = -RT\ln\frac{V_f}{V_i} \qquad \textit{(reversible, isothermal)}$$

The reversible, isothermal heat of expansion is

$$q_{rev} = -w = RT\ln\frac{V_f}{V_i}$$

From equation (19.2), we obtain the entropy change for the isothermal expansion of one mole of an ideal gas.

$$\Delta S = \frac{q_{rev}}{T} = R\ln\frac{V_f}{V_i} \qquad \textbf{(19.10)}$$

Using equation (19.10), we can now evaluate the entropy of an ideal gas under any conditions of pressure. From the ideal gas equation, we know that the volume of an ideal gas is inversely proportional to the pressure, so we can recast equation (19.10) as

$$\Delta S = S_f - S_i = R\ln\frac{V_f}{V_i} = R\ln\frac{P_i}{P_f} = -R\ln\frac{P_f}{P_i}$$

where P_i and P_f are the initial and final pressures, respectively. If we set $P_i = 1$ bar and designate P_i as P° and S_i as S°, we obtain for the entropy at any pressure P

$$S = S^\circ - R\ln\frac{P}{P^\circ} = S^\circ - R\ln\frac{P}{1} = S^\circ - R\ln P \qquad \textbf{(19.11)}$$

Now, let's return to the ammonia synthesis reaction and calculate the entropy change for that reaction. We begin by applying equation (19.11) to each of the three gases.

$$S_{NH_3} = S^\circ_{NH_3} - R\ln P_{NH_3} \qquad S_{N_2} = S^\circ_{N_2} - R\ln P_{N_2} \quad S_{H_2} = S^\circ_{H_2} - R\ln P_{H_2}$$

Then we substitute the above values into the equation $\Delta S = 2S_{NH_3} - S_{N_2} - 3S_{H_2}$ to obtain

$$\Delta S = 2S^\circ_{NH_3} - 2R\ln P_{NH_3} - S^\circ_{N_2} + R\ln P_{N_2} - 3S^\circ_{H_2} + 3R\ln P_{H_2}$$

By rearranging the terms, we get

$$\Delta S = 2S^\circ_{NH_3} - S^\circ_{N_2} - 3S^\circ_{H_2} - 2R\ln P_{NH_3} + R\ln P_{N_2} + 3R\ln P_{H_2}$$

and, since the first three terms on the right-hand side of the above equation represent ΔS°, we have

$$\Delta S = \Delta S^\circ - 2R\ln P_{NH_3} + R\ln P_{N_2} + 3R\ln P_{H_2}$$

$$\Delta S = \Delta S^\circ - R\ln P^2_{NH_3} + R\ln P_{N_2} + R\ln P^3_{H_2}$$

$$\Delta S = \Delta S^\circ + R\ln\frac{P_{N_2}P^3_{H_2}}{P^2_{NH_3}}$$

Finally, we can write the equation for ΔG by substituting the expression for ΔS into the equation

$$\Delta G = \Delta H^\circ - T\,\Delta S \qquad \text{(ideal gas)}$$

▶ It is commonly stated that we are headed for a state of maximum entropy. Although this is true, it gives the incorrect notion that entropy, as defined here, and time are related. They are not. Entropy is a property of an equilibrium state. Here we calculate the difference between the entropies of two different equilibrium states.

19-4 ARE YOU WONDERING...

If there is a microscopic approach to obtaining equation (19.10)?

To do this, we use the ideas of Ludwig Boltzmann. Consider an ideal gas at an initial volume V_i and allow the gas to expand isothermally to a final volume V_f. By using the Boltzmann equation, we find that for the change in entropy,

$$\Delta S = S_f - S_i = k\ln W_f - k\ln W_i$$

$$\Delta S = k\ln\frac{W_f}{W_i}$$

where k is the Boltzmann constant, S_i and S_f are the initial and final entropies, respectively, and W_i and W_f are the number of microstates for the initial and final macroscopic states of the gas, respectively. We must now obtain a value for the ratio W_f/W_i. To do that, suppose that there is only a single gas molecule in a container. The number of microstates available to this single molecule should be proportional to the number of positions where the molecule can be and, hence, to the volume of the container. That is also true for each molecule in a system of N_A particles—Avogadro's number of particles. The number of microstates available to the whole system is

$$W_{total} = W_{particle\,1} \times W_{particle\,2} \times W_{particle\,3} \times \cdots$$

Because the number of microstates for each particle is proportional to the volume V of the container, the number of microstates for N_A (Avogadro's number) ideal gas molecules is

$$W \propto V^{N_A}$$

Thus, the ratio of the microstates for isothermal expansion is

$$\frac{W_f}{W_i} = \left(\frac{V_f}{V_i}\right)^{N_A}$$

We can now calculate ΔS as follows:

$$\Delta S = k\ln\frac{W_f}{W_i} = k\ln\left(\frac{V_f}{V_i}\right)^{N_A} = N_A k\ln\left(\frac{V_f}{V_i}\right) = R\ln\left(\frac{V_f}{V_i}\right)$$

where R is the ideal gas constant. This equation, which gives the entropy change for the expansion of one mole of ideal gas, is simply equation (19.10).

This leads to

$$\Delta G = \Delta H^\circ - T\,\Delta S^\circ - RT\ln\frac{P_{N_2}P^3_{H_2}}{P^2_{NH_3}}$$

$$\Delta G = \underbrace{\Delta H^\circ - T\,\Delta S^\circ}_{} + RT\ln\frac{P^2_{NH_3}}{P_{N_2}P^3_{H_2}}$$

$$\Delta G = \Delta G^\circ + RT\ln\frac{P^2_{NH_3}}{P_{N_2}P^3_{H_2}}$$

To simplify, we designate the quotient in the logarithmic term as the *reaction quotient* Q (recall page 670).

$$\Delta G = \Delta G^\circ + RT\ln Q \qquad \textbf{(19.12)}$$

Equation (19.12) is the relationship between ΔG and ΔG° that we have been seeking in this section, and we see that the key term in the equation is the reaction quotient formulated for the actual, nonstandard conditions. We can use equation (19.12) to decide on the spontaneity of a reaction under any conditions of composition, provided that the temperature and pressure at which we observe the reaction are constant. We turn now to describing how the standard Gibbs energy change is related to the equilibrium constant.

◀ Equation (19.12) shows that the value of the reaction quotient affects whether the forward or reverse reaction is favored under a particular set of conditions. Recall that all reactions proceed toward equilibrium where Gibbs energy change is equal to zero.

Relationship of ΔG° to the Equilibrium Constant K

We encounter an interesting situation when we apply equation (19.12) to a reaction at equilibrium. We have learned that at equilibrium $\Delta G = 0$, and in Chapter 15 we saw that if a system is at equilibrium $Q = K$. So, we can write that, *at equilibrium*,

$$\Delta G = \Delta G^\circ + RT\ln K = 0$$

which means that

$$\Delta G^\circ = -RT\ln K \qquad \textbf{(19.13)}$$

If we have a value of ΔG° at a given temperature, we can use equation (19.13) to calculate an equilibrium constant K. This means that the tabulation of thermodynamic data in Appendix D can serve as a direct source of countless equilibrium constant values at 298.15 K.

We need to say a few words about the units required in equation (19.13). Because logarithms can be taken of dimensionless numbers only, K has no units; neither does $\ln K$. The right-hand side of equation (19.13) has the unit of "RT": $\mathrm{J\,mol^{-1}\,K^{-1}} \times \mathrm{K} = \mathrm{J\,mol^{-1}}$. ΔG°, on the left-hand side of the equation, must have the same unit: $\mathrm{J\,mol^{-1}}$. The "$\mathrm{mol^{-1}}$" part of this unit means "per mole of reaction." One mole of reaction is simply the reaction based on the stoichiometric coefficients chosen for the balanced equation. Strictly speaking the "$\mathrm{mol^{-1}}$" should be included. Remember that the "$\mathrm{mol^{-1}}$" is of reaction not per mole of substance.

◀ When a ΔG° value is accompanied by a chemical equation, the "$\mathrm{mol^{-1}}$" portion of the unit is often dropped.

19-4 CONCEPT ASSESSMENT

For the reaction below, $\Delta G^\circ = 326.4\ \mathrm{kJ\,mol^{-1}}$:

$$3\,O_2(g) \longrightarrow 2\,O_3(g)$$

What is the Gibbs energy change for the system when 1.75 mol $O_2(g)$ at 1 bar reacts completely to give $O_3(g)$ at 1 bar?

19-5 ARE YOU WONDERING...

Whether there is a relationship between thermodynamics and the reaction rates?

Recall that when a reaction achieves equilibrium, the forward rate and reverse rate are equal. When the elementary reaction $A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B$ reaches equilibrium we can write $k_1[A] = k_{-1}[B]$. Let us rearrange this expression such that the rate constants are on one side, and the concentrations are on the other.

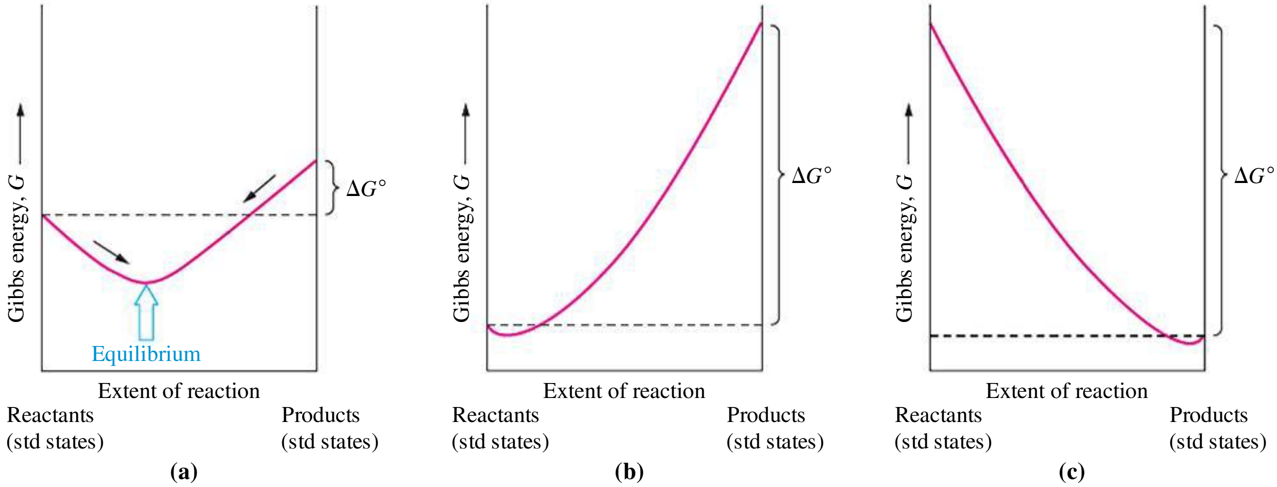
$$\frac{k_1}{k_{-1}} = \frac{[B]}{[A]}$$

The right side of the above equation is what we have defined as the equilibrium constant expression, $K = [B]/[A]$. The equilibrium constant is related to Gibbs energy by the expression $K = e^{-\Delta G^\circ/RT}$, showing that $\frac{k_1}{k_{-1}} = e^{-\Delta G^\circ/RT}$. This expression is valid only when the overall reaction mechanism is one step.

▶ From a theoretical standpoint, as can be seen from Figure 19-11, all chemical reactions reach equilibrium and no chemical reaction goes totally to completion.

Criteria for Spontaneous Change: Our Search Concluded

The graphs plotted in Figure 19-11 represent the culmination of our quest for criteria for spontaneous change. Unfortunately, to construct these plots in all their detail is beyond the scope of this text. However, we can rationalize their



▲ FIGURE 19-11
Gibbs energy change, equilibrium, and the direction of spontaneous change
Gibbs energy is plotted against the extent of reaction for a hypothetical reaction. ΔG° is the difference between the standard Gibbs energies of formation of products and reactants. The equilibrium point lies somewhere between pure reactants and pure products. **(a)** ΔG° is small, so the equilibrium mixture lies about midway between the two extremes of pure products or reactants in their standard states. The effect of nonstandard conditions can be deduced from the slope of the curve. Mixtures with $Q > K$ are to the right of the equilibrium point and undergo spontaneous change in the direction of lower Gibbs energy, eventually coming to equilibrium. Similarly, mixtures with $Q < K$ are to the left of the equilibrium point and spontaneously yield more products before reaching equilibrium. **(b)** ΔG° is large and positive, so the equilibrium point lies close to the extreme of pure reactants in their standard states. Consequently, very little reaction takes place before equilibrium is reached. **(c)** ΔG° is large and negative, so the equilibrium point lies close to the extreme of pure products in their standard states; the reaction goes essentially to completion.

▶ Here the system starts at standard conditions and runs down to equilibrium because the reactants are not replenished. At equilibrium there is no driving force for the reaction, so there is no further reaction and the Gibbs energy must be at a minimum.

TABLE 19.2 Significance of the Magnitude of $\Delta G°$ (at 298 K)

$\Delta G°$	K	Significance
$+200$ kJ/mol	9.1×10^{-36}	Equilibrium favors reactants
$+100$	3.0×10^{-18}	
$+50$	1.7×10^{-9}	
$+10$	1.8×10^{-2}	
$+1.0$	6.7×10^{-1}	Equilibrium calculation is necessary
0	1.0	
-1.0	1.5	
-10	5.6×10^{1}	
-50	5.8×10^{8}	Equilibrium favors products
-100	3.3×10^{17}	
-200	1.1×10^{35}	

general shape on the basis of two ideas: (1) Every chemical reaction consists of both a forward and a reverse reaction, even if one of these occurs only to a very slight extent. (2) The direction of spontaneous change in both the forward and reverse reactions is the direction in which Gibbs energy decreases ($\Delta G < 0$). As a consequence, Gibbs energy reaches a minimum at some point between the left-hand and right-hand sides of the graph. This minimum is the equilibrium point in the reaction.

Now consider the vertical distance between the two end points of the graph; this distance represents $\Delta G°$ of the reaction. If, as in Figure 19-11(a), $\Delta G°$ of a reaction is small, either positive or negative, the equilibrium condition is one in which significant amounts of both reactants and products will be found. If $\Delta G°$ is a *large, positive* quantity, as in Figure 19-11(b), the equilibrium point lies far to the left—that is, very close to the reactants side. If $\Delta G°$ is a *large, negative* quantity, as in Figure 19-11(c), the equilibrium point lies far to the right—that is, very close to the products side. Table 19.2 summarizes the conclusions of this discussion, gives approximate magnitudes to the terms *small* and *large*, and relates $\Delta G°$ values to values of K.

$\Delta G°$ and ΔG: Predicting the Direction of Chemical Change

We have considered both $\Delta G°$ and ΔG in relation to the spontaneity of chemical reactions, and this is a good time to summarize some ideas about them.

$\Delta G < 0$ signifies that a reaction or process is spontaneous in the forward direction (to the right) for the stated conditions.

$\Delta G° < 0$ signifies that the forward reaction is spontaneous when reactants and products are in their standard states. It further signifies that $K > 1$, whatever the initial concentrations or pressures of reactants and products.

$\Delta G = 0$ signifies that the reaction is at equilibrium under the stated conditions.

$\Delta G° = 0$ signifies that the reaction is at equilibrium when reactants and products are in their standard states. It further signifies that $K = 1$, which can occur only at a particular temperature.

$\Delta G > 0$ signifies that the reaction or process is nonspontaneous in the forward direction under the stated conditions.

$\Delta G° > 0$ signifies that the forward reaction is nonspontaneous when reactants and products are in their standard states. It further signifies that $K < 1$, whatever the initial concentrations or pressures of reactants and products.

$\Delta G = \Delta G°$ only when all reactants and products are in their standard states. Otherwise, $\Delta G = \Delta G° + RT \ln Q$.

The Thermodynamic Equilibrium Constant: Activities

When we derived the equation $\Delta G = \Delta G^\circ + RT \ln Q$, we used the relationship given in equation (19.11),

$$S = S^\circ - R \ln \frac{P}{P^\circ} = S^\circ - R \ln \frac{P}{1}$$

where for a gas, we defined a standard state of 1 bar, the reference state for values of entropy. The ratio P/P° is dimensionless, which is essential for a term appearing in a logarithm. At the time, we were considering a gas-phase reaction, but we must be able to discuss reactions in solutions also, so we need a more general approach. For this, we need to return to the concept of *activity* introduced in Section 15-2, which requires us to write

$$S = S^\circ - R \ln a$$

where a is the activity, defined as

$$a = \frac{\text{the effective concentration of a substance in the system}}{\text{the effective concentration of that substance in a standard reference state}}$$

KEEP IN MIND

that the ideal gas equation $PV = nRT$ can be rewritten as $(n/V) = [\text{concentration}] = (P/RT)$ so that pressure is an effective concentration.

In a gas-phase reaction, we express pressure in bars and take the reference state to be 1 bar. In this way and as expected, activity is a dimensionless quantity.

In extending the activity concept to solutions, we define the reference state as a 1 M solution, so the activity of a substance is the numerical value of its molarity. Thus, the activity of protons in a 0.1 M solution of HCl in water is

$$a_{H^+} = \frac{0.1\ \text{M}}{1\ \text{M}} = 0.1$$

KEEP IN MIND

that the precise definition of pH is

$$\text{pH} = -\log a_{H^+} \approx -\log\left(\frac{[H^+]}{1\ \text{M}}\right)$$

We often use a simplified version of the expression above, namely $\text{pH} = -\log[H^+]$. When we do, we must remember to use only the numerical part of $[H^+]$ in the logarithm.

Another situation that we have encountered is that of a heterogeneous equilibrium, such as

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

Recall that we choose the pure solids as the reference states, but the effective concentrations of the $CaCO_3(s)$ and CaO(s) in the system are also those of the pure solids. Consequently, the activity of a solid is unity. This conclusion agrees with our observation in Figure 15-4 that the addition of either CaO(s) or $CaCO_3(s)$ to an equilibrium mixture of $CaCO_3(s)$, $CO_2(g)$, and CaO(s) has no effect on the pressure of $CO_2(g)$. The activities of CaO(s) and $CaCO_3(s)$ are constant (unity).

19-6 ARE YOU WONDERING...

How to deal with activities under nonideal conditions?

For nonideal conditions, we sweep all deviations from ideality into an experimentally determined correction factor called the *activity coefficient*, γ. Thus, for real (nonideal) systems, we write

For a gas:	$a_G = \gamma P_G$
For a solute:	$a_X = \gamma[X]$
For a pure solid or liquid:	$a_L = a_S = 1$

More advanced treatments of this topic show how γ is related to the composition of the system. For dilute solutions or near ideal gases, we will assume that $\gamma = 1$. However, keep in mind that the results we obtain are limited by the validity of this assumption.

In summary, we can make these statements:

- *For pure solids and liquids:* The activity $a = 1$. The reference state is the pure solid or liquid.
- *For gases:* With ideal gas behavior assumed, the activity is replaced by the numerical value of the gas pressure in bars. The reference state is the gas at 1 bar at the temperature of interest. Thus, the activity of a gas at 0.50 bar pressure is $a = (0.50 \text{ bar})/(1 \text{ bar}) = 0.50$. (Recall also, that 1 bar of pressure is almost identical to 1 atm.)
- *For solutes in aqueous solution:* With ideal solution behavior assumed (for example, no interionic attractions), the activity is replaced by the numerical value of the molarity. The reference state is a 1 M solution. Thus, the activity of the solute in a 0.25 M solution is $a = (0.25 \text{ M})/(1 \text{ M}) = 0.25$.

When an equilibrium expression is written in terms of activities, the equilibrium constant is called the **thermodynamic equilibrium constant**. The thermodynamic equilibrium constant is dimensionless and thus appropriate for use in equation (19.13).

Thermodynamic equilibrium constants, K, are sometimes identical to K_c and K_p values, as in parts **(a)** and **(b)** of Example 19-6. In other instances, as in part **(c)**, this is not the case. In working through Example 19-6, keep in mind that the sole reason for writing thermodynamic equilibrium constants in this text is to get the proper value to use in equation (19.13). Note that the reaction quotient Q must also be written in the same manner as K when used in equation (19.12), as demonstrated in Example 19-7.

EXAMPLE 19-6 Writing Thermodynamic Equilibrium Constant Expressions

For the following reversible reactions, write thermodynamic equilibrium constant expressions, making appropriate substitutions for activities. Then equate K to K_c or K_p, where this can be done.

(a) The water gas reaction

$$C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g)$$

(b) Formation of a saturated aqueous solution of lead(II) iodide, a very slightly soluble solute

$$PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2\,I^-(aq)$$

(c) Oxidation of sulfide ion by oxygen gas (used in removing sulfides from wastewater, as in pulp and paper mills)

$$O_2(g) + 2\,S^{2-}(aq) + 2\,H_2O(l) \rightleftharpoons 4\,OH^-(aq) + 2\,S(s)$$

Analyze

In each case, once we have made the appropriate substitutions for activities, if all terms are molarities, the thermodynamic equilibrium constant is the same as K_c. If all terms are partial pressures, $K = K_p$. If both molarities *and* partial pressures appear in the expression, however, the equilibrium constant expression can be designated only as K.

Solve

(a) The activity of solid carbon is 1. Partial pressures are substituted for the activities of the gases.

$$K = \frac{a_{CO(g)}}{a_{C(s)}a_{H_2O(g)}} = \frac{(P_{CO})(P_{H_2})}{(P_{H_2O})} = \frac{(P_{CO})(P_{H_2})}{(P_{H_2O})} = K_p$$

(b) The activity of solid lead(II) iodide is 1. Molarities are substituted for activities of the ions in aqueous solution.

$$K = \frac{a_{Pb^{2+}(aq)}a^2_{I^-(aq)}}{a_{PbI_2(s)}} = [Pb^{2+}][I^-]^2 = K_c = K_{sp}$$

(continued)

(c) The activity of both the solid sulfur and the liquid water is 1. Molarities are substituted for the activities of $OH^-(aq)$ and $S^{2-}(aq)$. The partial pressure of $O_2(g)$ is substituted for its activity. Thus, the resulting K is neither a K_c nor a K_p.

$$K = \frac{a^4_{OH^-(aq)}\,a^2_{S(s)}}{a_{O_2(g)}\,a^2_{S^{2-}(aq)}\,a^2_{H_2O(l)}} = \frac{[OH^-]^4 \cdot (1)^2}{P_{O_2} \cdot [S^{2-}]^2 \cdot (1)^2} = \frac{[OH^-]^4}{P_{O_2} \cdot [S^{2-}]^2}$$

Assess

These are thermodynamic equilibrium expressions since they are written in terms of their activities. The values of the thermodynamic equilibrium constant will be dimensionless. The standard pressure and concentration terms have been left out for clarity.

PRACTICE EXAMPLE A: Write thermodynamic equilibrium constant expressions for each of the following reactions. Relate these to K_c or K_p where appropriate.

(a) $Si(s) + 2\,Cl_2(g) \rightleftharpoons SiCl_4(g)$

(b) $Cl_2(g) + H_2O(l) \rightleftharpoons HOCl(aq) + H^+(aq) + Cl^-(aq)$

PRACTICE EXAMPLE B: Write a thermodynamic equilibrium constant expression to represent the reaction of solid lead(II) sulfide with aqueous nitric acid to produce solid sulfur, a solution of lead(II) nitrate, and nitrogen monoxide gas. Base the expression on the balanced net ionic equation for the reaction.

EXAMPLE 19-7 Assessing Spontaneity for Nonstandard Conditions

For the decomposition of 2-propanol to form propanone (acetone) and hydrogen,

$$(CH_3)_2CHOH(g) \rightleftharpoons (CH_3)_2CO(g) + H_2(g)$$

the equilibrium constant is 0.444 at 452 K. Is this reaction spontaneous under standard conditions? Will the reaction be spontaneous when the partial pressures of 2-propanol, propanone, and hydrogen are 0.1 bar, respectively?

Analyze

We are asked two questions. The first is whether this reaction is spontaneous under standard conditions, which means the reactants and products are at 1 bar. We can easily answer by applying the equation $\Delta G^\circ = -RT \ln K$. The second part asks whether this reaction is spontaneous under a set of nonstandard conditions. We are asked to determine ΔG.

Solve

In each case, we first must obtain the value of ΔG°, which we can get from equation (19.13).

$$\Delta G^\circ = -RT \ln K = -8.3145 \text{ J mol}^{-1} \text{ K}^{-1} \times 452 \text{ K} \times \ln(0.444)$$
$$= 3.05 \times 10^3 \text{ J mol}^{-1}$$

This result enables us to state categorically that the reaction will not proceed spontaneously if all reactants and products are in their standard states—that is, with the partial pressures of reactants and products at 1 bar.

To determine whether the reaction is spontaneous under the nonstandard-state conditions given, we must calculate ΔG. We first write Q in terms of activities and then substitute the partial pressures of the gases for the activities of the gases.

$$Q = \frac{a_{(CH_3)_2CO}\,a_{H_2}}{a_{(CH_3)_2CHOH}} = \frac{P_{(CH_3)_2CO}\,P_{H_2}}{P_{(CH_3)_2CHOH}}$$

Then use this expression in equation (19.12).

$$\Delta G = \Delta G^\circ + RT \ln \frac{P_{(CH_3)_2CO}\,P_{H_2}}{P_{(CH_3)_2CHOH}}$$
$$= 3.05 \times 10^3 \text{ J mol}^{-1}$$
$$+ 8.3145 \text{ J mol}^{-1} \text{ K}^{-1} \times 452 \text{ K} \times \ln \frac{0.1 \times 0.1}{0.1}$$
$$= -5.60 \times 10^3 \text{ J mol}^{-1}$$

The value of ΔG is negative, so we can conclude that under this second set of conditions the reaction should proceed spontaneously.

Assess

Remember, however, that thermodynamics says nothing about the rate of the reaction, only that the reaction will proceed in its own good time!

PRACTICE EXAMPLE A: Use the data in Appendix D to decide whether the following reaction is spontaneous under standard conditions at 298.15 K.

$$N_2O_4(g) \longrightarrow 2\,NO_2(g)$$

PRACTICE EXAMPLE B: If a gaseous mixture of N_2O_4 and NO_2, both at a pressure of 0.5 bar, is introduced into a previously evacuated vessel, which of the two gases will spontaneously convert into the other at 298.15 K?

We have now acquired all the tools with which to perform one of the most practical calculations of chemical thermodynamics: *determining the equilibrium constant for a reaction from tabulated data*. Example 19-8, which demonstrates this application, uses thermodynamic properties of ions in aqueous solution as well as of compounds. An important idea to note about the thermodynamic properties of ions is that they are relative to $H^+(aq)$, which, by convention, is assigned values of *zero* for ΔH_f°, ΔG_f°, and S°. This means that entropies listed

EXAMPLE 19-8 Calculating the Equilibrium Constant of a Reaction from the Standard Gibbs Energy Change

Determine the equilibrium constant at 298.15 K for the dissolution of magnesium hydroxide in an acidic solution.

$$Mg(OH)_2(s) + 2\,H^+(aq) \rightleftharpoons Mg^{2+}(aq) + 2\,H_2O(l)$$

Analyze

The key to solving this problem is to find a value of ΔG° and then to use the expression $\Delta G^\circ = -RT \ln K$.

Solve

We can obtain ΔG° from standard Gibbs energies of formation listed in Appendix D. Note that because its value is zero, the term $\Delta G_f^\circ[H^+(aq)]$ is not included.

$$\begin{aligned}\Delta G^\circ &= 2\,\Delta G_f^\circ[H_2O(l)] + \Delta G_f^\circ[Mg^{2+}(aq)] - \Delta G_f^\circ[Mg(OH)_2(s)]\\ &= 2(-237.1\text{ kJ mol}^{-1}) + (-454.8\text{ kJ mol}^{-1}) - (-833.5\text{ kJ mol}^{-1})\end{aligned}$$

Now solve for ln K and K.

$$\Delta G^\circ = -RT\ln K = -95.5\text{ kJ mol}^{-1} = -95.5 \times 10^3\text{ J mol}^{-1}$$

$$\ln K = \frac{-\Delta G^\circ}{RT} = \frac{-(-95.5\times 10^3\text{ J mol}^{-1})}{8.3145\text{ J mol}^{-1}\text{ K}^{-1} \times 298.15\text{ K}} = 38.5$$

$$K = e^{38.5} = 5 \times 10^{16}$$

Assess

The value of K obtained here is the thermodynamic equilibrium constant. According to the conventions we have established, the activities of both $Mg(OH)_2(s)$ and $H_2O(l)$ are 1, and molarities can be substituted for the activities of the ions.

$$K = \frac{a_{Mg^{2+}(aq)}\,a^2_{H_2O(l)}}{a_{Mg(OH)_2(s)}\,a^2_{H^+(aq)}} = \frac{[Mg^{2+}]}{[H^+]^2} = K_c = 5 \times 10^{16}$$

PRACTICE EXAMPLE A: Determine the equilibrium constant at 298.15 K for $AgI(s) \rightleftharpoons Ag^+(aq) + I^-(aq)$. Compare your answer to the K_{sp} for AgI in Appendix D.

PRACTICE EXAMPLE B: At 298.15 K, should manganese dioxide react to an appreciable extent with 1 M HCl(aq), producing manganese(II) ion in solution and chlorine gas?

for ions are not absolute entropies, as they are for compounds. Negative values of $S°$ simply denote an entropy less than that of $H^+(aq)$.

When a question requires the use of thermodynamic properties, it is a good idea to think qualitatively about the problem before diving into calculations. The dissolution of $Mg(OH)_2(s)$ in acidic solution considered in Example 19-8 is an acid–base reaction that was used as an example in Chapter 18 to illustrate the effect of pH on solubility. It was also mentioned in Chapter 5 as the basis for using milk of magnesia as an antacid. We should certainly expect the reaction to be spontaneous. This means that the value of K should be large, which we found to be the case. If we had made an error in sign in our calculation (an easy thing to do using the expression $\Delta G° = -RT \ln K$), we would have obtained $K = 2 \times 10^{-17}$. But we would have seen immediately that this is the wrong answer. This erroneous value suggests a reaction in which the concentration of products is extremely low at equilibrium.

The data listed in Appendix D are for 25 °C. Thus, values of $\Delta G°$ and K obtained with these data are also at 25 °C. Most chemical reactions are carried out at temperatures other than 25 °C, however. In Section 19-7, we will learn how to calculate values of equilibrium constants at various temperatures.

19-7 $\Delta G°$ and K as Functions of Temperature

▶ In general, equilibrium constants for exothermic reactions will be lower at higher temperatures and higher at lower temperatures. Alternatively, equilibrium constants for endothermic reactions are lower at lower temperatures and higher at higher temperatures. This is seen by evaluating equation (19.15).

In Chapter 15, we used Le Châtelier's principle to make qualitative predictions of the effect of temperature on an equilibrium condition. We can now describe a *quantitative* relationship between the equilibrium constant and temperature. In the method illustrated in Example 19-9, we assume that $\Delta H°$ is practically independent of temperature. Although absolute entropies depend on temperature, we assume that the entropy *change* $\Delta S°$ for a reaction is also independent of temperature. Yet, the term "$T\Delta S$" is strongly temperature-dependent because of the temperature factor T. As a result, $\Delta G°$, which is equal to $\Delta H° - T\Delta S°$, is also dependent on temperature.

EXAMPLE 19-9 Determining the Relationship Between an Equilibrium Constant and Temperature by Using Equations for Gibbs Energy Change

At what temperature will the equilibrium constant for the formation of NOCl(g) be $K = K_p = 1.00 \times 10^3$? Data for this reaction at 25 °C are

$$2\,NO(g) + Cl_2(g) \rightleftharpoons 2\,NOCl(g)$$

$$\Delta G° = -40.9\ \text{kJ mol}^{-1} \qquad \Delta H = -77.1\ \text{kJ mol}^{-1}$$

$$\Delta S° = -121.3\ \text{J mol}^{-1}\ \text{K}^{-1}$$

Analyze

To determine an unknown temperature from a known equilibrium constant, we need an equation in which both of these terms appear. The required equation is $\Delta G° = -RT \ln K$. However, to solve for the unknown temperature, we need the value of $\Delta G°$ at that temperature. We know the value of $\Delta G°$ at 25 °C (-40.9 kJ mol^{-1}), but we also know that this value will be different at other temperatures. We can assume, however, that the values of $\Delta H°$ and $\Delta S°$ will not change much with temperature. This means that we can obtain a value of $\Delta G°$ from the equation $\Delta G° = \Delta H° - T\,\Delta S°$, where T is the *unknown* temperature and the values of $\Delta H°$ and $\Delta S°$ are those at 25 °C. Now we have two equations that we can set equal to each other.

Solve

That is,

$$\Delta G° = \Delta H° - T\,\Delta S° = -RT \ln K$$

We can gather the terms with T on the right,

$$\Delta H^\circ = T\,\Delta S^\circ - RT\ln K = T(\Delta S^\circ - R\ln K)$$

and solve for T.

$$T = \frac{\Delta H^\circ}{\Delta S^\circ - R\ln K}$$

Now substitute values for ΔH°, ΔS°, R, and $\ln K$.

$$\begin{aligned} T &= \frac{-77.1 \times 10^3\ \text{J mol}^{-1}}{-121.3\ \text{J mol}^{-1}\ \text{K}^{-1} - [8.3145\ \text{J mol}^{-1}\ \text{K}^{-1} \times \ln(1.00 \times 10^3)]} \\ &= \frac{-77.1 \times 10^3\ \text{J mol}^{-1}}{-121.3\ \text{J mol}^{-1}\ \text{K}^{-1} - (8.3145 \times 6.908)\ \text{J mol}^{-1}\ \text{K}^{-1}} \\ &= \frac{-77.1 \times 10^3\ \text{J mol}^{-1}}{-178.7\ \text{J mol}^{-1}\ \text{K}^{-1}} = 431\ \text{K} \end{aligned}$$

Assess

Although the answer shows three significant figures, the final result should probably be rounded to just two significant figures. The assumption we made about the constancy of ΔH° and ΔS° is probably no more valid than that.

PRACTICE EXAMPLE A: At what temperature will the formation of $NO_2(g)$ from NO(g) and $O_2(g)$ have $K_p = 1.50 \times 10^2$? For the reaction $2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$ at 25 °C, $\Delta H^\circ = -114.1\ \text{kJ mol}^{-1}$ and $\Delta S^\circ = -146.5\ \text{J mol}^{-1}\text{K}^{-1}$.

PRACTICE EXAMPLE B: For the reaction $2\,NO(g) + Cl_2(g) \rightleftharpoons 2\,NOCl(g)$, what is the value of K at **(a)** 25 °C; **(b)** 75 °C? Use data from Example 19-9. [*Hint:* The solution to part (a) can be done somewhat more simply than that for (b).]

An alternative to the method outlined in Example 19-9 is to relate the equilibrium constant and temperature directly, without specific reference to a Gibbs energy change. We start with the same two expressions as in Example 19-9,

$$-RT\ln K = \Delta G^\circ = \Delta H^\circ - T\,\Delta S^\circ$$

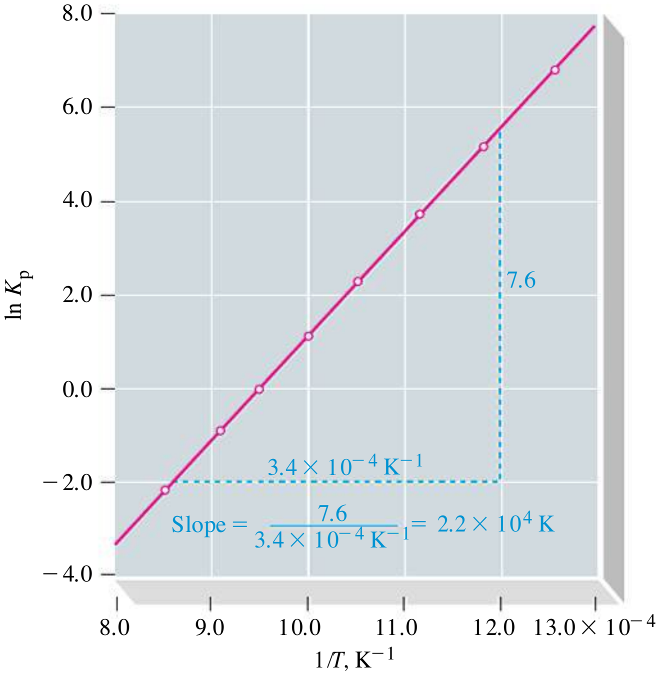
and divide by $-RT$.

$$\ln K = \frac{-\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \tag{19.14}$$

If we assume that ΔH° and ΔS° are constant, equation (19.14) describes a straight line with a slope of $-\Delta H^\circ/R$ and a y-intercept of $\Delta S^\circ/R$. Table 19.3 lists equilibrium constants as a function of the reciprocal of Kelvin temperature for

TABLE 19.3 Equilibrium Constants, K_p, for the Reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$ at Several Temperatures

T, K	$1/T$, K^{-1}	K_p	ln K_p
800	12.5×10^{-4}	9.1×10^{2}	6.81
850	11.8×10^{-4}	1.7×10^{2}	5.14
900	11.1×10^{-4}	4.2×10^{1}	3.74
950	10.5×10^{-4}	1.0×10^{1}	2.30
1000	10.0×10^{-4}	3.2×10^{0}	1.16
1050	9.52×10^{-4}	1.0×10^{0}	0.00
1100	9.09×10^{-4}	3.9×10^{-1}	−0.94
1170	8.5×10^{-4}	1.2×10^{-1}	−2.12



▶ FIGURE 19-12

Temperature dependence of the equilibrium constant K_p for the reaction

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$$

This graph can be used to establish the enthalpy of reaction, $\Delta H°$ (see equation 19.14).

$$\begin{aligned} \text{slope} &= \Delta H°/R = 2.2 \times 10^4\ \text{K} \\ \Delta H° &= -8.3145\ \text{J mol}^{-1}\ \text{K}^{-1} \times 2.2 \times 10^4\ \text{K} \\ &= -1.8 \times 10^5\ \text{J mol}^{-1} \\ &= -1.8 \times 10^2\ \text{kJ mol}^{-1} \end{aligned}$$

the reaction of $SO_2(g)$ and $O_2(g)$ that forms $SO_3(g)$. The ln K_p and $1/T$ data from Table 19.3 are plotted in Figure 19-12 and yield the expected straight line.

Now we can follow the procedure used in Appendix A-4 to derive the Clausius–Clapeyron equation. We can write equation (19.14) twice, for two different temperatures and with the corresponding equilibrium constants. Then, if we subtract one equation from the other, we obtain the result shown here,

$$\ln\frac{K_2}{K_1} = -\frac{\Delta H°}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \qquad \textbf{(19.15)}$$

where T_2 and T_1 are two Kelvin temperatures; K_2 and K_1 are the equilibrium constants at those temperatures; $\Delta H°$ is the enthalpy of reaction, expressed in J mol^{-1}; and R is the gas constant, expressed as 8.3145 J mol^{-1} K^{-1}. Jacobus van't Hoff (1852–1911) derived equation (19.15), which is often referred to as *the van't Hoff equation.*

KEEP IN MIND

that the Clausius–Clapeyron equation (12.2) is just a special case of equation (19.15) in which the equilibrium constants are equilibrium vapor pressures and $\Delta H° = \Delta H_{vap}$.

19-5 CONCEPT ASSESSMENT

The normal boiling point of water is 100 °C. At 120 °C and 1 atm, is ΔH or $T\,\Delta S$ greater for the vaporization of water?

EXAMPLE 19-10 Relating Equilibrium Constants and Temperature Through the Van't Hoff Equation

Use data from Table 19.3 and Figure 19-12 to estimate the temperature at which $K_p = 1.0 \times 10^6$ for the reaction

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$$

Analyze

To use the van't Hoff equation select one known temperature and equilibrium constant from Table 19.3 and the enthalpy change of the reaction, $\Delta H°$, from Figure 19-12.

Solve

The data to be substituted into equation (19.15) are $T_1 = ?$, $K_1 = 1.0 \times 10^6$; $T_2 = 800$ K, $K_2 = 9.1 \times 10^2$; and $\Delta H° = -1.8 \times 10^5 \text{ J mol}^{-1}$.

In the following setup, we have dropped the units for simplicity. However, you should be able to show that units cancel properly.

$$\ln\frac{K_2}{K_1} = \frac{\Delta H°}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

$$\ln\frac{9.1 \times 10^2}{1.0 \times 10^6} = \frac{-1.8 \times 10^5}{8.3145}\left(\frac{1}{T_1} - \frac{1}{800}\right)$$

$$-7.00 = -2.2 \times 10^4\left(\frac{1}{T_1} - \frac{1}{800}\right)$$

$$\frac{-7.00}{-2.2 \times 10^4} + \frac{1}{800} = \frac{1}{T_1}$$

$$\frac{1}{T_1} = (3.2 \times 10^{-4}) + (1.25 \times 10^{-3}) = 1.57 \times 10^{-3}$$

$$T_1 = \frac{1}{1.57 \times 10^{-3}} = 6.37 \times 10^2 \text{ K}$$

Assess

A common error in this type of problem is the use of incorrect temperature units. It should be Kelvin (K).

PRACTICE EXAMPLE A: Estimate the temperature at which $K_p = 5.8 \times 10^{-2}$ for the reaction in Example 19-10. Use data from Table 19.3 and Figure 19-12.

PRACTICE EXAMPLE B: What is the value of K_p for the reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$ at 235 °C? Use data from Table 19.3, Figure 19-12 and the van't Hoff equation (19.15).

19-8 Coupled Reactions

We have seen two ways to obtain product from a nonspontaneous reaction: (1) Change the reaction conditions to ones that make the reaction spontaneous (mostly by changing the temperature), and (2) carry out the reaction by electrolysis. But there is a third way also. Combine a pair of reactions, one with a positive ΔG and one with a negative ΔG, to obtain a spontaneous overall reaction. Such paired reactions are called **coupled reactions**. Consider the extraction of a metal from its oxide.

When copper(I) oxide is heated to 673 K, no copper metal is obtained. The decomposition of Cu_2O to form products in their standard states (for instance, $P_{O_2} = 1.00$ bar) is nonspontaneous at 673 K.

$$Cu_2O(s) \xrightarrow{\Delta} 2\,Cu(s) + \frac{1}{2}O_2(g) \qquad \Delta G°_{673K} = +125 \text{ kJ} \qquad \textbf{(19.16)}$$

◀ In general chemistry, simple examples of reactions are generally used. In fact, in almost all interesting cases, one reaction is coupled to another, and so forth. No better example exists than the complex cycles of coupled chemical reactions in biological processes.

Suppose this nonspontaneous decomposition reaction is coupled with the partial oxidation of carbon to carbon monoxide—a spontaneous reaction. The overall reaction (19.17), because it has a negative value of $\Delta G°$, is spontaneous when reactants and products are in their standard states.

$$\begin{aligned} Cu_2O(s) &\longrightarrow 2\,Cu(s) + \cancel{\tfrac{1}{2}O_2(g)} && \Delta G°_{673\,K} = +125 \text{ kJ} \\ C(s) + \cancel{\tfrac{1}{2}O_2(g)} &\longrightarrow CO(g) && \Delta G°_{673\,K} = -175 \text{ kJ} \\ Cu_2O(s) + C(s) &\longrightarrow 2\,Cu(s) + CO(g) && \Delta G°_{673\,K} = -50 \text{ kJ} \qquad \textbf{(19.17)} \end{aligned}$$

Note that reactions (19.16) and (19.17) are not the same, even though each has Cu(s) as a product. The purpose of coupled reactions, then, is to produce a spontaneous overall reaction by combining two other processes: one nonspontaneous and one spontaneous. Many metallurgical processes employ coupled reactions, especially those that use carbon or hydrogen as reducing agents.

To sustain life, organisms must synthesize complex molecules from simpler ones. If carried out as single-step reactions, these syntheses would generally be accompanied by increases in enthalpy, decreases in entropy, and increases in Gibbs energy—in short, they would be nonspontaneous and would not occur. In living organisms, changes in temperature and electrolysis are not viable options for dealing with nonspontaneous processes. Here, coupled reactions are crucial. See Focus On 19-1 on the MasteringChemistry website for an example.

MasteringCHEMISTRY **www.masteringchemistry.com**

Adenosine triphosphate (ATP) is the energy currency used in nature to drive reactions. The conversion of adenosine diphosphate (ADP) to ATP is a nonspontaneous process. For a discussion of how Nature is able to convert ADP to ATP, go to the Focus On feature for Chapter 19, Coupled Reactions in Biological Systems, on the MasteringChemistry site.

Summary

19-1 Spontaneity: The Meaning of Spontaneous Change—A process that proceeds without need of external intervention is said to be a **spontaneous process**. A **nonspontaneous process** cannot occur without external intervention. A process that is spontaneous in one direction is nonspontaneous in the reverse direction. Some spontaneous processes are exothermic, others are endothermic so that criteria other than enthalpy change are needed to define spontaneity.

19-2 The Concept of Entropy—**Entropy** is a thermodynamic property related to the distribution of a system's energy among the available microscopic energy levels. Boltzmann's formula (equation 19.1) illustrates the relationship between entropy and the number of microstates of a system. The thermodynamic definition of an **entropy change**, **ΔS**, is of a quantity of heat (q_{rev}) divided by a Kelvin temperature (equation 19.2), and having the units J K^{-1}. The quantity of heat released (or absorbed) during the process must be from a reversible process in order for the entropy change to be path-independent.

19-3 Evaluating Entropy and Entropy Changes—The **third law of thermodynamics states** that the entropy of a pure, perfect crystal at 0 K is zero. Thus there are absolute entropies, unlike internal energy and enthalpy. The entropy of a substance in its standard state is called **standard molar entropy**, S°. Standard molar entropies of **reactants** and products can be used to calculate standard entropy changes in chemical reactions (equation 19.5). Another important entropy-related relationship is **Trouton's rule**, which states that the standard entropy of vaporization at the normal boiling point is approximately constant at $87 \text{ J mol}^{-1} \text{ K}^{-1}$ (equation 19.4).

19-4 Criteria for Spontaneous Change: The Second Law of Thermodynamics—The basic criterion for spontaneous change is that the entropy change of the universe, which is the sum of the entropy change of the system plus that of the surroundings (equation 19.6), must be greater than zero (equation 19.7). This statement is known as the **second law of thermodynamics**. An equivalent criterion applied to the system alone is based on a thermodynamic function known as the **Gibbs energy**. The **Gibbs energy change**, **ΔG**, is the enthalpy change for the system (ΔH) minus the product of the temperature and entropy change for the system ($T\,\Delta S$) (equation 19.9). Table 19.1 summarizes the criteria for spontaneous change based on Gibbs energy change.

19-5 Standard Gibbs Energy Change, ΔG°—The **standard Gibbs energy change**, ΔG°, is based on the conversion of reactants in their standard states to products in their standard states. Tabulated Gibbs energy data are usually **standard Gibbs energies of formation**, ΔG_f°, and usually at 298.15 K.

19-6 Gibbs Energy Change and Equilibrium—The relationship between the standard Gibbs energy change and the equilibrium constant for a reaction is $\Delta G^\circ = -RT \ln K$. The constant, K, is called a **thermodynamic equilibrium constant**. It is based on the activities of reactants and products, but these activities can be related to solution molarities and gas partial pressures by means of a few simple conventions.

19-7 ΔG° and K as Functions of Temperature—By starting with the relationship between standard Gibbs energy change and the equilibrium constant, the van't Hoff equation—relating the equilibrium constant and temperature—can be written. With this equation, tabulated data at 25 °C can be used to determine equilibrium constants not just at 25 °C but at other temperatures as well.

19-8 Coupled Reactions—Nonspontaneous processes can be made spontaneous by coupling them with spontaneous reactions and by taking advantage of the state function property of G. **Coupled reactions**, that is, paired reactions that yield a spontaneous overall reaction, occur in metallurgical processes and in biochemical transformations.

Integrative Example

The synthesis of methanol is of great importance because methanol can be used directly as a motor fuel, mixed with gasoline for fuel use, or converted to other organic compounds. The synthesis reaction, carried out at about 500 K, is

$$\mathrm{CO(g)} + 2\,\mathrm{H_2(g)} \rightleftharpoons \mathrm{CH_3OH(g)}$$

What is the value of K_{p} at 500 K?

Analyze

Our approach to this problem begins with determining ΔG° from Gibbs energy of formation data and using ΔG° to find K_{p} at 298 K. The next step is to calculate ΔH° from enthalpy of formation data, and use this value together with K_{p} at 298 K in expression (19.15) to find K_{p} at 500 K.

Solve

Write the equation for methanol synthesis; place Gibbs energy of formation data from Appendix D under formulas in the equation, and use these data to calculate ΔG° at 298 K.

$$\begin{array}{lccc} & \mathrm{CO(g)} & +\,2\,\mathrm{H_2(g)} & \rightleftharpoons \mathrm{CH_3OH(g)} \\ \Delta G^\circ_{\mathrm{f}},\ \mathrm{kJ\,mol^{-1}} & -137.2 & 0 & -162.0 \end{array}$$

$$\begin{aligned} \Delta G^\circ &= 1\ \mathrm{mol\ CH_3OH} \times (-162.0\ \mathrm{kJ/mol\ CH_3OH}) \\ &\quad -1\ \mathrm{mol\ CO} \times (-137.2\ \mathrm{kJ/mol\ CO}) = -24.8\ \mathrm{kJ} \end{aligned}$$

To calculate K_{p} at 298 K, use ΔG° at 298 K, written as $-24.8 \times 10^3\ \mathrm{J\,mol^{-1}}$, in the expression $\Delta G^\circ = -RT \ln K_{\mathrm{p}}$.

$$\ln K_{\mathrm{p}} = -\Delta G^\circ/RT = \frac{-(-24.8 \times 10^3\ \mathrm{J\,mol^{-1}})}{8.3145\ \mathrm{J\,mol^{-1}\,K^{-1}} \times 298\ \mathrm{K}} = 10.0$$

$$K_{\mathrm{p}} = e^{10.0} = 2.2 \times 10^4$$

To determine ΔH° at 298 K, use standard enthalpy of formation data from Appendix D, applied in the same manner as was previously used for ΔG°.

$$\begin{array}{lccc} & \mathrm{CO(g)} & +\,2\,\mathrm{H_2(g)} & \rightleftharpoons \mathrm{CH_3OH(g)} \\ \Delta H^\circ_{\mathrm{f}},\ \mathrm{kJ\,mol^{-1}} & -110.5 & 0 & -200.7 \end{array}$$

$$\begin{aligned} \Delta H^\circ &= 1\ \mathrm{mol\ CH_3OH} \times (-200.7\ \mathrm{kJ/mol\ CH_3OH}) \\ &\quad -1\ \mathrm{mol\ CO} \times (-110.5\ \mathrm{kJ/mol\ CO}) = -90.2\ \mathrm{kJ} \end{aligned}$$

Use the van't Hoff equation with $K_{\mathrm{p}} = 2.2 \times 10^4$ at 298 K and $\Delta H^\circ = -90.2 \times 10^3\ \mathrm{J\,mol^{-1}}$. Solve for K_{p} at 500 K.

$$\begin{aligned} \ln \frac{K_{\mathrm{p}}}{2.2 \times 10^4} &= \frac{-90.2 \times 10^3\ \mathrm{J\,mol^{-1}}}{8.3145\ \mathrm{J\,mol^{-1}\,K^{-1}}}\left(\frac{1}{298\ \mathrm{K}} - \frac{1}{500\ \mathrm{K}}\right) \\ &= -14.7 \end{aligned}$$

$$\frac{K_{\mathrm{p}}}{2.2 \times 10^4} = e^{-14.7} = 4 \times 10^{-7} \qquad K_{\mathrm{p}} = 9 \times 10^{-3}$$

Assess

We have been successful in determining the equilibrium constant for the synthesis of methanol at 500 K by using tabulated thermodynamic data and the van't Hoff equation. Note that increasing the temperature favors the reverse reaction, as we should expect from Le Châtelier's principle. That is, an increase in temperature in a reversible reaction favors the heat absorbing (endothermic) reaction. Here, the forward reaction is exothermic and the reverse reaction is endothermic.

PRACTICE EXAMPLE A: Dinitrogen pentoxide, N_2O_5, is a solid with a high vapor pressure. Its vapor pressure at 7.5 °C is 100 mmHg, and the solid sublimes at a pressure of 1.00 atm at 32.4 °C. What is the standard Gibbs energy change for the process at $\mathrm{N_2O_5(s)} \longrightarrow \mathrm{N_2O_5(g)}$ at 25 °C?

PRACTICE EXAMPLE B: A plausible reaction for the production of ethylene glycol (used as antifreeze) is

$$2\,\mathrm{CO(g)} + 3\mathrm{H_2(g)} \longrightarrow \mathrm{CH_2OHCH_2OH(l)}$$

The following thermodynamic properties of $\mathrm{CH_2OHCH_2OH(l)}$ at 25 °C are given: $\Delta H^\circ_{\mathrm{f}} = -454.8\ \mathrm{kJ\,mol^{-1}}$ and $\Delta G^\circ_{\mathrm{f}} = -323.1\ \mathrm{kJ\,mol^{-1}}$. Use these data, together with values from Appendix D, to obtain a value of S°, the standard molar entropy of $\mathrm{CH_2OHCH_2OH(l)}$ at 25 °C.

Exercises

Spontaneous Change and Entropy

1. Indicate whether each of the following changes represents an increase or a decrease in entropy in a system, and explain your reasoning: **(a)** the freezing of ethanol; **(b)** the sublimation of dry ice; **(c)** the burning of a rocket fuel.

2. Arrange the entropy changes of the following processes, all at 25 °C, in the expected order of increasing ΔS, and explain your reasoning:
   (a) $H_2O(l, 1\ atm) \longrightarrow H_2O(g, 1\ atm)$
   (b) $CO_2(s, 1\ atm) \longrightarrow CO_2(g, 10\ mmHg)$
   (c) $H_2O(l, 1\ atm) \longrightarrow H_2O(g, 10\ mmHg)$

3. Use ideas from this chapter to explain this famous remark attributed to Rudolf Clausius (1865): “Die Energie der Welt ist konstant; die Entropie der Welt strebt einem Maximum zu.” (“The energy of the world is constant; the entropy of the world increases toward a maximum.”)

4. Comment on the difficulties of solving environmental pollution problems from the standpoint of entropy changes associated with the formation of pollutants and with their removal from the environment.

5. Indicate whether the entropy of the system would increase or decrease in each of the following reactions. If you cannot be certain simply by inspecting the equation, explain why.
   (a) $CCl_4(l) \longrightarrow CCl_4(g)$
   (b) $CuSO_4 \cdot 3\,H_2O(s) + 2\,H_2O(g) \longrightarrow CuSO_4 \cdot 5\,H_2O(s)$
   (c) $SO_3(g) + H_2(g) \longrightarrow SO_2(g) + H_2O(g)$
   (d) $H_2S(g) + O_2(g) \longrightarrow H_2O(g) + SO_2(g)$ (not balanced)

6. Which substance in each of the following pairs would have the greater entropy? Explain.
   (a) at 75 °C and 1 atm: 1 mol $H_2O(l)$ or 1 mol $H_2O(g)$
   (b) at 5 °C and 1 atm: 50.0 g Fe(s) or 0.80 mol Fe(s)
   (c) 1 mol Br_2 (l, 1 atm, 8 °C) or 1 mol Br_2 (s, 1 atm, −8 °C)
   (d) 0.312 mol SO_2 (g, 0.110 atm, 32.5 °C) or 0.284 mol O_2 (g, 15.0 atm, 22.3 °C)

7. For each of the following reactions, indicate whether ΔS for the reaction should be positive or negative. If it is not possible to determine the sign of ΔS from the information given, indicate why.
   (a) $CaO(s) + H_2O(l) \longrightarrow Ca(OH)_2(s)$
   (b) $2\,HgO(s) \longrightarrow 2\,Hg(l) + O_2(g)$
   (c) $2\,NaCl(l) \longrightarrow 2\,Na(l) + Cl_2(g)$
   (d) $Fe_2O_3(s) + 3\,CO(g) \longrightarrow 2\,Fe(s) + 3\,CO_2(g)$
   (e) $Si(s) + 2\,Cl_2(g) \longrightarrow SiCl_4(g)$

8. By analogy to ΔH_f° and ΔG_f° how would you define entropy of formation? Which would have the largest entropy of formation: $CH_4(g)$, $CH_3CH_2OH(l)$, or $CS_2(l)$? First make a qualitative prediction; then test your prediction with data from Appendix D.

Phase Transitions

9. In Example 19-2, we dealt with ΔH_{vap}° and ΔS_{vap}° for water at 100 °C.
   (a) Use data from Appendix D to determine values for these two quantities at 25 °C.
   (b) From your knowledge of the structure of liquid water, explain the differences in ΔH_{vap}° values and in ΔS_{vap}° values between 25 °C and 100 °C.

10. Pentane is one of the most volatile of the hydrocarbons in gasoline. At 298.15 K, the following enthalpies of formation are given for pentane: $\Delta H_f^\circ C_5H_{12}(l) = -173.5\ kJ\ mol^{-1}$; $\Delta H_f^\circ[C_5H_{12}(g)] = -146.9\ kJ\ mol^{-1}$.
    (a) Estimate the normal boiling point of pentane.
    (b) Estimate ΔG° for the vaporization of pentane at 298 K.
    (c) Comment on the significance of the sign of ΔG° at 298 K.

11. Which of the following substances would obey Trouton’s rule most closely: HF, $C_6H_5CH_3$ (toluene), or CH_3OH (methanol)? Explain your reasoning.

12. Estimate the normal boiling point of bromine, Br_2, in the following way: Determine ΔH_{vap}° for Br_2 from data in Appendix D. Assume that ΔH_{vap}° remains constant and that Trouton’s rule is obeyed.

13. In what temperature range can the following equilibrium be established? Explain.

$$H_2O(l, 0.50\ atm) \rightleftharpoons H_2O(g, 0.50\ atm)$$

14. Refer to Figures 12-28 and 19-9. Which has the lowest Gibbs energy at 1 atm and −60 °C: solid, liquid, or gaseous carbon dioxide? Explain.

Gibbs Energy and Spontaneous Change

15. Which of the following changes in a thermodynamic property would you expect to find for the reaction $Br_2(g) \longrightarrow 2\,Br(g)$ *at all temperatures:* **(a)** $\Delta H < 0$; **(b)** $\Delta S > 0$; **(c)** $\Delta G < 0$; **(d)** $\Delta S < 0$? Explain.

16. If a reaction can be carried out only by electrolysis, which of the following changes in a thermodynamic property *must* apply: **(a)** $\Delta H > 0$; **(b)** $\Delta S > 0$; **(c)** $\Delta G = \Delta H$; **(d)** $\Delta G > 0$? Explain.

17. Indicate which of the four cases in Table 19.1 applies to each of the following reactions. If you are unable to decide from only the information given, state why.
    (a) $PCl_3(g) + Cl_2(g) \longrightarrow PCl_5(g)\quad \Delta H^\circ = -87.9\ kJ$
    (b) $CO_2(g) + H_2(g) \longrightarrow CO(g) + H_2O(g)\quad \Delta H^\circ = +41.2\ kJ$
    (c) $NH_4CO_2NH_2(s) \longrightarrow 2\,NH_3(g) + CO_2(g)\quad \Delta H^\circ = +159.2\ kJ$

18. Indicate which of the four cases in Table 19.1 applies to each of the following reactions. If you are unable to decide from only the information given, state why.

(a) $H_2O(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O_2(g)$ $\Delta H° = +105.5\ \text{kJ}$

(b) $C_6H_6(l) + \frac{15}{2}O_2(g) \longrightarrow 6\,CO_2(g) + 3\,H_2O(g)$ $\Delta H° = -3135\ \text{kJ}$

(c) $NO(g) + \frac{1}{2}Cl_2(g) \longrightarrow NOCl(g)$ $\Delta H° = -38.54\ \text{kJ}$

19. For the mixing of ideal gases (see Figure 19-2), explain whether a positive, negative, or zero value is expected for ΔH, ΔS, and ΔG.

20. What values of ΔH, ΔS, and ΔG would you expect for the formation of an ideal solution of liquid components? (Is each value positive, negative, or zero?)

21. Explain why **(a)** some exothermic reactions do not occur spontaneously, and **(b)** some reactions in which the entropy of the system increases do not occur spontaneously.

22. Explain why you would expect a reaction of the type $AB(g) \longrightarrow A(g) + B(g)$ always to be spontaneous at *high* rather than at low temperatures.

Standard Gibbs Energy Change

23. From the data given in the following table, determine $\Delta S°$ for the reaction $NH_3(g) + HCl(g) \longrightarrow NH_4Cl(s)$. All data are at 298 K.

	$\Delta H_f°$, kJ mol^{-1}	$\Delta G_f°$, kJ mol^{-1}
$NH_3(g)$	−46.11	−16.48
$HCl(g)$	−92.31	−95.30
$NH_4Cl(s)$	−314.4	−202.9

24. Use data from Appendix D to determine values of $\Delta G°$ for the following reactions at 25 °C.

(a) $C_2H_2(g) + 2\,H_2(g) \longrightarrow C_2H_6(g)$

(b) $2\,SO_3(g) \longrightarrow 2\,SO_2(g) + O_2(g)$

(c) $Fe_3O_4(s) + 4\,H_2(g) \longrightarrow 3\,Fe(s) + 4\,H_2O(g)$

(d) $2\,Al(s) + 6\,H^+(aq) \longrightarrow 2\,Al^{3+}(aq) + 3\,H_2(g)$

25. At 298 K, for the reaction $2\,PCl_3(g) + O_2(g) \longrightarrow 2\,POCl_3(l)$, $\Delta H° = -620.2\ \text{kJ}$ and the standard molar entropies are $PCl_3(g)$, $311.8\ \text{J K}^{-1}$; $O_2(g)$, $205.1\ \text{J K}^{-1}$; and $POCl_3(l)$, $222.4\ \text{J K}^{-1}$. Determine **(a)** $\Delta G°$ at 298 K and **(b)** whether the reaction proceeds spontaneously in the forward or the reverse direction when reactants and products are in their standard states.

26. At 298 K, for the reaction $2\,H^+(aq) + 2\,Br^-(aq) + 2\,NO_2(g) \longrightarrow Br_2(l) + 2\,HNO_2(aq)$, $\Delta H° = -61.6\ \text{kJ}$ and the standard molar entropies are $H^+(aq)$, $0\ \text{J K}^{-1}$; $Br^-(aq)$, $82.4\ \text{J K}^{-1}$; $NO_2(g)$, $240.1\ \text{J K}^{-1}$; $Br_2(l)$, $152.2\ \text{J K}^{-1}$; $HNO_2(aq)$, $135.6\ \text{J K}^{-1}$. Determine **(a)** $\Delta G°$ at 298 K and **(b)** whether the reaction proceeds spontaneously in the forward or the reverse direction when reactants and products are in their standard states.

27. The following standard Gibbs energy changes are given for 25 °C.

(1) $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$ $\Delta G° = -33.0\ \text{kJ}$

(2) $4\,NH_3(g) + 5\,O_2(g) \longrightarrow 4\,NO(g) + 6\,H_2O(l)$ $\Delta G° = -1010.5\ \text{kJ}$

(3) $N_2(g) + O_2(g) \longrightarrow 2\,NO(g)$ $\Delta G° = +173.1\ \text{kJ}$

(4) $N_2(g) + 2\,O_2(g) \longrightarrow 2\,NO_2(g)$ $\Delta G° = +102.6\ \text{kJ}$

(5) $2\,N_2(g) + O_2(g) \longrightarrow 2\,N_2O(g)$ $\Delta G° = +208.4\ \text{kJ}$

Combine the preceding equations, as necessary, to obtain $\Delta G°$ values for each of the following reactions.

(a) $N_2O(g) + \frac{3}{2}O_2(g) \longrightarrow 2\,NO_2(g)$ $\Delta G° = ?$

(b) $2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(l)$ $\Delta G° = ?$

(c) $2\,NH_3(g) + 2\,O_2(g) \longrightarrow N_2O(g) + 3\,H_2O(l)$ $\Delta G° = ?$

Of reactions (a), (b), and (c), which would tend to go to completion at 25 °C, and which would reach an equilibrium condition with significant amounts of all reactants and products present?

28. The following standard Gibbs energy changes are given for 25 °C.

(1) $SO_2(g) + 3\,CO(g) \longrightarrow COS(g) + 2\,CO_2(g)$ $\Delta G° = -246.4\ \text{kJ}$

(2) $CS_2(g) + H_2O(g) \longrightarrow COS(g) + H_2S(g)$ $\Delta G° = -41.5\ \text{kJ}$

(3) $CO(g) + H_2S(g) \longrightarrow COS(g) + H_2(g)$ $\Delta G° = +1.4\ \text{kJ}$

(4) $CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$ $\Delta G° = -28.6\ \text{kJ}$

Combine the preceding equations, as necessary, to obtain $\Delta G°$ values for the following reactions.

(a) $COS(g) + 2\,H_2O(g) \longrightarrow SO_2(g) + CO(g) + 2\,H_2(g)$ $\Delta G° = ?$

(b) $COS(g) + 3\,H_2O(g) \longrightarrow SO_2(g) + CO_2(g) + 3\,H_2(g)$ $\Delta G° = ?$

(c) $COS(g) + H_2O(g) \longrightarrow CO_2(g) + H_2S(g)$ $\Delta G° = ?$

Of reactions (a), (b), and (c), which is spontaneous in the forward direction when reactants and products are present in their standard states?

29. Write an equation for the combustion of one mole of benzene, $C_6H_6(l)$, and use data from Appendix D to determine $\Delta G°$ at 298 K if the products of the combustion are **(a)** $CO_2(g)$ and $H_2O(l)$, and **(b)** $CO_2(g)$ and $H_2O(g)$. Describe how you might determine the *difference* between the values obtained in (a) and (b) without having either to write the combustion equation or to determine $\Delta G°$ values for the combustion reactions.

30. Use molar entropies from Appendix D, together with the following data, to estimate the bond-dissociation energy of the F_2 molecule.

$$F_2(g) \longrightarrow 2\,F(g) \quad \Delta G° = 123.9\ \text{kJ}$$

Compare your result with the value listed in Table 10.3.

31. Assess the feasibility of the reaction

$$N_2H_4(g) + 2\,OF_2(g) \longrightarrow N_2F_4(g) + 2\,H_2O(g)$$

by determining each of the following quantities for this reaction at 25 °C.
(a) ΔS° (The standard molar entropy of $N_2F_4(g)$ is 301.2 J K^{-1}.)
(b) ΔH° (Use data from Table 10.3 and F—O and N—F bond energies of 222 and 301 kJ mol^{-1}, respectively.)
(c) ΔG°

Is the reaction feasible? If so, is it favored at high or low temperatures?

32. Solid ammonium nitrate can decompose to dinitrogen oxide gas and liquid water. What is ΔG° at 298 K? Is the decomposition reaction favored at temperatures above or below 298 K?

The Thermodynamic Equilibrium Constant

33. For one of the following reactions, $K_c K_p = K$. Identify that reaction. For the other two reactions, what is the relationship between K_c, K_p, and K? Explain.
(a) $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$
(b) $HI(g) \rightleftharpoons \frac{1}{2}H_2(g) + \frac{1}{2}I_2(g)$
(c) $NH_4HCO_3(s) \rightleftharpoons NH_3(g) + CO_2(g) + H_2O(l)$

34. $H_2(g)$ can be prepared by passing steam over hot iron: $3\,Fe(s) + 4\,H_2O(g) \rightleftharpoons Fe_3O_4(s) + 4\,H_2(g)$.
(a) Write an expression for the thermodynamic equilibrium constant for this reaction.
(b) Explain why the partial pressure of $H_2(g)$ is independent of the amounts of Fe(s) and $Fe_3O_4(s)$ present.
(c) Can we conclude that the production of $H_2(g)$ from $H_2O(g)$ could be accomplished regardless of the proportions of Fe(s) and $Fe_3O_4(s)$ present? Explain.

35. In the synthesis of gaseous methanol from carbon monoxide gas and hydrogen gas, the following equilibrium concentrations were determined at 483 K: $[CO(g)] = 0.0911$ M, $[H_2O(g)] = 0.0822$ M, and $[CH_3OH(g)] = 0.00892$ M. Calculate the equilibrium constant and Gibbs energy for this reaction.

36. Calculate the equilibrium constant and Gibbs energy for the reaction $CO(g) + 2\,H_2(g) \longrightarrow CH_3OH(g)$ at 483 K by using the data tables from Appendix D. Are the values determined here different from or the same as those in exercise 35? Explain.

Relationships Involving ΔG, ΔG°, Q, and K

37. Use data from Appendix D to determine K_p at 298 K for the reaction $N_2O(g) + \frac{1}{2}O_2(g) \rightleftharpoons 2\,NO(g)$.

38. Use data from Appendix D to establish for the reaction $2\,N_2O_4(g) + O_2(g) \rightleftharpoons 2\,N_2O_5(g)$:
(a) ΔG° at 298 K for the reaction as written;
(b) K_p at 298 K.

39. Use data from Appendix D to determine values at 298 K of ΔG° and K for the following reactions. (*Note:* The equations are not balanced.)
(a) $HCl(g) + O_2(g) \rightleftharpoons H_2O(g) + Cl_2(g)$
(b) $Fe_2O_3(s) + H_2(g) \rightleftharpoons Fe_3O_4(s) + H_2O(g)$
(c) $Ag^+(aq) + SO_4{}^{2-}(aq) \rightleftharpoons Ag_2SO_4(s)$

40. In Example 19-1, we were unable to conclude by inspection whether ΔS° for the reaction $CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$ should be positive or negative. Use data from Appendix D to obtain ΔS° at 298 K.

41. Use thermodynamic data at 298 K to decide in which direction the reaction

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$$

is spontaneous when the partial pressures of SO_2, O_2, and SO_3 are 1.0×10^{-4}, 0.20, and 0.10 atm, respectively.

42. Use thermodynamic data at 298 K to decide in which direction the reaction

$$H_2(g) + Cl_2(g) \rightleftharpoons 2\,HCl(g)$$

is spontaneous when the partial pressures of H_2, Cl_2, and HCl are all 0.5 atm.

43. The standard Gibbs energy change for the reaction

$$CH_3CO_2H(aq) + H_2O(l) \rightleftharpoons CH_3CO_2{}^-(aq) + H_3O^+(aq)$$

is 27.07 kJ mol^{-1} at 298 K. Use this thermodynamic quantity to decide in which direction the reaction is spontaneous when the concentrations of $CH_3CO_2H(aq)$, $CH_3CO_2{}^-(aq)$, and $H_3O^+(aq)$ are 0.10 M, 1.0×10^{-3} M, and 1.0×10^{-3} M, respectively.

44. The standard Gibbs energy change for the reaction

$$NH_3(aq) + H_2O(l) \rightleftharpoons NH_4{}^+(aq) + OH^-(aq)$$

is 29.05 kJ mol^{-1} at 298 K. Use this thermodynamic quantity to decide in which direction the reaction is spontaneous when the concentrations of $NH_3(aq)$, $NH_4{}^+(aq)$, and $OH^-(aq)$ are 0.10 M, 1.0×10^{-3} M, and 1.0×10^{-3} M, respectively.

45. For the reaction $2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g)$ all but one of the following equations is correct. Which is *incorrect*, and why? **(a)** $K = K_p$; **(b)** $\Delta S^\circ = (\Delta G^\circ - \Delta H^\circ)/T$; **(c)** $K_p = e^{-\Delta G^\circ/RT}$; **(d)** $\Delta G = \Delta G^\circ + RT \ln Q$.

46. Why is ΔG° such an important property of a chemical reaction, even though the reaction is generally carried out under *nonstandard* conditions?

47. At 1000 K, an equilibrium mixture in the reaction $CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g)$ contains 0.276 mol H_2, 0.276 mol CO_2, 0.224 mol CO, and 0.224 mol H_2O.
(a) What is K_p at 1000 K?

(b) Calculate ΔG° at 1000 K.
(c) In which direction would a spontaneous reaction occur if the following were brought together at 1000 K: 0.0750 mol CO_2, 0.095 mol H_2, 0.0340 mol CO, and 0.0650 mol H_2O?

48. For the reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$, $K_c = 2.8 \times 10^2$ at 1000 K.
(a) What is ΔG° at 1000 K? [*Hint:* What is K_p?]
(b) If 0.40 mol SO_2, 0.18 mol O_2, and 0.72 mol SO_3 are mixed in a 2.50 L flask at 1000 K, in what direction will a net reaction occur?

49. For the following equilibrium reactions, calculate ΔG° at the indicated temperature. [*Hint:* How is each equilibrium constant related to a thermodynamic equilibrium constant, *K*?]
(a) $H_2(g) + I_2(g) \rightleftharpoons 2\,HI(g) \quad K_c = 50.2$ at 445 °C
(b) $N_2O(g) + \frac{1}{2}O_2(g) \rightleftharpoons 2NO(g)$
$K_c = 1.7 \times 10^{-13}$ at 25 °C
(c) $N_2O_4(g) \rightleftharpoons 2NO_2(g)$
$K_c = 4.61 \times 10^{-3}$ at 25 °C
(d) $2\,Fe^{3+}(aq) + Hg_2^{\,2+}(aq) \rightleftharpoons 2\,Fe^{2+}(aq) + 2\,Hg^{2+}(aq)$
$K_c = 9.14 \times 10^{-6}$ at 25 °C

50. Two equations can be written for the dissolution of $Mg(OH)_2(s)$ in acidic solution.

$$Mg(OH)_2(s) + 2\,H^+(aq) \rightleftharpoons Mg^{2+}(aq) + 2\,H_2O(l) \qquad \Delta G^\circ = -95.5\ kJ\ mol^{-1}$$

$$\frac{1}{2}Mg(OH)_2(s) + H^+(aq) \rightleftharpoons \frac{1}{2}Mg^{2+}(aq) + H_2O(l) \qquad \Delta G^\circ = -47.8\ kJ\ mol^{-1}$$

(a) Explain why these two equations have different ΔG° values.
(b) Will *K* for these two equations be the same or different? Explain.
(c) Will the solubilities of $Mg(OH)_2(s)$ in a buffer solution at pH = 8.5 depend on which of the two equations is used as the basis of the calculation? Explain.

51. At 298 K, $\Delta G_f^\circ[CO(g)] = -137.2$ kJ/mol and $K_p = 6.5 \times 10^{11}$ for the reaction $CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$. Use these data to determine $\Delta G_f^\circ[COCl_2(g)]$, and compare your result with the value in Appendix D.

52. Use thermodynamic data from Appendix D to calculate values of K_{sp} for the following sparingly soluble solutes: **(a)** AgBr; **(b)** $CaSO_4$; **(c)** $Fe(OH)_3$. [*Hint:* Begin by writing solubility equilibrium expressions.]

53. To establish the law of conservation of mass, Lavoisier carefully studied the decomposition of mercury(II) oxide:

$$HgO(s) \longrightarrow Hg(l) + \frac{1}{2}O_2(g)$$

At 25 °C, $\Delta H^\circ = +90.83$ kJ and $\Delta G^\circ = +58.54$ kJ.
(a) Show that the partial pressure of $O_2(g)$ in equilibrium with HgO(s) and Hg(l) at 25 °C is extremely low.
(b) What conditions do you suppose Lavoisier used to obtain significant quantities of oxygen?

54. Currently, CO_2 is being studied as a source of carbon atoms for synthesizing organic compounds. One possible reaction involves the conversion of CO_2 to methanol, CH_3OH.

$$CO_2(g) + 3\,H_2(g) \longrightarrow CH_3OH(g) + H_2O(g)$$

With the aid of data from Appendix D, determine
(a) if this reaction proceeds to any significant extent at 25 °C;
(b) if the production of $CH_3OH(g)$ is favored by raising or lowering the temperature from 25 °C;
(c) K_p for this reaction at 500 K;
(d) the partial pressure of $CH_3OH(g)$ at equilibrium if $CO_2(g)$ and $H_2(g)$, each initially at a partial pressure of 1 atm, react at 500 K.

ΔG° and *K* as Functions of Temperature

55. Use data from Appendix D to establish at 298 K for the reaction:

$$2\,NaHCO_3(s) \longrightarrow Na_2CO_3(s) + H_2O(l) + CO_2(g)$$

(a) ΔS°; **(b)** ΔH°; **(c)** ΔG°; **(d)** K.

56. A possible reaction for converting methanol to ethanol is

$$CO(g) + 2\,H_2(g) + CH_3OH(g) \longrightarrow C_2H_5OH(g) + H_2O(g)$$

(a) Use data from Appendix D to calculate ΔH°, ΔS°, and ΔG° for this reaction at 25 °C.
(b) Is this reaction thermodynamically favored at high or low temperatures? At high or low pressures? Explain.
(c) Estimate K_p for the reaction at 750 K.

57. What must be the temperature if the following reaction has $\Delta G^\circ = -45.5$ kJ, $\Delta H^\circ = -24.8$ kJ, and $\Delta S^\circ = 15.2\ J\ K^{-1}$?

$$Fe_2O_3(s) + 3\,CO(g) \longrightarrow 2\,Fe(s) + 3\,CO_2(g)$$

58. Estimate K_p at 100 °C for the reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$. Use data from Table 19.3 and Figure 19-12.

59. The synthesis of ammonia by the Haber process occurs by the reaction $N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g)$ at 400 °C. Using data from Appendix D and assuming that ΔH° and ΔS° are essentially unchanged in the temperature interval from 25 to 400 °C, estimate K_p at 400 °C.

60. Use data from Appendix D to determine **(a)** ΔH°, ΔS°, and ΔG° at 298 K and **(b)** K_p at 875 K for the water gas shift reaction, used commercially to produce $H_2(g)$: $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$.
[*Hint:* Assume that ΔH° and ΔS° are essentially unchanged in this temperature interval.]

61. In Example 19-10, we used the van't Hoff equation to determine the temperature at which $K_p = 1.0 \times 10^6$ for the reaction $2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g)$. Obtain another estimate of this temperature with data from Appendix D and equations (19.9) and (19.13). Compare your result with that obtained in Example 19-10.

62. The following equilibrium constants have been determined for the reaction $H_2(g) + I_2(g) \rightleftharpoons 2\,HI(g)$: $K_p = 50.0$ at 448 °C and 66.9 at 350 °C. Use these data to estimate $\Delta H°$ for the reaction.

63. For the reaction $N_2O_4(g) \rightleftharpoons 2\,NO_2(g)$, $\Delta H° = +57.2\ \text{kJ mol}^{-1}$ and $K_p = 0.113$ at 298 K.
(a) What is K_p at 0 °C?
(b) At what temperature will $K_p = 1.00$?

64. Use data from Appendix D and the van't Hoff equation (19.15) to estimate a value of K_p at 100 °C for the reaction $2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g)$. [*Hint:* First determine K_p at 25 °C. What is $\Delta H°$ for the reaction?]

65. For the reaction

$$CO(g) + 3\,H_2(g) \rightleftharpoons CH_4(g) + H_2O(g),$$
$$K_p = 2.15 \times 10^{11} \text{ at } 200\ °C$$
$$K_p = 4.56 \times 10^{8} \text{ at } 260\ °C$$

determine $\Delta H°$ by using the van't Hoff equation (19.15) and by using tabulated data in Appendix D. Compare the two results, and comment on how good the assumption is that $\Delta H°$ is essentially independent of temperature in this case.

66. Sodium carbonate, an important chemical used in the production of glass, is made from sodium hydrogen carbonate by the reaction

$$2\,NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + CO_2(g) + H_2O(g)$$

Data for the temperature variation of K_p for this reaction are $K_p = 1.66 \times 10^{-5}$ at 30 °C; 3.90×10^{-4} at 50 °C; 6.27×10^{-3} at 70 °C; and 2.31×10^{-1} at 100 °C.
(a) Plot a graph similar to Figure 19-12, and determine $\Delta H°$ for the reaction.
(b) Calculate the temperature at which the total gas pressure above a mixture of $NaHCO_3(s)$ and $Na_2CO_3(s)$ is 2.00 atm.

Coupled Reactions

67. Titanium is obtained by the reduction of $TiCl_4(l)$, which in turn is produced from the mineral rutile (TiO_2).
(a) With data from Appendix D, determine $\Delta G°$ at 298 K for this reaction.

$$TiO_2(s) + 2\,Cl_2(g) \longrightarrow TiCl_4(l) + O_2(g)$$

(b) Show that the conversion of $TiO_2(s)$ to $TiCl_4(l)$, with reactants and products in their standard states, is spontaneous at 298 K if the reaction in (a) is coupled with the reaction

$$2\,CO(g) + O_2(g) \longrightarrow 2\,CO_2(g)$$

68. Following are some standard Gibbs energies of formation, $\Delta G_f°$, per mole of metal oxide at 1000 K: NiO, −115 kJ; MnO, −280 kJ; TiO_2, −630 kJ. The standard Gibbs energy of formation of CO at 1000 K is −250 kJ per mol CO. Use the method of coupled reactions (page 851) to determine which of these metal oxides can be reduced to the metal by a spontaneous reaction with carbon at 1000 K and with all reactants and products in their standard states.

69. In biochemical reactions the phosphorylation of amino acids is an important step. Consider the following two reactions and determine whether the phosphorylation of arginine with ATP is spontaneous.

$$\text{ATP} + H_2O \longrightarrow \text{ADP} + \text{P} \quad \Delta G°' = -31.5\ \text{kJ mol}^{-1}$$
$$\text{arginine} + \text{P} \longrightarrow \text{phosphorarginine} + H_2O$$
$$\Delta G°' = 33.2\ \text{kJ mol}^{-1}$$

70. The synthesis of glutamine from glutamic acid is given by $\text{Glu}^- + NH_4^+ \longrightarrow \text{Gln} + H_2O$. The Gibbs energy for this reaction at pH = 7 and $T = 310$ K is $\Delta G°' = 14.8\ \text{kJ mol}^{-1}$. Will this reaction be spontaneous if coupled with the hydrolysis of ATP?

$$\text{ATP} + H_2O \longrightarrow \text{ADP} + \text{P}$$
$$\Delta G°' = -31.5\ \text{kJ mol}-1$$

Integrative and Advanced Exercises

71. Use data from Appendix D to estimate **(a)** the normal boiling point of mercury and **(b)** the vapor pressure of mercury at 25 °C.

72. Consider the vaporization of water: $H_2O(l) \longrightarrow H_2O(g)$ at 100 °C, with $H_2O(l)$ in its standard state, but with the partial pressure of $H_2O(g)$ at 2.0 atm. Which of the following statements about this vaporization at 100 °C are true? **(a)** $\Delta G° = 0$, **(b)** $\Delta G = 0$, **(c)** $\Delta G° > 0$, **(d)** $\Delta G > 0$? Explain.

73. At 298 K, 1.00 mol BrCl(g) is introduced into a 10.0 L vessel, and equilibrium is established in the reaction $BrCl(g) \rightleftharpoons \frac{1}{2}Br_2(g) + \frac{1}{2}Cl_2(g)$. Calculate the amounts of each of the three gases present when equilibrium is established. [*Hint:* Use data from Appendix D as necessary.]

74. Use data from Appendix D and other information from this chapter to estimate the temperature at which the dissociation of $I_2(g)$ becomes appreciable [for example, with the $I_2(g)$ 50% dissociated into I(g) at 1 atm total pressure].

75. The following table shows the enthalpies and Gibbs energies of formation of three metal oxides at 25 °C.
(a) Which of these oxides can be most readily decomposed to the free metal and $O_2(g)$?
(b) For the oxide that is most easily decomposed, to what temperature must it be heated to produce $O_2(g)$ at 1.00 atm pressure?

	$\Delta H_f°$, kJ mol^{-1}	$\Delta G_f°$, kJ mol^{-1}
PbO(red)	−219.0	−188.9
Ag_2O	−31.05	−11.20
ZnO	−348.3	−318.3

76. The following data are given for the two solid forms of HgI_2 at 298 K.

	ΔH°_f, kJ mol^{-1}	ΔG°_f, kJ mol^{-1}	S°, J mol^{-1} K^{-1}
HgI_2(red)	−105.4	−101.7	180
HgI_2(yellow)	−102.9	(?)	(?)

Estimate values for the two missing entries. To do this, assume that for the transition $HgI_2(red) \longrightarrow HgI_2(yellow)$, the values of ΔH° and ΔS° at 25 °C have the same values that they do at the equilibrium temperature of 127 °C.

77. Oxides of nitrogen are produced in high-temperature combustion processes. The essential reaction is $N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g)$. At what approximate temperature will an *equimolar* mixture of $N_2(g)$ and $O_2(g)$ be 1.0% converted to NO(g)? [*Hint:* Use data from Appendix D as necessary.]

78. Use the following data, as appropriate, to estimate the molarity of a saturated aqueous solution of $Sr(IO_3)_2$.

	ΔH°_f, kJ mol^{-1}	ΔG°_f, kJ mol^{-1}	S°, J mol^{-1} K^{-1}
$Sr(IO_3)_2(s)$	−1019.2	−855.1	234
$Sr^{2+}(aq)$	−545.8	−599.5	−32.6
$IO_3^-(aq)$	−221.3	−128.0	118.4

79. Use the following data together with other data from the text to determine the temperature at which the equilibrium pressure of water vapor above the two solids in the following reaction is 75 Torr.

$$CuSO_4 \cdot 3\,H_2O(s) \rightleftharpoons CuSO_4 \cdot H_2O(s) + 2\,H_2O(g)$$

	ΔH°_f, kJ mol^{-1}	ΔG°_f, kJ mol^{-1}	S°, J mol^{-1} K^{-1}
$CuSO_4 \cdot 3\,H_2O(s)$	−1684.3	−1400.0	221.3
$CuSO_4 \cdot H_2O(s)$	−1085.8	−918.1	146.0

80. For the dissociation of $CaCO_3(s)$ at 25 °C, $CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$ $\Delta G^\circ = +131$ kJ mol^{-1}. A sample of pure $CaCO_3(s)$ is placed in a flask and connected to an ultrahigh vacuum system capable of reducing the pressure to 10^{-9} mmHg.

(a) Would $CO_2(g)$ produced by the decomposition of $CaCO_3(s)$ at 25 °C be detectable in the vacuum system at 25 °C?

(b) What additional information do you need to determine P_{CO_2} as a function of temperature?

(c) With necessary data from Appendix D, determine the minimum temperature to which $CaCO_3(s)$ would have to be heated for $CO_2(g)$ to become detectable in the vacuum system.

81. Introduced into a 1.50 L flask is 0.100 mol of $PCl_5(g)$; the flask is held at a temperature of 227 °C until equilibrium is established. What is the total pressure of the gases in the flask at this point?

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$$

[*Hint:* Use data from Appendix D and appropriate relationships from this chapter.]

82. From the data given in Exercise 66, estimate a value of ΔS° at 298 K for the reaction

$$2\,NaHCO_3(s) \longrightarrow Na_2CO_3(s) + H_2O(g) + CO_2(g)$$

83. The normal boiling point of cyclohexane, C_6H_{12}, is 80.7 °C. Estimate the temperature at which the vapor pressure of cyclohexane is 100.0 mmHg.

84. The term *thermodynamic stability* refers to the sign of ΔG°_f. If ΔG°_f is negative, the compound is stable with respect to decomposition into its elements. Use the data in Appendix D to determine whether $Ag_2O(s)$ is thermodynamically stable at **(a)** 25 °C and **(b)** 200 °C.

85. At 0 °C, ice has a density of 0.917 g mL^{-1} and an absolute entropy of 37.95 J mol^{-1} K^{-1}. At this temperature, liquid water has a density of 1.000 g mL^{-1} and an absolute entropy of 59.94 J mol^{-1} K^{-1}. The pressure corresponding to these values is 1 bar. Calculate ΔG, ΔG°, ΔS°, and ΔH° for the melting of two moles of ice at its normal melting point.

86. The decomposition of the poisonous gas phosgene is represented by the equation $COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g)$. Values of K_p for this reaction are $K_p = 6.7 \times 10^{-9}$ at 99.8 °C and $K_p = 4.44 \times 10^{-2}$ at 395 °C. At what temperature is $COCl_2$ 15% dissociated when the total gas pressure is maintained at 1.00 atm?

87. Use data from Appendix D to estimate the aqueous solubility, in milligrams per liter, of AgBr(s) at 100 °C.

88. The standard molar entropy of solid hydrazine at its melting point of 1.53 °C is 67.15 J mol^{-1} K^{-1}. The enthalpy of fusion is 12.66 kJ mol^{-1}. For $N_2H_4(l)$ in the interval from 1.53 °C to 298.15 K, the molar heat capacity at constant pressure is given by the expression $C_p = 97.78 + 0.0586(T - 280)$. Determine the standard molar entropy of $N_2H_4(l)$ at 298.15 K. [*Hint:* The heat absorbed to produce an infinitesimal change in the temperature of a substance is $dq_{rev} = C_p\,dT$.]

89. Use the following data to estimate the standard molar entropy of gaseous benzene at 298.15 K; that is, $S^\circ[C_6H_6(g, 1\ atm)]$. For C_6H_6 (s, 1 atm) at its melting point of 5.53 °C, S° is 128.82 J mol^{-1} K^{-1}. The enthalpy of fusion is 9.866 kJ mol^{-1}. From the melting point to 298.15 K, the average heat capacity of liquid benzene is 134.0 J K^{-1} mol^{-1}. The enthalpy of vaporization of $C_6H_6(l)$ at 298.15 K is 33.85 kJ mol^{-1}, and in the vaporization, $C_6H_6(g)$ is produced at a pressure of 95.13 Torr. Imagine that this vapor could be compressed to 1 atm pressure without condensing and while behaving as an ideal gas. Calculate $S^\circ[C_6H_6(g, 1\ atm)]$. [*Hint:* Refer to Exercise 88, and note the following: For infinitesimal quantities, $dS = dq/dT$; for the compression of an ideal gas, $dq = -dw$; and for pressure–volume work, $dw = -P\,dV$.]

90. On page 822 the terms *states* and *microstates* were introduced. Consider a system that has four states (i.e., energy levels), with energy $\varepsilon = 0, 1, 2$, and 3 energy units, and three particles labeled A, B, and C. The total energy of the system, in energy units, is 3. How many microstates can be generated?

91. In Figure 19-7, page 830, the temperature dependence of the standard molar entropy for chloroform is plotted. **(a)** Explain why the slope for the standard molar entropy of the solid is greater than the slope for the standard molar entropy of the liquid, which is greater than the slope for the standard molar entropy of the gas. **(b)** Explain why the change in the standard molar entropy from solid to liquid is smaller than that for the liquid to gas.

92. The following data are from a laboratory experiment that examines the relationship between solubility and thermodynamics. In this experiment $KNO_3(s)$ is placed in a test tube containing some water. The solution is heated until all the $KNO_3(s)$ is dissolved and then allowed to cool. The temperature at which crystals appear is then measured. From this experiment we can determine the equilibrium constant, Gibbs energy, enthalpy, and entropy for the reaction. Use the following data to calculate ΔG, ΔH, and ΔS for the dissolution of $KNO_3(s)$. (Assume the initial mass of $KNO_3(s)$ was 20.2 g.)

Total Volume, mL	Temperature Crystals Formed, K
25.0	340
29.2	329
33.4	320
37.6	313
41.8	310
46.0	306
51.0	303

Data reported by J. O. Schreck, *J. Chem. Educ.*, **73**, 426 (1996).

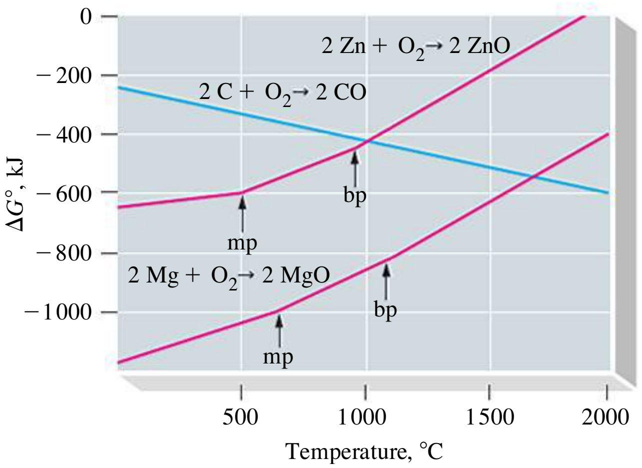
Feature Problems

93. A tabulation of more precise thermodynamic data than are presented in Appendix D lists the following values for $H_2O(l)$ and $H_2O(g)$ at 298.15 K, at a standard state pressure of 1 bar.

	ΔH_f°, $kJ\ mol^{-1}$	ΔG_f°, $kJ\ mol^{-1}$	S°, $J\ mol^{-1}\ K^{-1}$
$H_2O(l)$	−285.830	−237.129	69.91
$H_2O(g)$	−241.818	−228.572	188.825

(a) Use these data to determine, in two different ways, ΔG° at 298.15 K for the vaporization: $H_2O(l, 1\ bar) \rightleftharpoons H_2O(g, 1\ bar)$. The value you obtain will differ slightly from that on page 838, because here, the standard state pressure is 1 bar, and there, it is 1 atm.
(b) Use the result of part (a) to obtain the value of K for this vaporization and, hence, the vapor pressure of water at 298.15 K.
(c) The vapor pressure in part (b) is in the unit bar. Convert the pressure to millimeters of mercury.
(d) Start with the value $\Delta G^\circ = 8.590$ kJ, given on page 838 and calculate the vapor pressure of water at 298.15 K in a fashion similar to that in parts (b) and (c). In this way, demonstrate that the results obtained in a thermodynamic calculation do not depend on the convention we choose for the standard state pressure, as long as we use standard state thermodynamic data consistent with that choice.

94. The graph shows how ΔG° varies with temperature for three different oxidation reactions: the oxidations of C(graphite), Zn, and Mg to CO, ZnO, and MgO, respectively. Such graphs as these can be used to show the temperatures at which carbon is an effective reducing agent to reduce metal oxides to the free metals. As a result, such graphs are important to metallurgists. Use these graphs to answer the following questions.
(a) Why can Mg be used to reduce ZnO to Zn at all temperatures, but Zn cannot be used to reduce MgO to Mg at any temperature?
(b) Why can C be used to reduce ZnO to Zn at some temperatures but not at others? At what temperatures can carbon be used to reduce zinc oxide?
(c) Is it possible to produce Zn from ZnO by its direct decomposition without requiring a coupled reaction? If so, at what approximate temperatures might this occur?
(d) Is it possible to decompose CO to C and O_2 in a spontaneous reaction? Explain.



▲ ΔG° for three reactions as a function of temperature. The reactions are indicated by the equations written above the graphs. The points noted by arrows are the melting points (mp) and boiling points (bp) of zinc and magnesium.

(e) To the set of graphs, add straight lines representing the reactions

$$C(graphite) + O_2(g) \longrightarrow CO_2(g)$$
$$2\,CO(g) + O_2(g) \longrightarrow 2\,CO_2(g)$$

given that the three lines representing the formation of oxides of carbon intersect at about 800 °C. [*Hint:* At what other temperature can you relate ΔG° and temperature?]

The slopes of the three lines described above differ sharply. Explain why this is so—that is, explain the slope of each line in terms of principles governing Gibbs energy change.
(f) The graphs for the formation of oxides of other metals are similar to the ones shown for Zn and Mg; that is, they all have positive slopes. Explain why carbon is such a good reducing agent for the reduction of metal oxides.

95. In a heat engine, heat (q_h) is absorbed by a working substance (such as water) at a high temperature (T_h). Part of this heat is converted to work (w), and the rest (q_l) is released to the surroundings at the lower temperature (T_l). The *efficiency* of a heat engine is the ratio w/q_h. The second law of thermodynamics establishes the following equation for the maximum efficiency of a heat engine, expressed on a percentage basis.

$$\text{efficiency} = \frac{w}{q_h} \times 100\% = \frac{T_h - T_l}{T_h} \times 100\%$$

In a particular electric power plant, the steam leaving a steam turbine is condensed to liquid water at 41 °C(T_l) and the water is returned to the boiler to be regenerated as steam. If the system operates at 36% efficiency,
(a) What is the minimum temperature of the steam [$H_2O(g)$] used in the plant?
(b) Why is the actual steam temperature probably higher than that calculated in part (a)?
(c) Assume that at T_h the $H_2O(g)$ is in equilibrium with $H_2O(l)$. Estimate the steam pressure at the temperature calculated in part (a).
(d) Is it possible to devise a heat engine with greater than 100 percent efficiency? With 100 percent efficiency? Explain.

96. The Gibbs energy available from the complete combustion of 1 mol of glucose to carbon dioxide and water is

$$C_6H_{12}O_6(aq) + 6\,O_2(g) \longrightarrow 6\,CO_2(g) + 6\,H_2O(l)$$
$$\Delta G^\circ = -2870\ \text{kJ mol}^{-1}$$

(a) Under biological standard conditions, compute the maximum number of moles of ATP that could form from ADP and phosphate if all the energy of combustion of 1 mol of glucose could be utilized.
(b) The actual number of moles of ATP formed by a cell under aerobic conditions (that is, in the presence of oxygen) is about 38. Calculate the efficiency of energy conversion of the cell.
(c) Consider these typical physiological conditions.

$$P_{CO_2} = 0.050\ \text{bar};\ P_{O_2} = 0.132\ \text{bar};$$
$$[\text{glucose}] = 1.0\ \text{mg/mL};\ \text{pH} = 7.0;$$
$$[\text{ATP}] = [\text{ADP}] = [P_i] = 0.00010\ \text{M}.$$

Calculate ΔG for the conversion of 1 mol ADP to ATP and ΔG for the oxidation of 1 mol glucose under these conditions.
(d) Calculate the efficiency of energy conversion for the cell under the conditions given in part (c). Compare this efficiency with that of a diesel engine that attains 78% of the theoretical efficiency operating with $T_h = 1923$ K and $T_l = 873$ K. Suggest a reason for your result. [*Hint:* See Feature Problem 95.]

97. The entropy of materials at $T = 0$ K should be zero; however, for some substances, such as CO and H_2O, this is not true. The difference between the measured value and expected value of zero is known as residual entropy. **(a)** Calculate the residual entropy for one mole of CO by using the Boltzmann equation for entropy. **(b)** Calculate the residual entropy for one mole of H_2O in the same manner.

Self-Assessment Exercises

98. In your own words, define the following symbols: **(a)** ΔS_{univ}; **(b)** ΔG_f°; **(c)** K.

99. Briefly describe each of the following ideas, methods, or phenomena: **(a)** absolute molar entropy; **(b)** coupled reactions; **(c)** Trouton's rule; **(d)** evaluation of an equilibrium constant from tabulated thermodynamic data.

100. Explain the important distinctions between each of the following pairs: **(a)** spontaneous and nonspontaneous processes; **(b)** the second and third laws of thermodynamics; **(c)** ΔG and ΔG°.

101. For a process to occur spontaneously, **(a)** the entropy of the system must increase; **(b)** the entropy of the surroundings must increase; **(c)** both the entropy of the system and the entropy of the surroundings must increase; **(d)** the net change in entropy of the system and surroundings considered together must be a positive quantity; **(e)** the entropy of the universe must remain constant.

102. The Gibbs energy change of a reaction can be used to assess **(a)** how much heat is absorbed from the surroundings; **(b)** how much work the system does on the surroundings; **(c)** the net direction in which the reaction occurs to reach equilibrium; **(d)** the proportion of the heat evolved in an exothermic reaction that can be converted to various forms of work.

103. The reaction, $2\,Cl_2O(g) \longrightarrow 2\,Cl_2(g) + O_2(g)\ \Delta H = -161$ kJ, is expected to be **(a)** spontaneous at all temperatures; **(b)** spontaneous at low temperatures, but nonspontaneous at high temperatures; **(c)** nonspontaneous at all temperatures; **(d)** spontaneous at high temperatures only.

104. If $\Delta G^\circ = 0$ for a reaction, it must also be true that **(a)** $K = 0$; **(b)** $K = 1$; **(c)** $\Delta H^\circ = 0$; **(d)** $\Delta S^\circ = 0$; **(e)** the equilibrium activities of the reactants and products do not depend on the initial conditions.

105. Two correct statements about the reversible reaction $N_2(g) + O_2(g) \rightleftharpoons 2\,NO(g)$ are **(a)** $K = K_p$; **(b)** the equilibrium amount of NO increases with an increased total gas pressure; **(c)** the equilibrium amount of NO increases if an equilibrium mixture is transferred from a 10.0 L container to a 20.0 L container; **(d)** $K = K_c$; **(e)** the composition of an equilibrium mixture of the gases is independent of the temperature.

106. Suppose a graph similar to (Figure 19-9) were drawn for the process $I_2(s) \longrightarrow I_2(l)$ at 1 atm.
(a) Refer to Figure 12-27 and determine the temperature at which the two lines would intersect.
(b) What would be the value of $\Delta G°$ at this temperature? Explain.

107. *Without performing detailed calculations,* indicate whether any of the following reactions would occur to a measurable extent at 298 K.
(a) Conversion of dioxygen to ozone:

$$3\,O_2(g) \longrightarrow 2\,O_3(g)$$

(b) Dissociation of N_2O_4 to NO_2:

$$N_2O_4(g) \longrightarrow 2\,NO_2(g)$$

(c) Formation of BrCl:

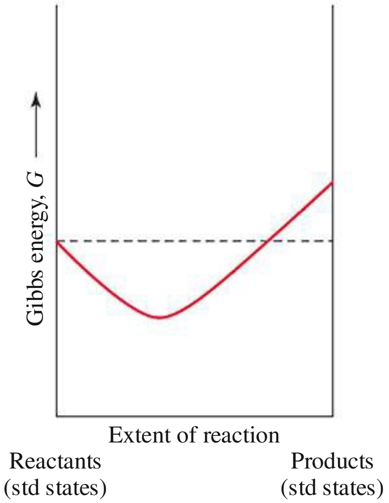
$$Br_2(l) + Cl_2(g) \longrightarrow 2\,BrCl(g)$$

108. Explain briefly why
(a) the change in entropy in a system is not always a suitable criterion for spontaneous change;
(b) $\Delta G°$ is so important in dealing with the question of spontaneous change, even though the conditions employed in a reaction are very often nonstandard.

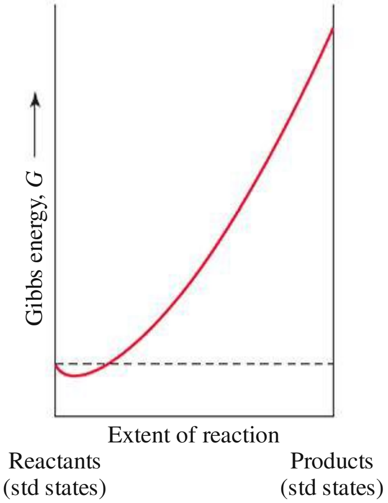
109. A handbook lists the following standard enthalpies of formation at 298 K for cyclopentane, C_5H_{10}: $\Delta H^\circ_f[C_5H_{10}(l)] = -105.9$ kJ/mol and $\Delta H^\circ_f[C_5H_{10}(g)] = -77.2$ kJ/mol.
(a) Estimate the normal boiling point of cyclopentane.
(b) Estimate $\Delta G°$ for the vaporization of cyclopentane at 298 K.
(c) Comment on the significance of the sign of $\Delta G°$ at 298 K.

110. Consider the reaction $NH_4NO_3(s) \longrightarrow N_2O(g) + 2\,H_2O(l)$ at 298 K.
(a) Is the forward reaction endothermic or exothermic?
(b) What is the value of $\Delta G°$ at 298 K?
(c) What is the value of K at 298 K?
(d) Does the reaction tend to occur spontaneously at temperatures above 298 K, below 298 K, both, or neither?

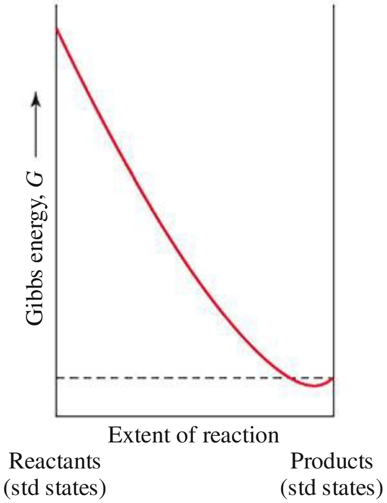
111. Which of the following diagrams represents an equilibrium constant closest to 1?



(a)



(b)



(c)

112. At room temperature and normal atmospheric pressure, is the entropy of the universe positive, negative, or zero for the transition of carbon dioxide solid to liquid?

A conventional gasoline-powered automobile is only about 25% efficient in converting chemical energy into kinetic energy (energy of motion). An electric-powered auto is about three times as efficient. Unfortunately, when automotive technology was first being developed, devices for converting chemical energy to electrical energy did not perform at their intrinsic efficiencies. This fact, together with the availability of high-quality gasoline at a low cost, resulted in the preeminence of the internal combustion automobile. Now, with concern about long-term energy supplies and environmental pollution, there is a renewed interest in electric-powered buses and automobiles.

In this chapter, we will see how chemical reactions can be used to produce electricity and how electricity can be used to cause chemical reactions. The practical applications of electrochemistry are countless, ranging from batteries and fuel cells as electric power sources to the manufacture of key chemicals, the refining of metals, and methods for controlling corrosion. Also important, however, are the theoretical implications. Because electricity involves a flow of electric charge, a study of the relationship between chemistry and electricity gives us additional insight into reactions in which electrons are transferred—*oxidation–reduction reactions*.

20-1 Electrode Potentials and Their Measurement

The criteria for spontaneous change developed in Chapter 19 apply to reactions of all types—precipitation, acid–base, and oxidation–reduction (redox). We can devise an additional useful criterion for redox reactions, however.

Figure 20-1 shows that a redox reaction occurs between Cu(s) and $Ag^+(aq)$, but not between Cu(s) and $Zn^{2+}(aq)$. Specifically, we see that silver ions are reduced to silver atoms on a copper surface, whereas zinc ions are *not* reduced to zinc atoms on a copper surface. We can say that Ag^+ is more readily reduced than is Zn^{2+}. In this section, we will introduce the *electrode potential*, a property related to these reduction tendencies.

▶ The term *electrode* is sometimes used for the entire half-cell assembly.

When used in electrochemical studies, a strip of metal, M, is called an **electrode**. An electrode immersed in a solution containing ions of the same metal, M^{n+}, is called a **half-cell**. Two kinds of interactions are possible between metal atoms on the electrode and metal ions in solution (Fig. 20-2):

1. A metal ion M^{n+} from solution may collide with the electrode, gain n electrons from it, and be converted to a metal atom M. *The ion is reduced.*
2. A metal atom M on the surface may lose n electrons to the electrode and enter the solution as the ion M^{n+}. *The metal atom is oxidized.*

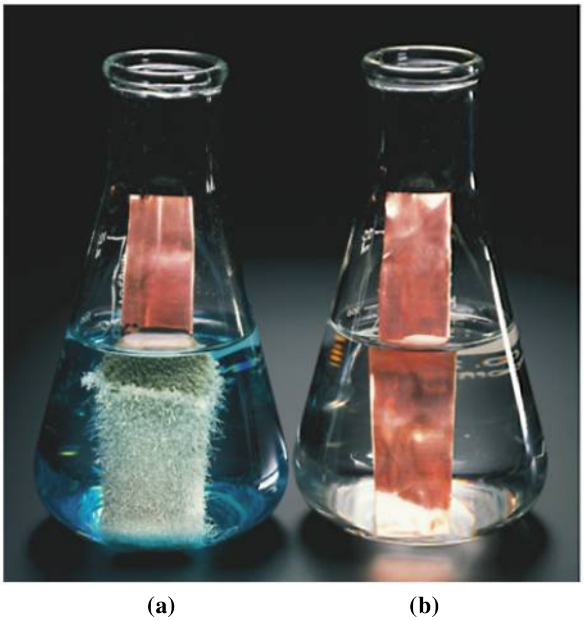
An equilibrium is quickly established between the metal and the solution, which can be represented as

$$M(s) \underset{\text{reduction}}{\overset{\text{oxidation}}{\rightleftharpoons}} M^{n+}(aq) + ne^- \qquad \textbf{(20.1)}$$

KEEP IN MIND

that although $M^{n+}(aq)$ and ne^- appear together on the right-hand side of this expression, only the ion M^{n+} enters the solution. The electrons remain on the electrode, M(s). Free electrons are never found in an aqueous solution.

However, any changes produced at the electrode or in the solution as a consequence of this equilibrium are too slight to measure. Instead, measurements must be based on a combination of *two different* half-cells. Specifically, we must measure the tendency for electrons to flow from the electrode of one half-cell to the electrode of the other. Electrodes are classified according to whether oxidation or reduction takes place there. If oxidation takes place, the electrode is called the **anode**. If reduction takes place, the electrode is called the **cathode**.

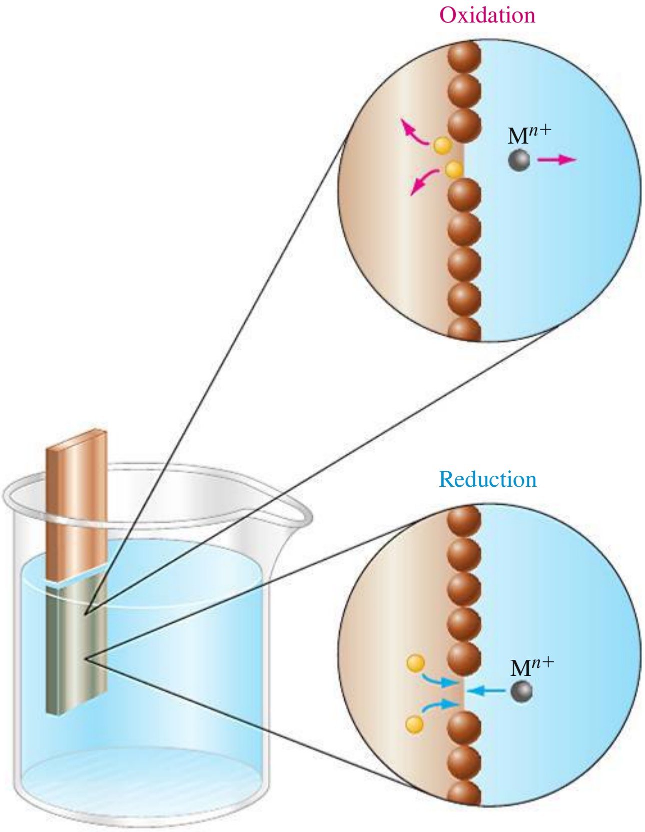


▶ FIGURE 20-1
Behavior of $Ag^+(aq)$ and $Zn^+(aq)$ in the presence of copper
(a) Copper metal displaces silver ions from colorless $AgNO_3(aq)$ as a deposit of silver metal; the copper enters the solution as blue $Cu^{2+}(aq)$.

$$Cu(s) + 2\,Ag^+(aq) \longrightarrow Cu^{2+}(aq) + 2\,Ag(s)$$

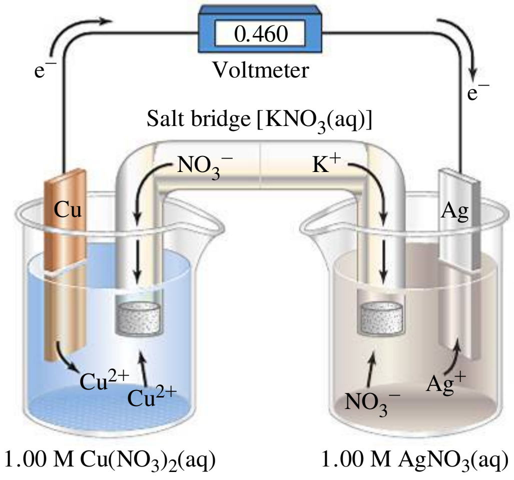
(b) Cu(s) *does not* displace colorless Zn^{2+} from $Zn(NO_3)_2(aq)$.

$$Cu(s) + Zn^{2+}(aq) \longrightarrow \text{no reaction}$$



◀ FIGURE 20-2
An electrochemical half-cell
The half-cell consists of a metal electrode, M, partially immersed in an aqueous solution of its ions, M^{n+}. (The anions required to maintain electrical neutrality in the solution are not shown.) The situation illustrated here is limited to metals that do not react with water.

Figure 20-3 depicts a combination of two half-cells, one with a Cu electrode in contact with $Cu^{2+}(aq)$, and the other with an Ag electrode in contact with $Ag^{+}(aq)$. The two electrodes are joined by wires to an electric meter—here, a *voltmeter*. To complete the electric circuit, the two solutions must also be connected electrically. However, because charge is carried through solutions by the migration of *ions*, a wire cannot be used for this connection. The solutions



▲ FIGURE 20-3
Measurement of the electromotive force of an electrochemical cell
An electrochemical cell consists of two half-cells with electrodes joined by a wire and solutions joined by a salt bridge. (The ends of the salt bridge are plugged with a porous material that allows ions to migrate but prevents the bulk flow of liquid.) Electrons flow from the Cu electrode, the anode, where oxidation occurs to the Ag electrode, the cathode, where reduction occurs. For precise measurements, the amount of electric current drawn from the cell must be kept very small by means of either a specially designed voltmeter or a device called a potentiometer.

◀ Anions migrate toward the anode, and cations toward the cathode.

must either be in direct contact through a porous barrier or joined by a third solution in a U-tube called a **salt bridge**. The properly connected combination of two half-cells is called an **electrochemical cell**.

Now, we will consider the changes that occur in the electrochemical cell in Figure 20-3. As the arrows suggest, Cu atoms release electrons at the anode and enter the $Cu(NO_3)_2(aq)$ as Cu^{2+} ions. Electrons lost by the Cu atoms pass through the wires and the voltmeter to the cathode, where they are gained by Ag^+ ions from the $AgNO_3(aq)$, producing a deposit of metallic silver. Simultaneously, anions (NO_3^-) from the salt bridge migrate into the copper half-cell and neutralize the positive charge of the excess Cu^{2+} ions; cations (K^+) migrate into the silver half-cell and neutralize the negative charge of the excess NO_3^- ions. Each copper atom loses two electrons to produce Cu^{2+}; each Ag^+ ion requires one electron to produce Ag(s); consequently, two silver atoms are produced for every Cu^{2+} ion formed. The overall reaction that occurs as the electrochemical cell spontaneously produces electric current is

$$\begin{array}{lrcl} \textit{Oxidation:} & Cu(s) & \longrightarrow & Cu^{2+}(aq) + 2\,e^- \\ \textit{Reduction:} & 2\{Ag^+(aq) + e^- & \longrightarrow & Ag(s)\} \\ \hline \textit{Overall:} & Cu(s) + 2\,Ag^+(aq) & \longrightarrow & Cu^{2+}(aq) + 2\,Ag(s) \end{array} \qquad \textbf{(20.2)}$$

KEEP IN MIND

that the overall reaction occurring in the electrochemical cell is identical to what happens in the direct addition of Cu(s) to $Ag^+(aq)$ pictured in Figure 20-1(a).

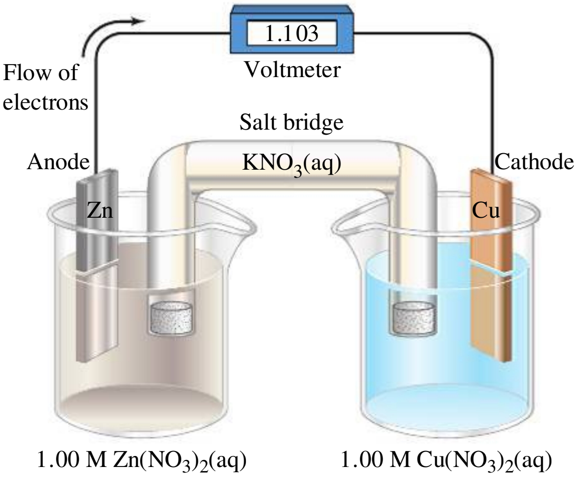
The reading on the voltmeter (0.460 V) is significant. It is the **cell voltage**, or the *potential difference* between the two half-cells. The unit of cell voltage, **volt (V)**, is the energy per unit charge. Thus, a potential difference of one volt signifies an energy of one joule for every coulomb of charge passing through an electric circuit: 1 V = 1 J/C. We can think of a voltage, or potential difference, as the driving force for electrons; the greater the voltage, the greater the driving force. The flow of water from a higher to a lower level is analogous to this situation. The greater the difference in water levels, the greater the force behind the flow of water. Cell voltage is also called **electromotive force (emf)**, or **cell potential**, and represented by the symbol E_{cell}.

▶ Such formulations as $Zn(s)/Zn^{2+}(aq)$ are called *couples* and are often used as abbreviations for half-cells.

Now let's return to the question raised by Figure 20-1: Why does copper *not* displace Zn^{2+} from solution? In an electrochemical cell consisting of a $Zn(s)/Zn^{2+}(aq)$ half-cell and a $Cu^{2+}(aq)/Cu(s)$ half-cell, electrons flow *from the Zn to the Cu*. The spontaneous reaction in the electrochemical cell in Figure 20-4 is

$$\begin{array}{lrcl} \textit{Oxidation:} & Zn(s) & \longrightarrow & Zn^{2+}(aq) + 2\,e^- \\ \textit{Reduction:} & Cu^{2+}(aq) + 2\,e^- & \longrightarrow & Cu(s) \\ \hline \textit{Overall:} & Zn(s) + Cu^{2+}(aq) & \longrightarrow & Zn^{2+}(aq) + Cu(s) \end{array} \qquad \textbf{(20.3)}$$

Because reaction (20.3) is a spontaneous reaction, the displacement of $Zn^{2+}(aq)$ by Cu(s)—the *reverse* of reaction (20.3)—does *not* occur spontaneously. This is the observation made in Figure 20-1. In Section 20-3, we will discuss how to predict the direction of spontaneous change for oxidation–reduction reactions:



▶ FIGURE 20-4
The reaction $Zn(s) + Cu^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Cu(s)$ in an electrochemical cell

Cell Diagrams and Terminology

Drawing sketches of electrochemical cells, as in Figures 20-3 and 20-4, is helpful, but more often a simpler representation is used. A **cell diagram** shows the components of an electrochemical cell in a symbolic way. We will use the following, generally accepted conventions in writing cell diagrams.

- The anode, the electrode at which *oxidation* occurs, is placed at the *left* side of the diagram.
- The cathode, the electrode at which *reduction* occurs, is placed at the *right* side of the diagram.
- A boundary between different phases (for example, an electrode and a solution) is represented by a *single vertical line* (|).
- The boundary between half-cell compartments, commonly a salt bridge, is represented by a *double vertical line* (‖). Species in aqueous solution are placed on either side of the double vertical line. Different species within the same solution are separated from each other by a comma. Although IUPAC recommends the use of double dashed vertical lines to represent the salt bridge, the recommendation has not yet been universally adopted by chemists. In this text, we will continue to use the double vertical line (‖) for a salt bridge.

◀ Several memory devices have been proposed for the oxidation/anode and reduction/cathode relationships. Perhaps the simplest is that in the oxidation/anode relationship, both terms begin with a vowel: *o*/*a*; in the reduction/cathode relationship, both begin with a consonant: *r*/*c*.

The cell diagram corresponding to both Figure 20-4 and reaction (20.3) is customarily written as

$$\text{anode} \longrightarrow \underset{\substack{\text{Half-cell}\\\text{(oxidation)}}}{\mathrm{Zn(s)}|\mathrm{Zn^{2+}(aq)}} \quad \underset{\substack{\text{Salt}\\\text{bridge}}}{\|} \quad \underset{\substack{\text{Half-cell}\\\text{(reduction)}}}{\mathrm{Cu^{2+}(aq)}|\mathrm{Cu(s)}} \longleftarrow \text{cathode} \qquad \underset{\text{Cell voltage}}{E_{\text{cell}} = 1.103\ \mathrm{V}} \tag{20.4}$$

KEEP IN MIND

that the spectator ions are not shown in a cell diagram, but they are present. They pass through the salt bridge to maintain electrical neutrality.

The electrochemical cells of Figures 20-3 and 20-4 produce electricity as a result of spontaneous chemical reactions; as such, they are called **voltaic**, or **galvanic**, **cells**. In Section 20-7 we will consider *electrolytic cells*—electrochemical cells in which electricity is used to accomplish a nonspontaneous chemical change.

EXAMPLE 20-1 Representing a Redox Reaction by Means of a Cell Diagram

Aluminum metal displaces zinc(II) ion from aqueous solution.

(a) Write oxidation and reduction half-equations and an overall equation for this redox reaction.

(b) Write a cell diagram for a voltaic cell in which this reaction occurs.

Analyze

The term *displaces* means that aluminum goes into solution as $\mathrm{Al^{3+}(aq)}$, forcing $\mathrm{Zn^{2+}(aq)}$ out of solution as zinc metal. Al is oxidized to $\mathrm{Al^{3+}}$, and $\mathrm{Zn^{2+}}$ is reduced to Zn. In combining the half-equations to produce the overall equation, we must take care to ensure that the *number of electrons involved in reduction equals the number involved in oxidation.* (This is the half-reaction method of balancing redox equations discussed in Section 5-5.) The cell diagram is written with the reduction half-equation as the right-hand electrode.

Solve

(a) The two half equations are

$$\begin{aligned} &\textit{Oxidation:} && \mathrm{Al(s)} \longrightarrow \mathrm{Al^{3+}(aq)} + 3\,e^- \\ &\textit{Reduction:} && \mathrm{Zn^{2+}(aq)} + 2\,e^- \longrightarrow \mathrm{Zn(s)} \end{aligned}$$

On inspecting these half-equations, we see that the number of electrons involved in oxidation and reduction are different. In writing the overall equation, the coefficients must be adjusted so that equal numbers of electrons are involved in oxidation and in reduction.

$$\begin{aligned} &\textit{Oxidation:} && 2\,\{\mathrm{Al(s)} \longrightarrow \mathrm{Al^{3+}(aq)} + 3\,e^-\} \\ &\textit{Reduction:} && \underline{3\,\{\mathrm{Zn^{2+}(aq)} + 2\,e^- \longrightarrow \mathrm{Zn(s)}\}} \\ &\textit{Overall:} && 2\,\mathrm{Al(s)} + 3\,\mathrm{Zn^{2+}(aq)} \longrightarrow 2\,\mathrm{Al^{3+}(aq)} + 3\,\mathrm{Zn(s)} \end{aligned}$$

(continued)

(b) Al(s) is oxidized to $Al^{3+}(aq)$ in the anode half-cell (written on the left of the cell diagram), and $Zn^{2+}(aq)$ is reduced to Zn(s) in the cathode half-cell (written on the right of the cell diagram).

$$Al(s)|Al^{3+}(aq)||Zn^{2+}(aq)|Zn(s)$$

Assess

Whenever balancing redox equations, it is important to ensure that the number of electrons in the oxidation step equals the number of electrons in the reduction step. This is achieved by multiplying the entire half-reaction(s) by the appropriate factor(s).

PRACTICE EXAMPLE A: Write the overall equation for the redox reaction that occurs in the voltaic cell $Sc(s)|Sc^{3+}(aq)||Ag^{+}(aq)|Ag(s)$.

PRACTICE EXAMPLE B: Draw a voltaic cell in which silver ion is displaced from solution by aluminum metal. Label the cathode, the anode, and other features of the cell. Show the direction of flow of electrons. Also, indicate the direction of flow of cations and anions from a $KNO_3(aq)$ salt bridge. Write an equation for the half-reaction occurring at each electrode, write a balanced equation for the overall cell reaction, and write a cell diagram.

EXAMPLE 20-2 Deducing the Balanced Redox Reaction from a Cell Diagram

The cell diagram for an electrochemical cell is written as

$$Ni(s)|NiCl_2(aq)||Ce(ClO_4)_4(aq), Ce(ClO_4)_3(aq)|Pt(s)$$

Write the equations for the half-reactions that occur at the electrodes. Balance the overall cell reaction.

Analyze

When inspecting a cell diagram, we first need to identify the species involved in oxidation and in reduction. Then we can write balanced half-cell equations. Finally, we can combine the half-cell equations to give the overall cell reaction. The new part to this example is the Ce^{4+}/Ce^{3+} couple in the presence of the inert platinum electrode at which the reduction takes place. Again, when balancing redox equations, it is important to ensure that the number of electrons in the oxidation step equals the number of electrons in the reduction step.

Solve

The cerium reduction reaction is

$$Ce^{4+}(aq) + e^{-} \longrightarrow Ce^{3+}(aq)$$

The nickel oxidation reaction is

$$Ni(s) \longrightarrow Ni^{2+}(aq) + 2\,e^{-}$$

In these half-equations the number of electrons involved in oxidation and reduction are different. In writing the overall equation, the coefficients must be adjusted so that equal numbers of electrons are involved in oxidation and in reduction.

$$\begin{array}{ll} \textit{Oxidation:} & Ni(s) \longrightarrow Ni^{2+}(aq) + 2\,e^{-} \\ \textit{Reduction:} & 2\{Ce^{4+}(aq) + e^{-} \longrightarrow Ce^{3+}(aq)\} \\ \hline \textit{Overall:} & Ni(s) + 2\,Ce^{4+}(aq) \longrightarrow Ni^{2+}(aq) + 2\,Ce^{3+}(aq) \end{array}$$

Assess

We can see the importance of balancing each half-equation with respect to charge and mass.

PRACTICE EXAMPLE A: The cell diagram for an electrochemical cell is written as

$$Sn(s)|SnCl_2(aq)||AgNO_3(aq)|Ag(s)$$

Write the equations for the half-reactions that occur at the electrodes. Balance the overall cell reaction.

PRACTICE EXAMPLE B: The cell diagram for an electrochemical cell is written as

$$In(s)|In(ClO_4)_3(aq)||CdCl_2(aq)|Cd(s)$$

Write the equations for the half-reactions that occur at the electrodes. Balance the overall cell reaction.

20-1 CONCEPT ASSESSMENT

Add appropriate arrows to Figure 20-4 to show the direction of migration of ions through the electrochemical cell.

20-2 Standard Electrode Potentials

Cell voltages—*potential differences* between electrodes—are among the most precise scientific measurements possible. Potentials of individual electrodes, however, cannot be precisely established. If we could make such measurements, cell voltages could be obtained just by subtracting one electrode potential from another. The same result can be achieved by *arbitrarily* choosing a particular half-cell that is assigned an electrode potential of *zero*. Other half-cells can then be compared with this reference. The commonly accepted reference is the standard hydrogen electrode.

◀ This method is comparable to establishing standard enthalpies or Gibbs energies of formation on the basis of an arbitrary zero value.

The **standard hydrogen electrode (SHE)** is depicted in Figure 20-5. The SHE involves equilibrium established on the surface of an inert metal (such as platinum) between H_3O^+ ions from a solution in which they are at unit activity (that is, $a_{H_3O^+} = 1$) and H_2molecules from the gaseous state at a pressure of 1 bar. The equilibrium reaction produces a particular potential on the metal surface, but this potential is arbitrarily taken to be *zero*.

$$2\,H^+(a = 1) + 2\,e^- \overset{\text{on Pt}}{\rightleftharpoons} H_2(g, 1\text{ bar}) \qquad E^\circ = 0\text{ volt (V)} \tag{20.5}$$

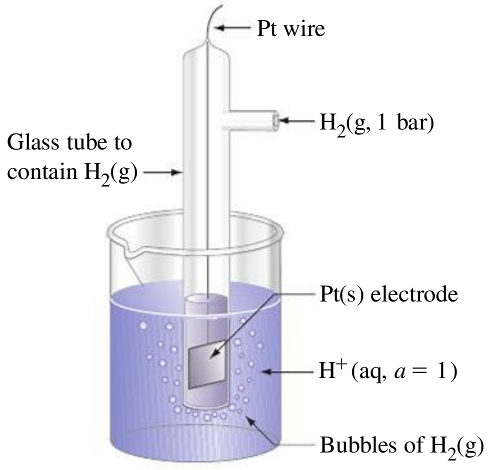
The diagram for this half-cell is

$$Pt|H_2(g, 1\text{ bar})|H^+(a = 1)$$

The two vertical lines signify that three phases are present: solid platinum, gaseous hydrogen, and aqueous hydrogen ion. For simplicity, we will usually write H^+ for H_3O^+, assume that unit activity $(a = 1)$ exists at roughly $[H^+] = 1$ M, and replace a pressure of 1 bar by 1 atm.

◀ In this chapter, we shall use the units bar and atm interchangeably. The reason is that, although the current standard pressure is defined as 1 bar, the most extensive and authoritative tabulations of E° values are based on the old standard of 1 atm. Fortunately, the difference between 1 bar and 1 atm is small and so too are the differences between E° values based on the old and new standards.

By international agreement, a **standard electrode potential, E°**, measures the tendency for a *reduction* process to occur at an electrode. In all cases, the



▲ FIGURE 20-5
The standard hydrogen electrode (SHE)
Because hydrogen is a gas at room temperature, electrodes cannot be constructed from it. The standard hydrogen electrode consists of a piece of platinum dipped into a solution containing 1 M H^+(aq) with a stream of hydrogen passing over its surface. The platinum does not react but provides a surface for the reduction of $H_3O(aq)^+$ to $H_2(g)$ as well as the reverse oxidation half-reaction.

ionic species are present in aqueous solution at unit activity (approximately 1 M), and gases are at 1 bar pressure (approximately 1 atm). Where no metallic substance is indicated, the potential is established on an inert metallic electrode, such as platinum.

To emphasize that $E°$ refers to a reduction, we will write a reduction couple as a subscript to $E°$, as shown in half-reaction (20.6). The substance being reduced is written on the left of the slash sign (/), and the chief reduction product on the right.

$$Cu^{2+}(1\ M) + 2\,e^- \longrightarrow Cu(s) \qquad E°_{Cu^{2+}/Cu} = ? \tag{20.6}$$

To determine the value of $E°$ for a standard electrode such as that to which half-reaction (20.6) applies, we compare it with a standard hydrogen electrode (SHE). In this comparison, the SHE is always taken as the electrode on the *left* of the cell diagram—the anode—and the compared electrode is the electrode on the *right*—the cathode. In the following voltaic cell, the measured potential difference is 0.340 V, with electrons flowing from the H_2 to the Cu electrode.

$$\underset{\text{anode}}{Pt|H_2(g, 1\ atm)|H^+(1\ M)}\,||\,\underset{\text{cathode}}{Cu^{2+}(1\ M)|Cu(s)} \qquad E°_{cell} = 0.340\ V \tag{20.7}$$

A **standard cell potential, $E°_{cell}$**, is the potential difference, or voltage, of a cell formed from two *standard* electrodes. The *difference* is always taken in the following way:

$$E°_{cell} = \underset{\text{(cathode)}}{E°(\text{right})} - \underset{\text{(anode)}}{E°(\text{left})}$$

Applied to the cell diagram (20.7), we get

$$\begin{aligned} E°_{cell} &= E°_{Cu^{2+}/Cu} - E°_{H^+/H_2} = 0.340\ V \\ &= E°_{Cu^{2+}/Cu} - 0\ V = 0.340\ V \\ E°_{Cu^{2+}/Cu} &= 0.340\ V \end{aligned}$$

Thus, the standard *reduction* half-reaction can be written as

$$Cu^{2+}(1\ M) + 2\,e^- \longrightarrow Cu(s) \qquad E°_{Cu^{2+}/Cu} = +0.340\ V \tag{20.8}$$

The overall reaction occurring in the voltaic cell diagrammed in (20.7) can be represented as

$$H_2(g, 1\ atm) + Cu^{2+}(1\ M) \longrightarrow 2\,H^+(1\ M) + Cu(s) \qquad E°_{cell} = 0.340\ V \tag{20.9}$$

Cell reaction (20.9) indicates that $Cu^{2+}(1\ M)$ is more easily reduced than is $H^+(1\ M)$.

Suppose the standard copper electrode in cell diagram (20.7) is replaced by a standard zinc electrode, and the potential difference between the standard hydrogen and zinc electrodes is measured by using the same voltmeter connections as in (20.7). In this case, the voltage is found to be −0.763 V. The negative sign indicates that electrons flow in the direction *opposite* that in (20.7)—that is, *from* the zinc electrode to the hydrogen electrode. Here $H^+(1\ M)$ is more easily reduced than is $Zn^{2+}(1\ M)$. These findings are represented in the following cell diagram, in which the zinc electrode appears on the *right*.

$$Pt|H_2(g, 1\ atm)|H^+(1\ M)||Zn^{2+}(1\ M)|Zn(s) \qquad E°_{cell} = -0.763\ V \tag{20.10}$$

The standard electrode potential for the Zn^{2+}/Zn couple can be written as

$$\begin{aligned} E°_{cell} &= E°(\text{right}) - E°(\text{left}) \\ &= E°_{Zn^{2+}/Zn} - 0\ V = -0.763\ V \\ E°_{Zn^{2+}/Zn} &= -0.763\ V \end{aligned}$$

Thus, the standard *reduction* half-reaction is

$$Zn^{2+}(1\ M) + 2\,e^- \longrightarrow Zn(s) \qquad E°_{Zn^{2+}/Zn} = -0.763\ V \tag{20.11}$$

In summary, the potential of the standard hydrogen electrode is set at exactly 0 V. Any electrode at which a reduction half-reaction shows a *greater* tendency to occur than does the reduction of H^+ (1 M) to H_2 (g, 1 atm) has a *positive* value for its standard electrode potential, $E°$. Any electrode at which a reduction half-reaction shows a *lesser* tendency to occur than does the reduction of H^+(1 M) to H_2 (g, 1 atm) has a *negative* value for its standard reduction potential, $E°$. Comparisons of the standard copper and zinc electrodes to the standard hydrogen electrode are illustrated in Figure 20-6. Table 20.1 on the next page lists some common reduction half-reactions and their standard electrode potentials at 25 °C.

20-2 CONCEPT ASSESSMENT

For Figure 20-6, describe any changes in mass that might be detected at the Pt, Cu, and Zn electrodes as electric current passes through the electrochemical cells.

Standard reduction potentials are used throughout this chapter for many purposes. Our first objective will be to calculate standard cell potentials for redox reactions—$E°_{\text{cell}}$ values—from standard electrode potentials for half-cell reactions—$E°$ values. The procedure used is illustrated here for reaction (20.3) and cell diagram (20.4). Note that the first three equations are alternative ways of stating the same thing; we will generally not write all of them.

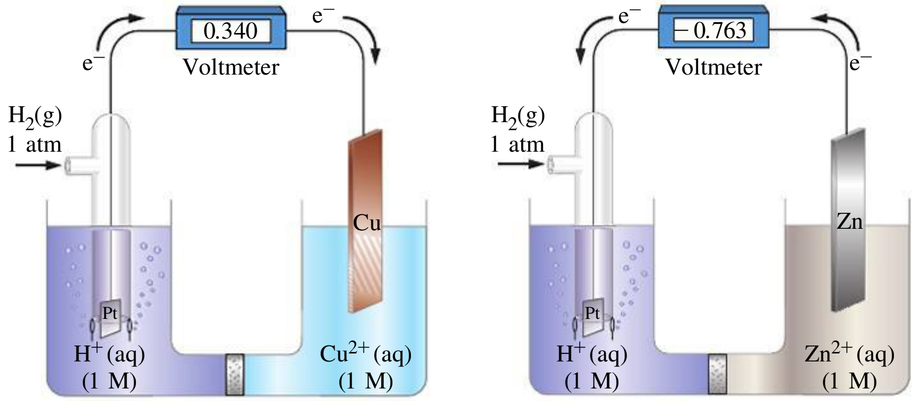
◀ Reaction (20.3) is shown on page 866 and diagram (20.4) on page 867.

$$\begin{aligned} E°_{\text{cell}} &= E°(\text{right}) - E°(\text{left}) \\ &= E°(\text{cathode}) - E°(\text{anode}) \\ &= E°(\text{reduction half-cell}) - E°(\text{oxidation half-cell}) \\ &= E°_{\text{Cu}^{2+}/\text{Cu}} - E°_{\text{Zn}^{2+}/\text{Zn}} \\ &= 0.340\text{ V} - (-0.763\text{ V}) = 1.103\text{ V} \end{aligned}$$

KEEP IN MIND

that the $E°$ values in this formulation are for a reduction half-reaction, regardless of whether oxidation or reduction occurs in the half-cell.

Example 20-3 predicts $E°_{\text{cell}}$ for a new battery system. Example 20-4 uses one known electrode potential and a measured $E°_{\text{cell}}$ value to determine an unknown $E°$.



(a) **(b)**

▲ FIGURE 20-6
Measuring standard electrode potentials
(a) A standard hydrogen electrode is the anode, and copper is the cathode. Contact between the half-cells occurs through a porous plate that prevents bulk flow of the solutions while allowing ions to pass. **(b)** This cell has the same connections as that in part (a), but with zinc substituting for copper. However, the electron flow is opposite that in (a), as noted by the *negative* voltage. (Zinc is the anode.)

▶ A more extensive listing of reduction half-reactions and their potentials is given in Appendix D.

▶ The placement of *oxidizing agents* is as follows: strongest oxidizing agents ($F_2, O_3, \ldots$), *left* sides, *top* of the list; weakest oxidizing agents ($Li^+, K^+, \ldots$), *left* sides, *bottom* of list. The placement of *reducing agents* is as follows: strongest reducing agents ($Li, K, \ldots$), *right* sides, *bottom* of list; weakest reducing agents ($F^-, O_2, \ldots$), *right* sides, *top* of list.

TABLE 20.1 Some Selected Standard Electrode (Reduction) Potentials at 25 °C

Reduction Half-Reaction	E°, V
Acidic solution	
$F_2(g) + 2\,e^- \longrightarrow 2\,F^-(aq)$	+2.866
$O_3(g) + 2\,H^+(aq) + 2\,e^- \longrightarrow O_2(g) + H_2O(l)$	+2.075
$S_2O_8{}^{2-}(aq) + 2\,e^- \longrightarrow 2\,SO_4{}^{2-}(aq)$	+2.01
$H_2O_2(aq) + 2\,H^+(aq) + 2\,e^- \longrightarrow 2\,H_2O(l)$	+1.763
$MnO_4{}^-(aq) + 8\,H^+(aq) + 5\,e^- \longrightarrow Mn^{2+}(aq) + 4\,H_2O(l)$	+1.51
$PbO_2(s) + 4\,H^+(aq) + 2\,e^- \longrightarrow Pb^{2+}(aq) + 2\,H_2O(l)$	+1.455
$Cl_2(g) + 2\,e^- \longrightarrow 2\,Cl^-(aq)$	+1.358
$Cr_2O_7{}^{2-}(aq) + 14\,H^+(aq) + 6\,e^- \longrightarrow 2\,Cr^{3+}(aq) + 7\,H_2O(l)$	+1.33
$MnO_2(s) + 4\,H^+(aq) + 2\,e^- \longrightarrow Mn^{2+}(aq) + 2\,H_2O(l)$	+1.23
$O_2(g) + 4\,H^+(aq) + 4\,e^- \longrightarrow 2\,H_2O(l)$	+1.229
$2\,IO_3{}^-(aq) + 12\,H^+(aq) + 10\,e^- \longrightarrow I_2(s) + 6\,H_2O(l)$	+1.20
$Br_2(l) + 2\,e^- \longrightarrow 2\,Br^-(aq)$	+1.065
$NO_3{}^-(aq) + 4\,H^+(aq) + 3\,e^- \longrightarrow NO(g) + 2\,H_2O(l)$	+0.956

$Fe^{3+}(aq) + e^- \longrightarrow Fe^{2+}(aq)$	+0.771
$O_2(g) + 2\,H^+(aq) + 2\,e^- \longrightarrow H_2O_2(aq)$	+0.695
$I_2(s) + 2\,e^- \longrightarrow 2\,I^-(aq)$	+0.535
$Cu^{2+}(aq) + 2\,e^- \longrightarrow Cu(s)$	+0.340
$SO_4{}^{2-}(aq) + 4\,H^+(aq) + 2\,e^- \longrightarrow 2\,H_2O(l) + SO_2(g)$	+0.17
$Sn^{4+}(aq) + 2\,e^- \longrightarrow Sn^{2+}(aq)$	+0.154
$S(s) + 2\,H^+(aq) + 2\,e^- \longrightarrow H_2S(g)$	+0.14
$2\,H^+(aq) + 2\,e^- \longrightarrow H_2(g)$	0
$Pb^{2+}(aq) + 2\,e^- \longrightarrow Pb(s)$	−0.125
$Sn^{2+}(aq) + 2\,e^- \longrightarrow Sn(s)$	−0.137
$Fe^{2+}(aq) + 2\,e^- \longrightarrow Fe(s)$	−0.440
$Zn^{2+}(aq) + 2\,e^- \longrightarrow Zn(s)$	−0.763
$Al^{3+}(aq) + 3\,e^- \longrightarrow Al(s)$	−1.676
$Mg^{2+}(aq) + 2\,e^- \longrightarrow Mg(s)$	−2.356
$Na^+(aq) + e^- \longrightarrow Na(s)$	−2.713
$Ca^{2+}(aq) + 2\,e^- \longrightarrow Ca(s)$	−2.84
$K^+(aq) + e^- \longrightarrow K(s)$	−2.924
$Li^+(aq) + e^- \longrightarrow Li(s)$	−3.040
Basic solution	
$O_3(g) + H_2O(l) + 2\,e^- \longrightarrow O_2(g) + 2\,OH^-(aq)$	+1.246
$OCl^-(aq) + H_2O(l) + 2\,e^- \longrightarrow Cl^-(aq) + 2\,OH^-(aq)$	+0.890
$O_2(g) + 2\,H_2O(l) + 4\,e^- \longrightarrow 4\,OH^-(aq)$	+0.401
$2\,H_2O(l) + 2\,e^- \longrightarrow H_2(g) + 2\,OH^-(aq)$	−0.828

EXAMPLE 20-3 Combining E° Values into E°_{cell} for a Reaction

A new battery system currently under study for possible use in electric vehicles is the zinc–chlorine battery. The overall reaction producing electricity in this cell is $Zn(s) + Cl_2(g) \longrightarrow ZnCl_2(aq)$. What is E°_{cell} of this voltaic cell?

Analyze

First we identify the species that are oxidized and reduced. Then we obtain the standard reduction potentials for the cathode and anode from Table 20.1 or Appendix D and calculate E°_{cell}.

Solve

The oxidation state of zinc changes from 0 to +2 and therefore is oxidized; consequently, the chlorine is reduced. The half-reactions are indicated below and are combined into the overall equation (20.12).

$$\begin{array}{lrcl} \textit{Oxidation:} & Zn(s) & \longrightarrow & Zn^{2+}(aq) + 2\,e^- \\ \textit{Reduction:} & Cl_2(g) + 2\,e^- & \longrightarrow & 2\,Cl^-(aq) \\ \hline \textit{Overall:} & Zn(s) + Cl_2(g) & \longrightarrow & Zn^{2+}(aq) + 2\,Cl^-(aq) \end{array} \tag{20.12}$$

$$\begin{aligned} E^\circ_{\text{cell}} &= E^\circ(\text{reduction half-cell}) - E^\circ(\text{oxidation half-cell}) \\ &= 1.358\text{ V} - (-0.763\text{ V}) = 2.121\text{ V} \end{aligned}$$

Assess

Once the oxidized and reduced species are identified, we can establish E°_{cell}.

PRACTICE EXAMPLE A: What is E°_{cell} for the reaction in which $Cl_2(g)$ oxidizes $Fe^{2+}(aq)$ to $Fe^{3+}(aq)$?

$$2\,Fe^{2+}(aq) + Cl_2(g) \longrightarrow 2\,Fe^{3+}(aq) + 2\,Cl^-(aq) \qquad E^\circ_{\text{cell}} = ?$$

PRACTICE EXAMPLE B: Use data from Table 20.1 to determine E°_{cell} for the redox reaction in which $Fe^{2+}(aq)$ is oxidized to $Fe^{3+}(aq)$ by $MnO_4^-(aq)$ in acidic solution.

EXAMPLE 20-4 Determining an Unknown E° from an E°_{cell} Measurement

Cadmium is found in small quantities wherever zinc is found. Unlike zinc, which in trace amounts is an essential element, cadmium is an environmental poison. To determine cadmium ion concentrations by electrical measurements, we need the standard electrode potential for the Cd^{2+}/Cd electrode. The voltage of the following voltaic cell is measured.

$$Cd(s)|Cd^{2+}(1\text{ M})||Cu^{2+}(1\text{ M})|Cu(s) \qquad E^\circ_{\text{cell}} = 0.743\text{ V}$$

What is the standard electrode potential for the Cd^{2+}/Cd electrode?

Analyze

We know one half-cell potential and E°_{cell} for the overall redox reaction. We can solve for the unknown standard electrode potential, $E^\circ_{Cd^{2+}/Cd}$.

Solve

$$\begin{aligned} E^\circ_{\text{cell}} &= E^\circ(\text{right}) - E^\circ(\text{left}) \\ 0.743\text{ V} &= E^\circ_{Cu^{2+}/Cu} - E^\circ_{Cd^{2+}/Cd} \\ &= 0.340\text{ V} - E^\circ_{Cd^{2+}/Cd} \\ E^\circ_{Cd^{2+}/Cd} &= 0.340\text{ V} - 0.743\text{ V} = -0.403\text{ V} \end{aligned}$$

Assess

Based on the entries in Table 20.1 we see that Cd(s) is a stronger reducing agent than Sn(s), but weaker than Fe(s). $Cd^{2+}(aq)$ is a weaker oxidizing agent than $Sn^{2+}(aq)$.

PRACTICE EXAMPLE A: In acidic solution, dichromate ion oxidizes oxalic acid, $H_2C_2O_4(aq)$, to $CO_2(g)$ in a reaction with $E^\circ_{\text{cell}} = 1.81$ V.

$$Cr_2O_7^{2-}(aq) + 3\,H_2C_2O_4(aq) + 8\,H^+(aq) \longrightarrow 2\,Cr^{3+}(aq) + 7\,H_2O + 6\,CO_2(g)$$

Use the value of E°_{cell} for this reaction, together with appropriate data from Table 20.1, to determine E° for the $CO_2(g)/H_2C_2O_4(aq)$ electrode.

PRACTICE EXAMPLE B: In an acidic solution, $O_2(g)$ oxidizes $Cr^{2+}(aq)$ to $Cr^{3+}(aq)$. The $O_2(g)$ is reduced to $H_2O(l)$. E°_{cell} for the reaction is 1.653 V. What is the standard electrode potential for the couple Cr^{3+}/Cr^{2+}?

20-3 CONCEPT ASSESSMENT

For the half-cell reaction $ClO_4^-(aq) + 8\,H^+(aq) + 7\,e^- \longrightarrow \frac{1}{2}Cl_2(g) + 4\,H_2O(l)$, what are the standard-state conditions for the reactants and products?

20-3 E_{cell}, ΔG, and K

▶ It is quite common to see the symbol n used for the number of electrons; however, IUPAC recommends z to avoid confusion with the use of n as the amount of substance, such as the number of moles of gas in the ideal gas equation.

When a reaction occurs in a voltaic cell, the cell does work—electrical work. Think of this as the work of moving electric charges. The total work done is the product of three terms: (a) E_{cell}; (b) z, the number of electrons transferred between the electrodes; and (c) the electric charge per mole of electrons, called the **Faraday constant (*F*)**. The Faraday constant is equal to 96,485 coulombs per mole of electrons (96,485 C/mol). Because the product volt × coulomb = joule, the unit of w_{elec} is joules (J).

$$w_{elec} = zFE_{cell} \tag{20.13}$$

Expression (20.13) applies only if the cell operates reversibly.* The last paragraph in Section 19-4 on page 836 described the amount of available energy (work) that can be derived from a process as equal to $-\Delta G$. Thus,

$$\Delta G = -zFE_{cell} \tag{20.14}$$

In the special case in which the reactants and products are in their standard states,

$$\Delta G^\circ = -zFE^\circ_{cell} \tag{20.15}$$

▲ Michael Faraday (1791–1867)
Faraday, an assistant to Humphry Davy and often called "Davy's greatest discovery," made many contributions to both physics and chemistry, including systematic studies of electrolysis.

At this point we should clear up some issues of units and definitions. The symbol z in equations (20.14) and (20.15) is properly called the *electron number* of an electrochemical reaction and is occasionally referred to as the *charge number*. The electron number has no units; that is, it is simply a number. For any given cell reaction we can write the reaction with a charge number of one or two. Thus, the hydrogen electrode reaction can be written as either

$$2\,H^+(aq) + 2\,e^- \longrightarrow H_2(g) \quad \text{or} \quad H^+(aq) + e^- \longrightarrow \frac{1}{2}H_2(g)$$

However, in considering an overall cell reaction, we must balance the electrons. Thus for the cell

$$Pt(s)|H_2(g)|H^+(aq, 1\,M)||Cu^{2+}(aq)|Cu(s)$$

the half-cell reactions can be written as

$$2\,H^+(aq) + 2\,e^- \longrightarrow H_2(g) \quad \text{and} \quad 2\,e^- + Cu^{2+}(aq) \longrightarrow Cu(s)$$

Thus, the electron number is two and the overall electrochemical reaction is

$$H_2(g) + Cu^{2+}(aq) \longrightarrow 2\,H^+(aq) + Cu(s)$$

The standard reduction potential for this reaction is

$$\begin{aligned} E^\circ_{cell} &= E^\circ(\text{right}) - E^\circ(\text{left}) \\ &= E^\circ_{Cu^{2+}/Cu} - 0\text{ V} = 0.340\text{ V} \end{aligned}$$

The standard Gibbs energy is given by

$$\begin{aligned} \Delta G^\circ_{rxn} &= -zFE^\circ_{cell} = 2 \times \frac{96485\text{ C}}{\text{mol}} \times 0.340\text{ V} \\ &= -6.5610\times10^4\text{ J mol}^{-1} = -65.6\text{ kJ mol}^{-1} \end{aligned}$$

---

*The meaning of a reversible process was illustrated by Figure 7-12 on page 258. The reversible operation of a voltaic cell requires that electric current be drawn from the cell only very, very slowly.

That is, 65.6 kJ of energy is generated when 1 mole of Cu^{2+} ions is reduced or 2 moles of H^+ are produced. The process is accompanied by the passage of two moles of electrons around the outer circuit. We could also have written the reactions as

$$\begin{array}{lrcl} \textit{Oxidation:} & \frac{1}{2}H_2(g) & \longrightarrow & H^+(aq) + e^- \\ \textit{Reduction:} & \frac{1}{2}Cu^{2+}(aq) + e^- & \longrightarrow & \frac{1}{2}Cu(s) \\ \hline \textit{Overall:} & \frac{1}{2}H_2(g) + \frac{1}{2}Cu^{2+}(aq) & \longrightarrow & \frac{1}{2}Cu(s) + H^+(aq) \end{array}$$

This reaction is represented by the same cell diagram given above, but the electron number is one; consequently, the Gibbs energy is one-half of that previously calculated, but the value of E°_{cell} is the same. This result supports the fact that the standard reduction potential is an intensive property but the Gibbs energy is an extensive property. Finally, the reaction tells us that when 0.5 mole of Cu^{2+} is reduced, 32.8 kJ of energy is released and one mole of electrons passes from the anode to the cathode.

Our primary interest is not in calculating quantities of work but in using expression (20.15) as a means of evaluating Gibbs energy changes from measured cell potentials, as illustrated in Example 20-5.

EXAMPLE 20-5 Determining a Gibbs Energy Change from a Cell Potential

Use E° data to determine ΔG° for the reaction

$$Zn(s) + Cl_2(g, 1\text{ atm}) \longrightarrow ZnCl_2(aq, 1\text{ M})$$

Solution

This reaction is cell reaction (20.12) occurring in the voltaic cell described in Example 20-3. In this type of problem, the overall equation generally needs to be separated into two half-equations. Then the value of E°_{cell} and the number of moles of electrons (n) involved in the cell reaction can be determined. Refer to Example 20-3 to see that $E^\circ_{\text{cell}} = 2.121$ V and $z = 2$ mol e^-. Now use equation (20.15).

$$\Delta G^\circ = -zFE^\circ_{\text{cell}} = -\left(2\text{ mol e}^- \times \frac{96{,}485\text{ C}}{1\text{ mol e}^-} \times 2.121\text{ V}\right)$$
$$= -4.093 \times 10^5\text{ J} = -409.3\text{ kJ mol}^{-1}$$

PRACTICE EXAMPLE A: Use electrode potential data to determine ΔG° for the reaction

$$2\,Al(s) + 3\,Br_2(l) \longrightarrow 2\,Al^{3+}(aq, 1\text{ M}) + 6\,Br^-(aq, 1\text{ M}) \qquad \Delta G^\circ = ?$$

PRACTICE EXAMPLE B: The hydrogen–oxygen fuel cell is a voltaic cell with a cell reaction of $2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(l)$. Calculate E°_{cell} for this reaction. [*Hint:* Use thermodynamic data from Appendix D (Table D-2).]

Combining Reduction Half-Equations

Not only can equation (20.15) be used to determine ΔG° from E°_{cell}, as in Example 20-5, but the calculation can be reversed and an E°_{cell} value determined from ΔG°. Moreover, equation (20.15) can be applied to half-cell reactions and half-cell potentials—that is, to standard electrode potentials, E°. That is what we must do, for example, to determine E° for the half-reaction

$$Fe^{3+}(aq) + 3\,e^- \longrightarrow Fe(s)$$

Both in Table 20.1 and in Appendix D, the only entries that deal with Fe(s) and its ions are

$$Fe^{2+}(aq) + 2\,e^- \longrightarrow Fe(s),\ E^\circ = -0.440\text{ V} \quad \text{and} \quad Fe^{3+}(aq) + e^- \longrightarrow Fe^{2+}(aq),\ E^\circ = 0.771\text{ V}$$

The half-equation we are seeking is simply the sum of these two half-equations, but the $E°$ value we are seeking is *not* the sum of −0.440 V and 0.771 V. What we *can* add together, though, are the $\Delta G°$ values for the two known half-reactions.

$$\begin{array}{ll} \mathrm{Fe^{2+}(aq)} + 2\,\mathrm{e^-} \longrightarrow \mathrm{Fe(s)}; & \Delta G° = -2 \times F \times (-0.440\ \mathrm{V}) \\ \mathrm{Fe^{3+}(aq)} + \mathrm{e^-} \longrightarrow \mathrm{Fe^{2+}(aq)}; & \Delta G° = -1 \times F \times (0.771\ \mathrm{V}) \\ \hline \mathrm{Fe^{3+}(aq)} + 3\,\mathrm{e^-} \longrightarrow \mathrm{Fe(s)}; & \Delta G° = (0.880F)\ \mathrm{V} - (0.771F)\ \mathrm{V} = (0.109F)\ \mathrm{V} \end{array}$$

Now, to get $E°_{\mathrm{Fe^{3+}/Fe}}$, we can again use equation (20.15) and solve for $E°_{\mathrm{Fe^{3+}/Fe}}$.

$$\Delta G° = -zFE°_{\mathrm{Fe^{3+}/Fe}} = -3FE°_{\mathrm{Fe^{3+}/Fe}} = (0.109F)\ \mathrm{V}$$

$$E°_{\mathrm{Fe^{3+}/Fe}} = (-0.109F/3F)\ \mathrm{V} = -0.0363\ \mathrm{V}$$

KEEP IN MIND

that Gibbs energy changes are functions of state and therefore ΔG values can be combined to determine Gibbs energy changes for new reactions.

20-1 ARE YOU WONDERING...

How the procedure for combining two $E°$ values to obtain an unknown $E°_{\mathrm{cell}}$ relates to combining two $E°$ values to obtain an unknown $E°$?

We have just seen how to obtain an unknown $E°$ from two known values of $E°$ by working through the expression $\Delta G = -zFE°$. As shown below for a hypothetical displacement reaction, we can similarly calculate an unknown $E°_{\mathrm{cell}}$ through the expression $\Delta G° = -zFE°_{\mathrm{cell}}$. (Note that for the oxidation half-reaction, $\Delta G°_{\mathrm{ox}}$ is simply the negative of the value for the reverse half-reaction, $\Delta G°_{\mathrm{red}}$.)

$$\begin{array}{lll} \textit{Reduction:} & \mathrm{M^{z+}(aq)} + z\,\mathrm{e^-} \longrightarrow \mathrm{M(s)} & \Delta G°_{\mathrm{red}} = -zFE°_{\mathrm{M^{2+}/M}} \\ \textit{Oxidation:} & \mathrm{N(s)} \longrightarrow \mathrm{N^{z+}(aq)} + z\,\mathrm{e^-} & \\ & \multicolumn{2}{r}{\Delta G°_{\mathrm{ox}} = -(\Delta G°_{\mathrm{red}}) = -(-zFE°_{\mathrm{N^{z+}/N}}) = zFE°_{\mathrm{N^{2+}/N}}} \\ \textit{Overall:} & \mathrm{M^{z+}(aq)} + \mathrm{N(s)} \longrightarrow \mathrm{M(s)} + \mathrm{N^{z+}(aq)} & \\ & \multicolumn{2}{r}{\Delta G° = \Delta G°_{\mathrm{red}} + \Delta G°_{\mathrm{ox}} = -zFE°_{\mathrm{cell}} = -zFE°_{\mathrm{M^{2+}/M}} + zFE°_{\mathrm{N^{2+}/N}}} \end{array}$$

Dividing through the above equation by the term $-zF$, we obtain $E°_{\mathrm{cell}}$ as the familiar difference in two electrode potentials.

$$E°_{\mathrm{cell}} = E°_{\mathrm{M^{z+}/M}} - E°_{\mathrm{N^{z+}/N}}$$

We have been able to skip this calculation based on $\Delta G°$ values and proceed straight to the expression

$$E°_{\mathrm{cell}} = E°(\mathrm{reduction}) - E°(\mathrm{oxidation})$$

because the term $-zF$ always cancels out. That is, z, the number of electrons, must have the same value for the oxidation and reduction half-reactions and the overall reaction. By contrast, when obtaining an unknown $E°$ from the known $E°$ values, the value for z will not be the same in all three places where it appears, and so we do have to work through the $\Delta G°$ expressions.

Spontaneous Change in Oxidation–Reduction Reactions

Our main criterion for spontaneous change is that $\Delta G < 0$. According to equation (20.14), however, redox reactions have the property that, if $\Delta G < 0$, then $E_{\mathrm{cell}} > 0$. That is, E_{cell} must be *positive* if ΔG is to be negative. Predicting the direction of spontaneous change in a redox reaction is a relatively simple matter by using the following ideas:

- If E_{cell} is *positive*, a reaction occurs spontaneously in the *forward* direction for the stated conditions. If E_{cell} is *negative*, the reaction occurs spontaneously in the *reverse* direction for the stated conditions. If $E_{\mathrm{cell}} = 0$, the reaction is at equilibrium for the stated conditions.
- If a cell reaction is *reversed*, E_{cell} changes sign.

EXAMPLE 20-6 Applying the Criterion for Spontaneous Change in a Redox Reaction

Will aluminum metal displace Cu^{2+} ion from aqueous solution? That is, will a spontaneous reaction occur in the forward direction for the following reaction?

$$2\,Al(s) + 3\,Cu^{2+}(1\,M) \longrightarrow 3\,Cu(s) + 2\,Al^{3+}(1\,M)$$

Analyze

We need to identify the species reduced in the reaction as it is written. We then calculate E°_{cell}. If E°_{cell} is positive, then the reaction will occur spontaneously.

Solve

The cell diagram corresponding to the reaction is $Al(s)|Al^{3+}(aq)||Cu^{2+}(aq)|Cu(s)$, and E°_{cell} is

$$\begin{aligned} E^\circ_{\text{cell}} &= E^\circ(\text{cathode}) - E^\circ(\text{anode}) \\ &= E^\circ_{Cu^{2+}/Cu} - E^\circ_{Al^{3+}/Al} \\ &= 0.340\ V - (-1.676\ V) = 2.016\ V \end{aligned}$$

Because E°_{cell} is positive, the direction of spontaneous change is that of the forward reaction. Al(s) will displace Cu^{2+} from aqueous solution under standard-state conditions.

Assess

The positive value of E°_{cell} means that the Gibbs energy change for the reaction is negative; hence, the reaction as written is spontaneous. Keep in mind that both E° and E°_{cell} are *intensive* properties. They do not depend on the quantities of materials involved, which means that their values are not affected by the choice of coefficients used to balance the equation for the cell reaction. We could just as well have written:

$$Al(s) + \frac{3}{2}Cu^{2+}(1\,M) \longrightarrow \frac{3}{2}Cu(s) + Al^{3+}(1\,M) \text{ or}$$

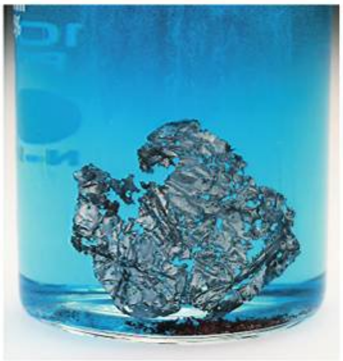
$$\frac{2}{3}Al(s) + Cu^{2+}(1\,M) \longrightarrow Cu(s) + \frac{2}{3}Al^{3+}(1\,M)$$

PRACTICE EXAMPLE A: Name one metal ion that Cu(s) will displace from aqueous solution, and determine E°_{cell} for the reaction.

PRACTICE EXAMPLE B: When sodium metal is added to seawater, which has $[Mg^{2+}] = 0.0512$ M, no magnesium metal is obtained. According to E° values, should this displacement reaction occur? What reaction does occur?

In the special case in which reactants and products are in their standard states, we work with ΔG° and E°_{cell} values, as illustrated in Examples 20-6 and 20-7.

Even though we used electrode potentials and cell voltage to predict a spontaneous reaction in Example 20-6, we do not have to carry out the reaction in a voltaic cell. This is an important point to keep in mind. Thus, Cu^{2+} is displaced from aqueous solution simply by adding aluminum metal, as shown in Figure 20-7. Another point, illustrated by Example 20-7, is that qualitative answers to questions concerning redox reactions can be found without going through a complete calculation of E°_{cell}.



▲ FIGURE 20-7
Reaction of Al(s) and Cu^{2+}(aq)
Notice the holes in the foil where Al(s) has dissolved. Notice also the dark deposit of Cu(s) at the bottom of the beaker.

The Behavior of Metals Toward Acids

In the discussion of redox reactions in Chapter 5, it was noted that most metals react with an acid, such as HCl, but that a few do not. This observation can now be explained. When a metal, M, reacts with an acid, such as HCl, the metal is oxidized to the metal ion, such as M^{2+}. The reduction involves H^+ being reduced to $H_2(g)$. These ideas can be expressed as

$$\begin{array}{ll} \textit{Oxidation:} & M(s) \longrightarrow M^{2+}(aq) + 2\,e^- \\ \textit{Reduction:} & \underline{2\,H^+(aq) + 2\,e^- \longrightarrow H_2(g)} \\ \textit{Overall:} & M(s) + 2\,H^+(aq) \longrightarrow M^{2+}(aq) + H_2(g) \end{array}$$

$$E^\circ_{\text{cell}} = E^\circ_{H^+/H_2} - E^\circ_{M^{2+}/M} = 0\ V - E^\circ_{M^{2+}/M} = -E^\circ_{M^{2+}/M}$$

EXAMPLE 20-7 Making Qualitative Predictions with Electrode Potential Data

Peroxodisulfate salts, such as $Na_2S_2O_8$, are oxidizing agents used in bleaching. Dichromates such as $K_2Cr_2O_7$ have been used as laboratory oxidizing agents. Which is the better oxidizing agent in acidic solution under standard conditions, $S_2O_8{}^{2-}$ or $Cr_2O_7{}^{2-}$?

Analyze

In a redox reaction, the oxidizing agent is reduced; the greater the tendency for this reduction to occur, the better the oxidizing agent. The reduction tendency, in turn, is measured by the $E°$ value.

Solve

Because the $E°$ value for the reduction of $S_2O_8{}^{2-}(aq)$ to $SO_4{}^{2-}(aq)$ (2.01 V) is larger than that for the reduction of $Cr_2O_7{}^{2-}(aq)$ to $Cr^{3+}(aq)$ (1.33 V), $S_2O_8{}^{2-}(aq)$ should be the better oxidizing agent.

Assess

Inspection of standard reduction potentials enables us to qualitatively assess the spontaneity of a particular redox reaction.

PRACTICE EXAMPLE A: An inexpensive way to produce peroxodisulfates would be to pass $O_2(g)$ through an acidic solution containing sulfate ion. Is this method feasible under standard conditions? [*Hint:* What would be the reduction half-reaction?]

PRACTICE EXAMPLE B: Consider the following observations: (1) Aqueous solutions of Sn^{2+} are difficult to maintain because atmospheric oxygen easily oxidizes Sn^{2+} to Sn^{4+}. (2) One way to preserve the $Sn^{2+}(aq)$ solutions is to add some metallic tin. *Without doing detailed calculations,* explain these two statements by using $E°$ data.

Metals with *negative* standard electrode potentials yield *positive* values of $E°_{cell}$ in the above expression. These are the metals that should displace $H_2(g)$ from acidic solutions. Thus, all the metals listed *below* hydrogen in Table 20.1 (Pb through Li) should react with acids.

In acids, such as HCl, HBr, and HI, the oxidizing agent is H^+ (that is, H_3O^+). Certain metals that will not react with HCl will react with an acid in the presence of an *anion* that is a better oxidizing agent than H^+. Nitrate ion is a good oxidizing agent in acidic solution, and silver metal, which does not react with HCl(aq), readily reacts with nitric acid, $HNO_3(aq)$.

$$3\,Ag(s) + NO_3{}^-(aq) + 4\,H^+(aq) \longrightarrow 3\,Ag^+(aq) + NO(g) + 2\,H_2O \qquad E°_{cell} = 0.156\text{ V}$$

▶ Note that any electrochemical cell, if left in a completed circuit, will eventually die as the redox reaction goes to completion. This means that the cell potential will eventually drop to zero. In Chapter 19, the relationship between Gibbs energy and equilibrium was established in a similar way.

▶ Equation 20.16 gives the expected result that reactions with equilibrium constants larger than one have a positive standard cell potential.

The Relationship Between $E°_{cell}$ and K

$\Delta G°$ and $E°_{cell}$ were related through equation (20.15). In Chapter 19, $\Delta G°$ and K were related through equation (19.12). The three quantities are thus related in this way.

$$\Delta G° = -RT \ln K = -zFE°_{cell}$$

and therefore,

$$E°_{cell} = \frac{RT}{zF} \ln K \qquad \textbf{(20.16)}$$

In equation (20.16), R has a value of 8.3145 J mol^{-1} K^{-1} and z represents the number of electrons involved in the reaction. If we then specify a temperature of 25 °C = 298.15 K (the temperature at which electrode potentials are generally determined), the combined terms "RT/F" in equation (20.16) can be replaced by a single constant. This constant has the value 0.025693 J/C = 0.025693 V.

$$E°_{cell} = \frac{RT}{zF} \ln K = \frac{8.3145\text{ J }\cancel{\text{mol}^{-1}}\ \cancel{\text{K}^{-1}} \times 298.15\ \cancel{\text{K}}}{z \times 96485\text{ C }\cancel{\text{mol}^{-1}}} \ln K$$

$$E^\circ_{\text{cell}} = \frac{0.025693\ \text{V}}{z} \ln K \qquad \textbf{(20.17)}$$

The relationship between E°_{cell} and K is illustrated in Example 20-8. Also, Figure 20-8 summarizes several important relationships from thermodynamics, equilibrium, and electrochemistry.

EXAMPLE 20-8 Relating K to E°_{cell} for a Redox Reaction

What is the value of the equilibrium constant K for the reaction between copper metal and iron(III) ions in aqueous solution at 25 °C?

$$\text{Cu(s)} + 2\,\text{Fe}^{3+}\text{(aq)} \longrightarrow \text{Cu}^{2+}\text{(aq)} + 2\,\text{Fe}^{2+}\text{(aq)} \qquad K = ?$$

Analyze

We first identify the reactant that is reduced and the reactant that is oxidized. We then use the data in Table 20.1 to obtain the standard reduction potentials and hence the cell potential. Finally, we use equation (20.17) to obtain K from E°_{cell}.

Solve

First, we use data from Table 20.1 to determine E°_{cell}.

$$\begin{aligned} E^\circ_{\text{cell}} &= E^\circ(\text{reduction half-cell}) - E^\circ(\text{oxidation half-cell}) \\ &= E^\circ_{\text{Fe}^{3+}/\text{Fe}^{2+}} - E^\circ_{\text{Cu}^{2+}/\text{Cu}} \\ &= 0.771\ \text{V} - 0.340\ \text{V} = 0.431\ \text{V} \end{aligned}$$

The charge number (z) for the cell reaction is 2.

$$E^\circ_{\text{cell}} = 0.431\ \text{V} = \frac{0.02569\ \text{V}}{2} \ln K$$

$$\ln K = \frac{2 \times 0.431\ \cancel{\text{V}}}{0.02569\ \cancel{\text{V}}} = 33.6$$

$$K = e^{33.6} = 4 \times 10^{14}$$

Assess

The positive value of the cell potential means that the equilibrium constant is greater than one. The value of the equilibrium constant is very large, and so we can expect this reaction to go to completion.

PRACTICE EXAMPLE A: Should the displacement of Cu^{2+} from aqueous solution by Al(s) go to completion? [*Hint:* Base your assessment on the value of K for the displacement reaction. We determined E°_{cell} for this reaction in Example 20-6.]

PRACTICE EXAMPLE B: Should the reaction of Sn(s) and Pb^{2+}(aq) go to completion? Explain.

▲ FIGURE 20-8
A summary of important thermodynamic, equilibrium, and electrochemical relationships under standard conditions

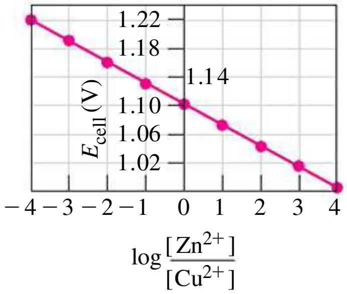
20-4 CONCEPT ASSESSMENT

When two cell reactions with reactants and products in their standard states are compared, one is found to have a negative value of E°_{cell} and the other a positive value. Which cell reaction will proceed toward the formation of more products to establish equilibrium? Will a net cell reaction occur in the other case? If so, how will the equilibrium concentrations compare with the initial concentrations?

20-4 E_{cell} as a Function of Concentrations

When we combine standard electrode potentials, we obtain a standard E°_{cell}, such as $E^\circ_{\text{cell}} = 1.103$ V for the voltaic cell of Figure 20-4. For the following cell reaction at *nonstandard* conditions, however, the measured E_{cell} is not 1.103 V.

$$\text{Zn(s)} + \text{Cu}^{2+}(2.0\ \text{M}) \longrightarrow \text{Zn}^{2+}(0.10\ \text{M}) + \text{Cu(s)} \qquad E_{\text{cell}} = 1.142\ \text{V}$$



▲ FIGURE 20-9
Variation of E_{cell} with ion concentrations
The cell reaction is $\text{Zn(s)} + \text{Cu}^{2+}(\text{aq}) \longrightarrow \text{Zn}^{2+}(\text{aq}) + \text{Cu(s)}$ and has $E^\circ_{\text{cell}} = 1.103$ V.

Experimental measurements of cell potentials are often made for nonstandard conditions; these measurements have great significance, especially for performing chemical analyses.

From Le Châtelier's principle, it would seem that *increasing* the concentration of a reactant (Cu^{2+}) while *decreasing* the concentration of a product (Zn^{2+}) should favor the forward reaction. Zn(s) should displace Cu^{2+}(aq) even more readily than for standard-state conditions and $E_{\text{cell}} > 1.103$ V. E_{cell} is found to vary linearly with $\log([\text{Zn}^{2+}]/[\text{Cu}^{2+}])$, as illustrated in Figure 20-9.

It is not difficult to establish the relationship between the cell potential, E_{cell}, and the concentrations of reactants and products. From Chapter 19 we can write equation (19.11).

$$\Delta G = \Delta G^\circ + RT \ln Q$$

For ΔG and ΔG°, we can substitute $-zFE_{\text{cell}}$ and $-zFE^\circ_{\text{cell}}$, respectively.

$$-zFE_{\text{cell}} = -zFE^\circ_{\text{cell}} + RT \ln Q$$

Dividing through by $-zF$ gives

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{RT}{zF} \ln Q$$

NOBELPRIS 1920
2KR
SVERIGE
NERNST
LENNART FORSBERG
1980
ARNE WALLHORN

▲ **Walther Nernst (1864–1941)**
Nernst was only 25 years old when he formulated his equation relating cell voltages and concentrations. He is also credited with proposing the solubility product concept in the same year. In 1906, he announced his "heat theorem," which we now know as the third law of thermodynamics.

This equation was first proposed by Walther Nernst in 1889. It is commonly used by analytical chemists in the form in which Nernst expressed it. The **Nernst equation** can be obtained by switching from natural to common logarithms ($\ln Q = 2.3026 \log Q$).

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{2.3026\ RT}{zF} \log Q$$

By specifying a temperature of 298.15 K and replacing RT/F by 0.025693 V, as in the development of equation (20.17), we find that the term $2.3026\ RT/F = 2.3026 \times 0.025693\ \text{V} = 0.059161$ V, usually rounded off to 0.0592 V. The final form of the Nernst equation is

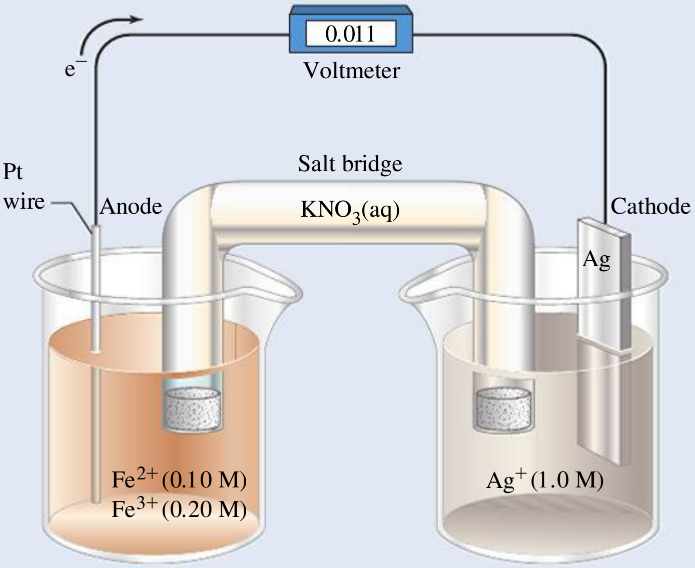
$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0592\ \text{V}}{z} \log Q \qquad \textbf{(20.18)}$$

In the Nernst equation, we make the usual substitutions into Q: $a = 1$ for the activities of pure solids and liquids, partial pressures (atm) for the activities of gases, and molarities for the activities of solution components. Example 20-9 demonstrates that the Nernst equation makes it possible to calculate E_{cell} for any chosen concentrations, not just for standard conditions.

EXAMPLE 20-9 Applying the Nernst Equation for Determining E_{cell}

What is the value of E_{cell} for the voltaic cell pictured in Figure 20-10 and diagrammed as follows?

$$\text{Pt}|\text{Fe}^{2+}(0.10\text{ M}),\,\text{Fe}^{3+}(0.20\text{ M})||\text{Ag}^{+}(1.0\text{ M})|\text{Ag(s)} \qquad E_{\text{cell}} = ?$$



▲ FIGURE 20-10
A voltaic cell with nonstandard conditions—Example 20-9 illustrated

Analyze

To use the Nernst equation we need to establish E°_{cell} and the reaction to which the cell diagram corresponds so that the form of the reaction quotient (Q) can be revealed (see Example 20-2). Once we have determined the form of the Nernst equation, we can insert the concentration of the species.

Solve

Two steps are required when using the Nernst equation. First, to determine E°_{cell}, use data from Table 20.1 to write

$$\begin{aligned} E^\circ_{\text{cell}} &= E^\circ(\text{cathode}) - E^\circ(\text{anode}) \\ &= E^\circ_{\text{Ag}^+/\text{Ag}} - E^\circ_{\text{Fe}^{3+}/\text{Fe}^{2+}} \qquad \textbf{(20.19)} \\ &= 0.800\text{ V} - 0.771\text{ V} = 0.029\text{ V} \end{aligned}$$

Now, to determine E_{cell} for the reaction

$$\text{Fe}^{2+}(0.10\text{ M}) + \text{Ag}^{+}(1.0\text{ M}) \longrightarrow \text{Fe}^{3+}(0.20\text{ M}) + \text{Ag(s)} \qquad E_{\text{cell}} = ? \qquad \textbf{(20.20)}$$

substitute appropriate values into the Nernst equation (20.18), starting with $E^\circ_{\text{cell}} = 0.029$ V and $z = 1$,

$$E_{\text{cell}} = 0.029\text{ V} - \frac{0.0592\text{ V}}{1}\log\frac{[\text{Fe}^{3+}]}{[\text{Fe}^{2+}][\text{Ag}^{+}]}$$

and for concentrations $[\text{Fe}^{2+}] = 0.10$ M; $[\text{Fe}^{3+}] = 0.20$ M; $[\text{Ag}^{+}] = 1.0$ M.

$$\begin{aligned} E_{\text{cell}} &= 0.029\text{ V} - 0.0592\text{ V} \times \log\frac{0.20}{0.10 \times 1.0} \\ &= 0.029\text{ V} - 0.0592\text{ V} \times \log 2 = 0.029\text{ V} - 0.018\text{ V} \\ &= 0.011\text{ V} \end{aligned}$$

Assess

The E_{cell} is positive so that the reaction is spontaneous in the direction of the reduction of silver.

PRACTICE EXAMPLE A: Calculate E_{cell} for the following voltaic cell.

$$\text{Al(s)}|\text{Al}^{3+}(0.36\text{ M})||\text{Sn}^{4+}(0.086\text{ M}),\,\text{Sn}^{2+}(0.54\text{ M})|\text{Pt}$$

PRACTICE EXAMPLE B: Calculate E_{cell} for the following voltaic cell.

$$\text{Pt(s)}|\text{Cl}_2(1\text{ atm})|\text{Cl}^{-}(1.0\text{ M})||\text{Pb}^{2+}(0.050\text{ M}),\,\text{H}^{+}(0.10\text{ M})|\text{PbO}_2\text{(s)}$$

20-5 CONCEPT ASSESSMENT

Describe *two* sets of conditions under which the measured E_{cell} for a reaction is equal to E°_{cell}.

In Section 20-3, we developed a criterion for spontaneous change ($E_{\text{cell}} > 0$), but we used the criterion only with E° data from Table 20.1 Qualitative conclusions reached with E°_{cell} values often hold over a broad range of nonstandard conditions as well. However, when E°_{cell} is within a few hundredths of a volt of zero, it is sometimes necessary to determine E_{cell} for nonstandard conditions in order to apply the criterion for spontaneity of redox reactions, as illustrated in Example 20-10.

EXAMPLE 20-10 Predicting Spontaneous Reactions for Nonstandard Conditions

Will the cell reaction proceed spontaneously as written for the following cell?

$$\text{Ag(s)}\,|\,\text{Ag}^+(0.075\text{ M})\,||\,\text{Hg}^{2+}(0.85\text{ M})\,|\,\text{Hg(l)}$$

Analyze

To decide whether a reaction is spontaneous, we need to calculate E_{cell} by using equation (20.18) with the concentrations given. We then identify the oxidized and reduced species and look up the appropriate standard half-cell potentials. Then we construct the chemical equation that corresponds to the cell diagram, choosing an appropriate electron number (z).

Solve

To determine E°_{cell} from E° data we write

$$\begin{array}{lrcl}
\textit{Oxidation:} & 2\,\text{Ag(s)} & \longrightarrow & 2\,\text{Ag}^+(\text{aq}) + 2\,e^- \\
\textit{Reduction:} & \text{Hg}^{2+}(\text{aq}) + 2\,e^- & \longrightarrow & \text{Hg(l)} \\
\hline
\textit{Overall:} & 2\,\text{Ag(s)} + \text{Hg}^{2+}(\text{aq}) & \longrightarrow & 2\,\text{Ag}^+(\text{aq}) + \text{Hg(l)}
\end{array}$$

$$\begin{aligned}
E^\circ_{\text{cell}} &= E^\circ(\text{reduction half-cell}) - E^\circ(\text{oxidation half-cell}) \\
&= 0.854\text{ V} - (0.800\text{ V}) = 0.054\text{ V}
\end{aligned}$$

The overall reaction that we have written has an electron number, $z = 2$, so that the Nernst equation is

$$E_{\text{cell}} = 0.054\text{ V} - \frac{0.0592\text{ V}}{2}\log\frac{[\text{Ag}^+]^2}{[\text{Hg}^{2+}]}$$

By using the concentrations $[\text{Ag}^+] = 0.075$ M and $[\text{Hg}^{2+}] = 0.85$ M provided, we obtain

$$\begin{aligned}
E_{\text{cell}} &= 0.054\text{ V} - 0.0296\text{ V}\log\frac{[0.075]^2}{[0.85]} \\
&= 0.054\text{ V} - 0.0296\text{ V}\log(0.0066) = 0.054 - 0.0296 \times (-2.179)\text{ V} \\
&= 0.054 + 0.065\text{ V} = -0.119\text{ V}
\end{aligned}$$

Because $E_{\text{cell}} > 0$, we conclude that the reaction as written is spontaneous.

Assess

If we had used an electron number of $z = 1$, the overall reaction would have been

$$\textit{Overall } (z = 1)\text{: } \text{Ag(s)} + \frac{1}{2}\text{Hg}^{2+}(\text{aq}) \longrightarrow \text{Ag}^+(\text{aq}) + \frac{1}{2}\text{Hg(l)}$$

The corresponding Nernst equation is

$$E_{\text{cell}} = 0.054\text{ V} - \frac{0.0592\text{ V}}{1}\log\frac{[\text{Ag}^+]}{[\text{Hg}^{2+}]^{1/2}}$$

By rearranging slightly and using a property of logarithms,

$$E_{\text{cell}} = 0.054\text{ V} - \frac{0.0592\text{ V}}{1}\log\left(\frac{[\text{Ag}^+]^2}{[\text{Hg}^{2+}]}\right)^{1/2} = 0.054\text{ V} - \frac{0.0592\text{ V}}{2}\log\frac{[\text{Ag}^+]^2}{[\text{Hg}^{2+}]}$$

we have recovered the Nernst equation for the cell reaction by using an electron number (z) of 2. We conclude that as long as we balance charge and the electron number correctly, we will always get the correct result.

PRACTICE EXAMPLE A: Will the cell reaction proceed spontaneously as written for the following cell?

$$\text{Cu(s)}|\text{Cu}^{2+}(0.15\text{ M})||\text{Fe}^{3+}(0.35\text{ M}), \text{Fe}^{2+}(0.25\text{ M})|\text{Pt(s)}$$

PRACTICE EXAMPLE B: For what ratio of $[\text{Ag}^+]^2/[\text{Hg}^{2+}]$ will the cell reaction in Example 20-10 not be spontaneous in either direction?

20-6 CONCEPT ASSESSMENT

The following cell is set up under standard-state conditions.

$$\text{Pb(s)}|\text{Pb}^{2+}||\text{Cu}^{2+}|\text{Cu(s)} \qquad E^\circ_{\text{cell}} = 0.47\text{ V}$$

When sodium sulfate is added to the anode half-cell, formation of a white precipitate is observed, accompanied by a change in the value of E_{cell}. Explain these observations, and predict whether the new E_{cell} is greater or less than E°_{cell}.

Concentration Cells

The voltaic cell in Figure 20-11 consists of two hydrogen electrodes. One is a standard hydrogen electrode (SHE), and the other is a hydrogen electrode immersed in a solution of unknown $[\text{H}^+]$, less than 1 M. The cell diagram is

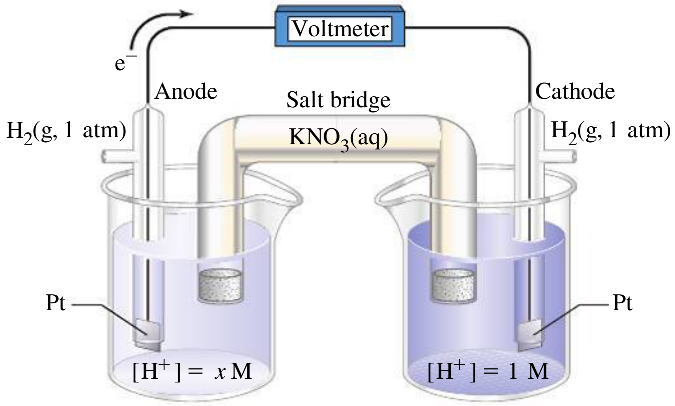
$$\text{Pt}|\text{H}_2(\text{g, 1 atm})|\text{H}^+(x\text{ M})||\text{H}^+(1\text{ M})|\text{H}_2(\text{g, 1 atm})|\text{Pt}$$

The reaction occurring in this cell is

$$\begin{array}{lrcl} \textit{Reduction:} & 2\,\text{H}^+(1\text{ M}) + \cancel{2\,e^-} & \longrightarrow & \cancel{\text{H}_2(\text{g, 1 atm})} \\ \textit{Oxidation:} & \cancel{\text{H}_2(\text{g, 1 atm})} & \longrightarrow & 2\,\text{H}^+(x\text{ M}) + \cancel{2\,e^-} \\ \hline \textit{Overall:} & 2\,\text{H}^+(1\text{ M}) & \longrightarrow & 2\,\text{H}^+(x\text{ M}) \end{array} \qquad \textbf{(20.21)}$$

$$E^\circ_{\text{cell}} = E^\circ_{\text{H}^+/\text{H}_2} - E^\circ_{\text{H}^+/\text{H}_2} = 0\text{ V}$$

The voltaic cell in Figure 20-11 is called a concentration cell. A **concentration cell** consists of two half-cells with *identical electrodes* but different ion concentrations. Because the electrodes are identical, the standard electrode potentials are numerically equal and subtracting one from the other leads to the value $E^\circ_{\text{cell}} = 0$. However, because the ion concentrations differ, there is a potential



◀ FIGURE 20-11
A concentration cell
The cell consists of two hydrogen electrodes. The electrode on the right is a SHE. Oxidation occurs at the anode on the left, where $[\text{H}^+]$ is less than 1 M. The reading on the voltmeter is directly proportional to the pH of the solution in the anode compartment.

difference between the two half-cells. The spontaneous change in a concentration cell always occurs such that the concentrated solution becomes more dilute, and the dilute solution becomes more concentrated. The final result is as if the solutions were simply mixed. In a concentration cell, however, the natural tendency for entropy to increase in a mixing process is used as a means of producing electricity.

The Nernst equation for reaction (20.21) takes the form

$$E_{\text{cell}} = E^{\circ}_{\text{cell}} - \frac{0.0592\ \text{V}}{2}\log\frac{x^2}{1^2}$$

which simplifies to

$$E_{\text{cell}} = 0 - \frac{0.0592\ \text{V}}{2} \times 2\log\frac{x}{1} = -0.0592\ \text{V}\log x$$

Because x is $[\text{H}^+]$ in the unknown solution and $-\log x = -\log[\text{H}^+] = \text{pH}$, the final result is

$$E_{\text{cell}} = (0.0592\ \text{pH})\ \text{V} \qquad \textbf{(20.22)}$$

where the pH is that of the unknown solution. If an unknown solution has a pH of 3.50, for example, the measured cell voltage in Figure 20-11 will be $E_{\text{cell}} = (0.0592 \times 3.50)\ \text{V} = 0.207\ \text{V}$.

Constructing and using a hydrogen electrode is difficult. The Pt metal surface must be specially prepared and maintained, gas pressure must be controlled, and the electrode cannot be used in the presence of strong oxidizing or reducing agents. The solution to these problems is discussed later in this chapter.

20-7 CONCEPT ASSESSMENT

Write a cell diagram for a possible voltaic cell in which the cell reaction is $\text{Cl}^-(0.50\ \text{M}) \longrightarrow \text{Cl}^-(0.10\ \text{M})$. What would be E_{cell} for this reaction?

Measurement of K_{sp}

The difference in concentration of ions in the two half-cells of a concentration cell accounts for the observed E_{cell}. It also provides a basis for determining K_{sp} values for sparingly soluble ionic compounds. Consider the following concentration cell.

$$\text{Ag(s)}|\text{Ag}^+(\text{satd AgI})||\text{Ag}^+(0.100\ \text{M})|\text{Ag} \qquad E_{\text{cell}} = 0.417\ \text{V}$$

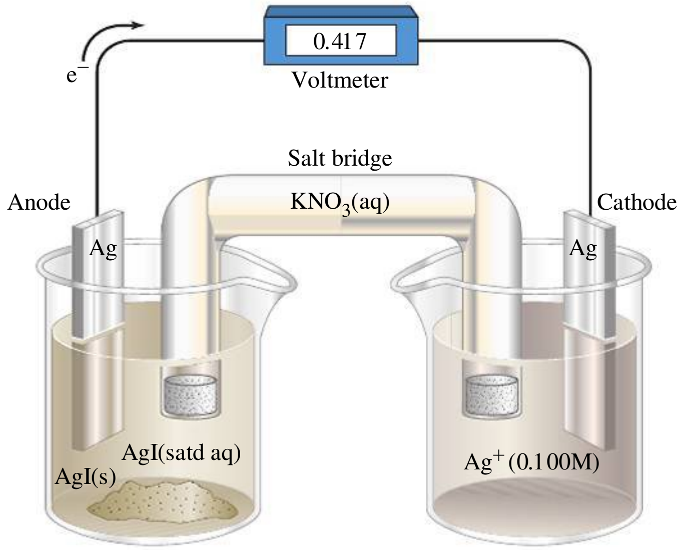
At the anode, a silver electrode is placed in a saturated aqueous solution of silver iodide. At the cathode, a second silver electrode is placed in a solution with $[\text{Ag}^+] = 0.100\ \text{M}$. The two half-cells are connected by a salt bridge, and the measured cell voltage is 0.417 V (Fig. 20-12). The cell reaction occurring in this *concentration cell* is

$$\begin{array}{lrcl}
\textit{Reduction:} & \text{Ag}^+(0.100\ \text{M}) + \text{e}^- & \longrightarrow & \text{Ag(s)} \\
\textit{Oxidation:} & \text{Ag(s)} & \longrightarrow & \text{Ag}^+(\text{satd AgI}) \\
\hline
\textit{Overall:} & \text{Ag}^+(0.100\ \text{M}) & \longrightarrow & \text{Ag}^+(\text{satd AgI})
\end{array} \qquad \textbf{(20.23)}$$

The calculation of K_{sp} of silver iodide is completed in Example 20-11.

Alternative Standard Electrodes

The standard hydrogen electrode is not the most convenient to use because it requires highly flammable hydrogen gas to be bubbled over the platinum electrode. Other electrodes can be used as secondary standard electrodes, such as the



▲ FIGURE 20-12
A concentration cell for determining K_{sp} of AgI
The silver electrode in the anode compartment is in contact with a saturated solution of AgI. In the cathode compartment, $[Ag^+] = 0.100$ M.

EXAMPLE 20-11 Using a Voltaic Cell to Determine K_{sp} of a Slightly Soluble Solute

With the data given for reaction (20.23), calculate K_{sp} for AgI.

$$AgI(s) \rightleftharpoons Ag^+(aq) + I^-(aq) \qquad K_{sp} = ?$$

Analyze

Once we have determined the concentration of Ag^+ ions from the Nernst equation for the cell, we can calculate the equilibrium constant by using the expression for the solubility product.

Solve

$[Ag^+]$ in saturated silver iodide solution can be represented as x. The Nernst equation is then applied to reaction (20.23). (To simplify the equations that follow, we have dropped the unit V, which would otherwise appear in several places.)

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0592}{z}\log\frac{[Ag^+]_{\text{satd AgI}}}{[Ag^+]_{0.100\text{ M soln}}}$$

$$= E^\circ_{\text{cell}} - \frac{0.0592}{1}\log\frac{x}{0.100}$$

$$0.417 = 0 - 0.0592(\log x - \log 0.100)$$

Divide both sides of the equation by 0.0592.

$$\frac{0.417}{0.0592} = -\log x + \log 0.100$$

$$\log x = \log 0.100 - \frac{0.417}{0.0592} = -1.00 - 7.04 = -8.04$$

$$x = [Ag^+] = 10^{-8.04} = 9.1 \times 10^{-9}\text{ M}$$

Because in saturated AgI the concentrations of Ag^+ and I^- are equal,

$$K_{sp} = [Ag^+][I^-] = (9.1 \times 10^{-9})(9.1 \times 10^{-9}) = 8.3 \times 10^{-17}$$

Assess

Apart from the use of the Nernst equation, the other essential aspect is the realization that the only source of Ag^+ and I^- is from the AgI present; the saturated AgI(s) electrode has $[Ag^+] = [I^-]$.

PRACTICE EXAMPLE A: K_{sp} for AgCl $= 1.8 \times 10^{-10}$. What would be the measured E_{cell} for the voltaic cell in Example 20-11 if the contents of the anode half-cell were saturated AgCl(aq) and AgCl(s)?

PRACTICE EXAMPLE B: Calculate the K_{sp} for PbI_2 given the following concentration cell information.

$$Pb(s)|Pb^{2+}(\text{satd } PbI_2)||Pb^{2+}(0.100\text{ M})|Pb(s) \qquad E_{\text{cell}} = 0.0567\text{ V}$$

silver–silver chloride electrode, in which a silver wire is covered with a layer of insoluble solid silver chloride. The silver-chloride-coated silver wire is immersed in a 1 M potassium chloride solution (see Fig. 20-13a), giving the electrode

$$\mathrm{Ag(s)}|\mathrm{AgCl(s)}|\mathrm{Cl^-(1.0\ M)}$$

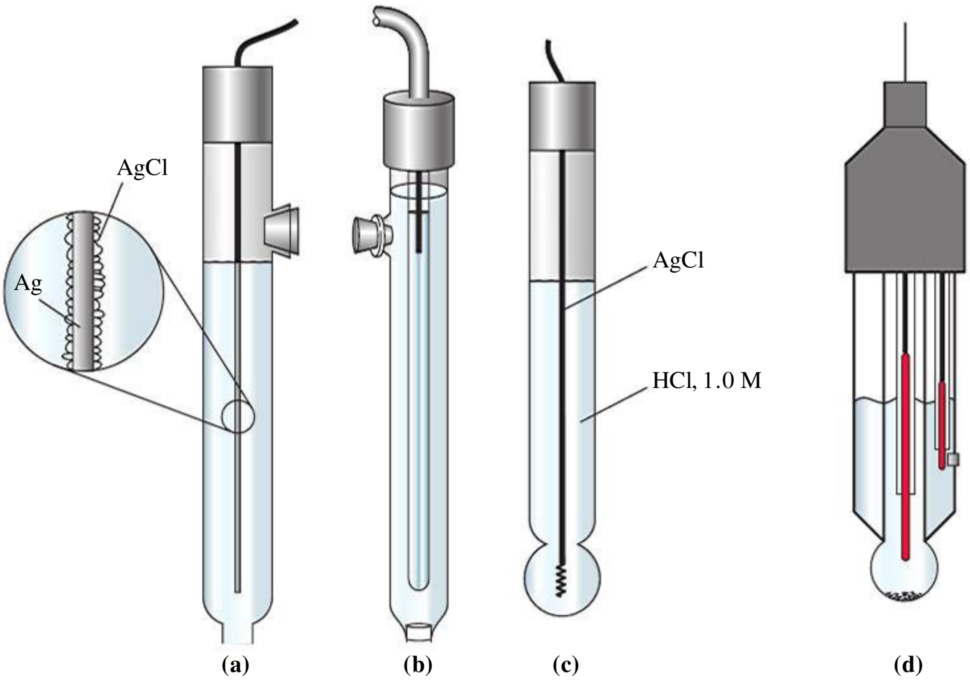
with a half-cell reaction of

$$\mathrm{AgCl(s)} + e^- \longrightarrow \mathrm{Ag(s)} + \mathrm{Cl^-(aq)}$$

This electrode has been measured against the standard hydrogen electrode, and the electrode potential has been found to be 0.22233 V at 25 °C. Since all components of this electrode are in their standard states, the standard electrode potential of the silver–silver chloride electrode is 0.22233 V at 25 °C.

An alternative electrode is the calomel electrode, illustrated in Figure 20-13(b). In this electrode, mercurous chloride (calomel, Hg_2Cl_2) is mixed with mercury to form a paste, which is in contact with liquid mercury, Hg(l), and the whole setup is immersed in either a 1.0 M solution of potassium chloride or a saturated solution of potassium chloride. The electrode is

$$\mathrm{Hg(l)}|\mathrm{Hg_2Cl_2(s)}|\mathrm{Cl^-(1.0\ M)}$$



▲ FIGURE 20-13
Schematic diagrams of some common electrodes
(a) The silver–silver chloride electrode. Silver wire is coated with silver chloride and immersed in a 1 M aqueous solution of KCl. At the bottom of the tube is a fritted (porous) disc to allow contact with a solution of interest. **(b)** The standard calomel electrode is a tube containing a paste of calomel and mercury, immersed in a 1.0 M solution of KCl. Contact with an external circuit is made with a Pt wire inserted in the inner tube; the inner tube makes contact with the outer 1.0 M solution of KCl through a small hole in the bottom of the inner tube. **(c)** A glass electrode consists of tube with a very thin glass bulb at the end and a Ag–AgCl electrode immersed in a 1.0 M HCl solution. When the glass electrode is dipped into a solution, ions interact with the membrane. The potential established on the silver wire depends on the solution being tested. **(d)** A modern pH electrode consists of a glass electrode and an internal Ag–AgCl reference electrode. There is a small sintered disc in the side of the outer tube that acts as a salt bridge between the electrode and the unknown solution.

and the half-cell reaction is

$$\frac{1}{2}Hg_2Cl_2(s) + e^- \longrightarrow Hg(l) + Cl^-(aq)$$

The standard electrode potential at 25 °C is 0.2680 V. If, however, a saturated solution of KCl is used, as opposed to one of 1 M, the reduction potential is 0.2412 V. This electrode is known as the saturated calomel electrode (SCE) and is often used as a reference.

In practice a variety of reference electrodes are used; therefore, it is necessary to quote reduction potentials with respect to a specific reference.

20-8 CONCEPT ASSESSMENT

Why do the calomel standard reduction potential and the saturated calomel electrode have different potentials?

The Glass Electrode and the Electrochemical Measurement of pH

To measure the pH of a solution electrochemically, we need an electrode that responds to changes in $[H^+(aq)]$. We noted that the standard hydrogen electrode is difficult to use for this purpose, and so, for routine use, a simpler and safer electrode is needed. Such an electrode is the *glass electrode*, which consists of a very thin walled glass bulb (see Fig. 20-13c) at the end of a tube that contains a silver–silver chloride electrode and a HCl solution of known composition (e.g., 1 M). When the bulb is placed in a solution of unknown pH, a potential develops because of the concentration difference across the membrane, analogous to a concentration cell. To measure this potential difference, a reference electrode is used, which can be either a saturated calomel electrode or a second silver–silver chloride electrode, as in the combination electrode shown in Figure 20-13(d). The overall cell can be represented as

$$\text{Ag(s)}|\text{AgCl(s)}|\text{Cl}^-(1.0\text{ M}), \text{H}^+(1.0\text{ M})|\text{glass membrane}|\text{H}^+(\text{unknown})||\text{Cl}^-(1.0\text{ M})|\text{AgCl(s)}|\text{Ag(s)}$$

where the two electrodes are connected by a salt bridge. The half-reactions are

$$\begin{aligned} Ag(s) + Cl^-(aq) &\longrightarrow AgCl(s) + e^- \\ H^+(1.0\text{ M}) &\longrightarrow H^+(\text{unknown}) \\ AgCl(s) + e^- &\longrightarrow Ag(s) + Cl^-(aq) \end{aligned}$$

The half-cell potentials of the two half-reactions for the silver–silver chloride electrodes cancel each other out and make no contribution to the cell potential. The Gibbs energy change corresponding to the dilution of protons from a known concentration of 1.0 M to the unknown solution is the source of the potential difference across the glass membrane. The Gibbs energy difference across the membrane, using $G = G° + RT \ln[H^+]$, is

$$\begin{aligned} \Delta G &= G(\text{unknown}) - G(1.0\text{ M}) \\ &= G° + RT \ln[\text{unknown}] - G° - RT \ln 1.0 \\ &= RT \ln[\text{unknown}] \end{aligned}$$

Converting this to a potential by dividing by $-zF$, $z = 1$, and assuming $T = 25\ °C$, we obtain

$$E_{\text{cell}} = 0.0592\ \text{pH}$$

after converting the logarithm to base 10 and using the definition of $\text{pH} = -\log_{10}[\text{unknown}]$. The cell potential is measured with a pH meter, a voltage measuring device that electronically converts E_{cell} to pH and displays the result in pH units.

The glass electrode was devised in 1906 by German biologist Max Cremer, and it was the prototype for a large number of membrane electrodes that are selective for a particular ion, such as the ions K^+, NH_4^+, Cl^-, and many others. Such electrodes are known collectively as *ion-selective electrodes*, and they have many applications in environmental chemistry and biochemistry.

20-5 Batteries: Producing Electricity Through Chemical Reactions

▶ Batteries are vitally important to modern society. Annual production in developed nations has been estimated at more than 10 batteries per person per year.

A **battery** is a device that stores chemical energy for later release as electricity. Some batteries consist of a single voltaic cell with two electrodes and the appropriate electrolyte(s); an example is a flashlight cell. Other batteries consist of two or more voltaic cells joined in series fashion—plus to minus—to increase the total voltage; an example is an automobile battery. In this section, we will consider three types of voltaic cells and the batteries based on them.

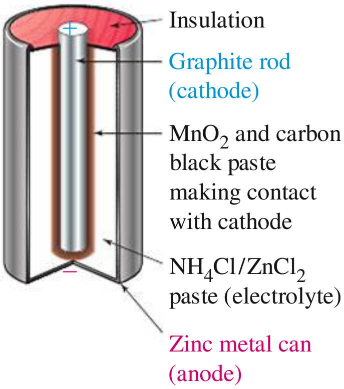
- **Primary cells.** The cell reaction in a primary cell is not reversible. When the reactants have been mostly converted to products, no more electricity is produced and a battery employing a primary cell(s) is dead.
- **Secondary cells.** The cell reaction in a secondary cell *can* be reversed by passing electricity through the cell (charging). A battery employing secondary cells can be used through several hundred or more cycles of discharging followed by charging.
- **Flow batteries** and **fuel cells.** Materials (reactants, products, and electrolytes) pass through the battery, which is simply a converter of chemical energy to electric energy. These types of batteries can be run indefinitely as long as they are supplied by electrolytes.

▶ Cell phones, laptop computers, and many other devices rely heavily on rechargeable batteries. Advances in electrochemistry and engineering are leading to the development of batteries that weigh less, last longer, and provide more power for portable electronic devices.

The Leclanché (Dry) Cell

The most common form of voltaic cell is the *Leclanché cell*, invented by the French chemist Georges Leclanché (1839–1882) in the 1860s. Popularly called a *dry cell*, because no free liquid is present, or *flashlight battery*, the Leclanché cell is diagrammed in Figure 20-14. In this cell, oxidation occurs at a zinc anode and reduction at an inert carbon (graphite) cathode. The electrolyte is a moist paste of MnO_2, $ZnCl_2$, NH_4Cl, and carbon black (soot). The maximum cell voltage is 1.55 V. The anode (oxidation) half-reaction is simple.

$$\textit{Oxidation:}\quad \mathrm{Zn(s)} \longrightarrow \mathrm{Zn^{2+}(aq)} + 2\,e^-$$



Insulation
Graphite rod (cathode)
MnO2 and carbon black paste making contact with cathode
NH4Cl/ZnCl2 paste (electrolyte)
Zinc metal can (anode)

▲ FIGURE 20-14
The Leclanché (dry) cell
The chief components of the cell are a graphite (carbon) rod serving as the cathode, a zinc container serving as the anode, and an electrolyte.

The reduction is more complex. Essentially, it involves the reduction of MnO_2 to compounds having Mn in a +3 oxidation state, for example,

$$\textit{Reduction:}\quad 2\,\mathrm{MnO_2(s)} + \mathrm{H_2O(l)} + 2\,e^- \longrightarrow \mathrm{Mn_2O_3(s)} + 2\,\mathrm{OH^-(aq)}$$

An acid–base reaction occurs between NH_4^+ (from NH_4Cl) and OH^-.

$$\mathrm{NH_4^+(aq)} + \mathrm{OH^-(aq)} \longrightarrow \mathrm{NH_3(g)} + \mathrm{H_2O(l)}$$

A buildup of $NH_3(g)$ around the cathode would disrupt the current because the $NH_3(g)$ adheres to the cathode. That buildup is prevented by a reaction between Zn^{2+} and $NH_3(g)$ to form the complex ion $[Zn(NH_3)_2]^{2+}$, which crystallizes as the chloride salt.

$$\mathrm{Zn^{2+}(aq)} + 2\,\mathrm{NH_3(g)} + 2\,\mathrm{Cl^-(aq)} \longrightarrow [\mathrm{Zn(NH_3)_2}]\mathrm{Cl_2(s)}$$

The Leclanché cell is a *primary cell*; it cannot be recharged. This cell is cheap to make, but it has some drawbacks. When current is drawn rapidly from the cell, products, such as NH_3, build up on the electrodes, causing the voltage to drop. Also, because the electrolyte medium is acidic, zinc metal slowly dissolves.

A superior form of the Leclanché cell is the *alkaline cell*, which uses NaOH or KOH in place of NH_4Cl as the electrolyte. The reduction half-reaction is the same as that shown above, but the oxidation half-reaction involves the formation of $Zn(OH)_2(s)$, which can be thought of as occurring in two steps.

$$\begin{array}{rcl} Zn(s) & \longrightarrow & Zn^{2+}(aq) + 2\,e^- \\ Zn^{2+}(aq) + 2\,OH^-(aq) & \longrightarrow & Zn(OH)_2(s) \\ \hline Zn(s) + 2\,OH^-(aq) & \longrightarrow & Zn(OH)_2(s) + 2\,e^- \end{array}$$

The advantages of the alkaline cell are that zinc does not dissolve as readily in a basic (alkaline) medium as in an acidic medium, and the cell does a better job of maintaining its voltage as current is drawn from it.

▲ **E°_{cell} is an intensive property** The voltage of a dry cell battery does not depend on the size of the battery—all of those pictured here are 1.5 V batteries. Although these batteries deliver the same voltage, the total energy output of each battery is different.

The Lead–Acid (Storage) Battery

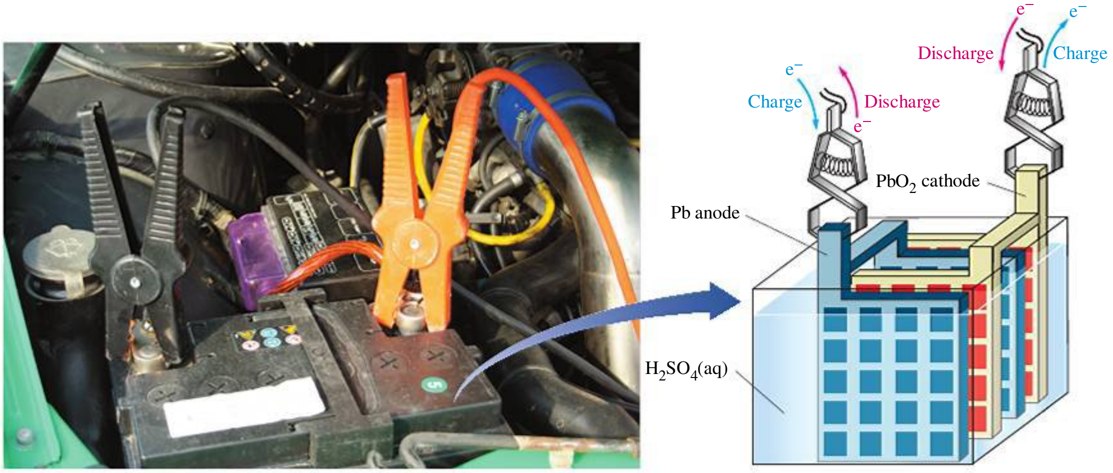
Secondary cells are commonly encountered joined together in series in the *lead–acid battery*, or *storage battery*, which has been used in automobiles since about 1915 (Fig. 20-15). A storage battery is capable of repeated use because its chemical reactions are reversible. That is, the discharged energy can be restored by supplying electric current to recharge the cells in the battery.

The reactants in a lead–acid cell are spongy lead packed into a lead grid at the anode, red-brown lead(IV) oxide packed into a lead grid at the cathode, and an electrolyte solution consisting of dilute sulfuric acid (about 35% H_2SO_4, by mass). In this strongly acidic medium, the ionization of H_2SO_4 does not go to completion. Both $HSO_4^-(aq)$ and $SO_4^{2-}(aq)$ are present, but $HSO_4^-(aq)$ predominates. The half-reactions and overall reaction are

$$\begin{array}{llcl} \textit{Reduction:} & PbO_2(s) + 3\,H^+(aq) + HSO_4^-(aq) + 2\,e^- & \longrightarrow & PbSO_4(s) + 2\,H_2O(l) \\ \textit{Oxidation:} & Pb(s) + HSO_4^-(aq) & \longrightarrow & PbSO_4(s) + H^+(aq) + 2\,e^- \\ \hline \textit{Overall:} & PbO_2(s) + Pb(s) + 2\,H^+(aq) + 2\,HSO_4^-(aq) & \longrightarrow & 2\,PbSO_4(s) + 2\,H_2O(l) \end{array}$$

$$E_{cell} = E_{PbO_2/PbSO_4} - E_{PbSO_4/Pb} = 1.74\text{ V} - (-0.28\text{ V}) = 2.02\text{ V} \qquad \textbf{(20.24)}$$

◀ You can think of the half-reactions as occurring in two steps: (1) oxidation of Pb(s) to $Pb^{2+}(aq)$ and reduction of $PbO_2(s)$ to $Pb^{2+}(aq)$, followed by (2) precipitation of $PbSO_4(s)$ at each electrode.



▲ FIGURE 20-15
A lead–acid (storage) cell
The composition of the electrodes is described in the text. The cell reaction that occurs as the cell is discharged is given in equation (20.24). The voltage of the cell is 2.02 V. In this figure, two anode plates are connected in parallel fashion, as are two cathode plates. The battery shown in this figure is the good battery used to charge a dead battery.

▶ In spite of its usefulness and ability to deliver a strong current, the lead storage battery is also a pollution hazard. All batteries should be disposed of properly and should not be dumped in land fills or garbage disposal sites.

When an automobile engine is started, the battery is at first discharged. Once the car is in motion, an alternator powered by the engine constantly recharges the battery. At times, the plates of the battery become coated with $PbSO_4(s)$ and the electrolyte becomes sufficiently diluted with water that the battery must be recharged by connecting it to an external electric source. This forces the reverse of reaction (20.24), a nonspontaneous reaction.

$$2\,PbSO_4(s) + 2\,H_2O(l) \longrightarrow Pb(s) + PbO_2(s) + 2\,H^+(aq) + 2\,HSO_4^-(aq) \qquad E_{cell} = -2.02\text{ V}$$

▶ Lead-acid storage batteries are also used to power golf carts, wheelchairs, and passenger carts in airport terminals.

To prevent the anode and cathode from coming into contact with each other, causing a *short circuit*, sheets of an insulating material are used to separate alternating anode and cathode plates. A group of anodes is connected together electrically, as is a group of cathodes. This parallel connection increases the electrode area in contact with the electrolyte solution and increases the current-delivering capacity of the cell. Cells are then joined in a series fashion, positive to negative, to produce a battery. The typical 12 V battery consists of six cells, each cell with a potential of about 2 V.

The Silver–Zinc Cell: A Button Battery

▶ Rechargeable silver oxide batteries have been developed and provide alternatives to lithium-ion batteries.

The cell diagram of a *silver–zinc cell* (Fig. 20-16) is

$$Zn(s), ZnO(s)|KOH(satd)|Ag_2O(s), Ag(s)$$

The half-reactions on discharging are

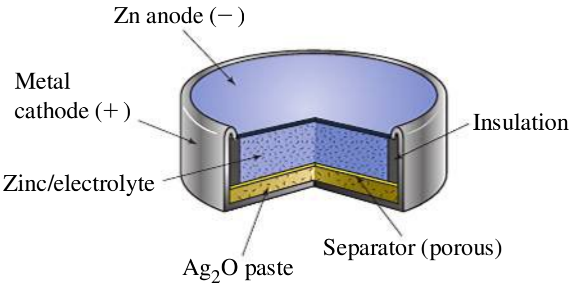
$$\begin{array}{lrcl} \textit{Reduction:} & Ag_2O(s) + H_2O(l) + 2\,e^- & \longrightarrow & 2\,Ag(s) + 2\,OH^-(aq) \\ \textit{Oxidation:} & Zn(s) + 2\,OH^-(aq) & \longrightarrow & ZnO(s) + H_2O(l) + 2\,e^- \\ \hline \textit{Overall:} & Zn(s) + Ag_2O(s) & \longrightarrow & ZnO(s) + 2\,Ag(s) \end{array} \qquad \textbf{(20.25)}$$

Because no solution species is involved in the cell reaction, the quantity of electrolyte is very small and the electrodes can be maintained very close together. The cell voltage is 1.8 V, and its storage capacity is six times greater than that of a lead–acid battery of the same size. These characteristics make batteries, such as the silver–zinc cell, useful in button batteries. These miniature batteries are used in watches, hearing aids, and cameras. In addition, silver–zinc batteries fulfill the requirements of spacecraft, satellites, missiles, rockets, space launch vehicles, torpedoes, underwater vehicles, and life-support systems. On the Mars *Pathfinder* mission, the rover and the cruise system were powered by solar cells. The energy storage requirements of the lander were met by modified silver–zinc batteries with about three times the storage capacity of the standard nickel–cadmium rechargeable battery.

The Nickel–Cadmium Cell: A Rechargeable Battery

The *nickel–cadmium cell* (or *nicad battery*) is commonly used in cordless electric devices, such as electric shavers and handheld calculators. The anode in this cell is cadmium metal, and the cathode is the Ni(III) compound NiO(OH)

▲ A rechargeable nickel–cadmium cell, or nicad battery.



▶ FIGURE 20-16
A silver–zinc button (miniature) cell

supported on nickel metal. The half-cell reactions for a nickel–cadmium battery during discharge are

$$\begin{array}{lrcl} \textit{Reduction:} & 2\,\mathrm{NiO(OH)(s)} + 2\,\mathrm{H_2O(l)} + 2\,\mathrm{e^-} & \longrightarrow & 2\,\mathrm{Ni(OH)_2(s)} + 2\,\mathrm{OH^-(aq)} \\ \textit{Oxidation:} & \mathrm{Cd(s)} + 2\,\mathrm{OH^-(aq)} & \longrightarrow & \mathrm{Cd(OH)_2(s)} + 2\,\mathrm{e^-} \\ \hline \textit{Overall:} & \mathrm{Cd(s)} + 2\,\mathrm{NiO(OH)(s)} + 2\,\mathrm{H_2O(l)} & \longrightarrow & 2\,\mathrm{Ni(OH)_2(s)} + \mathrm{Cd(OH)_2(s)} \end{array}$$

This cell gives a fairly constant voltage of 1.4 V. When the cell is recharged by connection to an external voltage source, the reactions above are reversed. Nickel–cadmium batteries can be recharged many times because the solid products adhere to the surface of the electrodes.

In primary cells the positive and negative electrodes are known as the cathode, where reduction takes place, and the anode, where oxidation takes place. In rechargeable systems, however, we have either a charging mode or a discharging mode, and so depending whether electrons are flowing out of the cell or flowing into the cell, the notion of the anode and the cathode changes. On the discharge of a nicad battery, the NiO(OH) electrode is the cathode because reduction is taking place, but on the charge, it is the anode because oxidation is taking place (the reverse reaction). In discharge mode the NiO(OH) electrode electrons are removed from the electrode because of the reduction process, and so this electrode is positively charged. In the charging mode electrons are being removed from this electrode by the oxidation process; this is the anode and it is positively charged. Therefore, regardless of charging or discharging, the NiO(OH) electrode is positive.

The negative electrode, the cadmium electrode in a nicad battery, is the anode on discharging (oxidation) and the cathode (reduction) on charging. In both charging and discharging, the anode is the electrode from which electrons exit the battery, and the cathode is the electrode at which electrons enter the battery.

In summary, when dealing with rechargeable batteries, it is better to speak of the positive and negative electrodes and avoid the terms *cathode* and *anode*.

The Lithium-Ion Battery

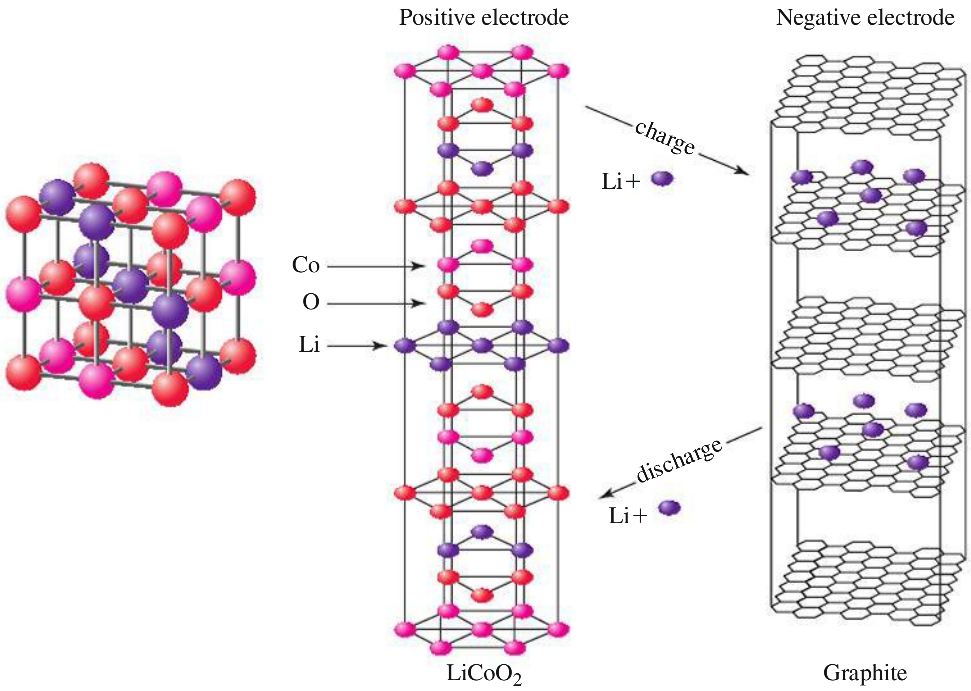
Lithium-ion batteries are a type of rechargeable battery now commonly used in consumer electronics, such as cell phones, laptop computers, and MP3 players. In a lithium-ion battery, the lithium ion moves between the positive and negative electrodes. The positive electrode consists of lithium cobalt(III) oxide, $LiCoO_2$, and the negative electrode is highly crystallized graphite. To complete the battery an electrolyte is needed, which can consist of an organic solvent and ions, such as $LiPF_6$. The structure of $LiCoO_2$ and graphite electrodes is illustrated in Figure 20-17. In the charging cycle at the positive electrode, lithium ions are released into the electrolyte solution as electrons are removed from the electrode. To maintain a charge balance, one cobalt(III) ion is oxidized to cobalt(IV) for each lithium ion released:

$$\mathrm{LiCoO_2(s)} \longrightarrow \mathrm{Li_{(1-\mathit{x})}CoO_2(s)} + x\mathrm{Li^+(solvent)} + x\,\mathrm{e^-}$$

At the negative electrode, lithium ions enter between the graphite layers and are reduced to lithium metal. This insertion of a guest atom into a host solid is called *intercalation*, and the resulting product is called an *intercalation compound*:

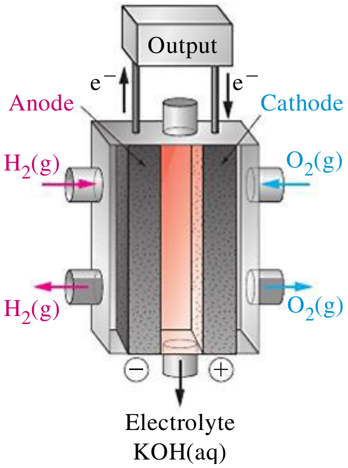
$$\mathrm{C(s)} + x\mathrm{Li^+(solvent)} + x\,\mathrm{e^-} \longrightarrow \mathrm{Li_{\mathit{x}}C(s)}$$

In the operation of a lithium-ion battery the source of the electrons is the oxidation of the Co(III) to Co(IV). The lithium ion takes these electrons to the graphite electrode during charging and returns them to the positive electrode during discharge.



▲ FIGURE 20-17
The electrodes of a lithium-ion battery
The layered graphite electrode is shown with lithium ions (violet) intercalated. The $LiCoO_2$ is shown as a face-centered cubic lattice, with the oxygen atoms (red) occupying the corners and the faces, the cobalt atoms (pink) occupying half of the edges, and the lithium atoms occupying half of the edges and the central octahedral hole. This arrangement leads to planes of oxygen, cobalt, oxygen, lithium, oxygen, cobalt, and oxygen atoms, as indicated in the figure.

Many other lithium batteries exist that use many different materials for the positive electrode, while graphite is the most common negative electrode. A major development is in the use of conducting polymers as the electrolyte, which has led to a whole range of *lithium-ion polymer batteries*. The development of new batteries based on lithium ions is currently an area of great interest.



▲ FIGURE 20-18
A hydrogen–oxygen fuel cell
A key requirement in fuel cells is porous electrodes that allow for easy access of the gaseous reactants to the electrolyte. The electrodes chosen should also catalyze the electrode reactions.

Fuel Cells

The three types of cells considered in the remainder of this section fall into the third category mentioned on page 888; they are found in flow batteries.

For most of the twentieth century, scientists explored the possibility of converting the chemical energy of fuels directly to electricity. The essential process in a fuel cell is *fuel* + *oxygen* ⟶ *oxidation products*. The first fuel cells were based on the reaction of hydrogen and oxygen. Figure 20-18 represents such a fuel cell. The overall change is that $H_2(g)$ and $O_2(g)$ in an alkaline medium produce $H_2O(l)$.

$$\begin{array}{lrcl} \textit{Reduction:} & O_2(g) + 2\,H_2O(l) + 4\,e^- & \longrightarrow & 4\,OH^-(aq) \\ \textit{Oxidation:} & \underline{2\,\{H_2(g) + 2\,OH^-(aq)} & \underline{\longrightarrow} & \underline{2\,H_2O(l) + 2\,e^-\}} \\ \textit{Overall:} & 2\,H_2(g) + O_2(g) & \longrightarrow & 2\,H_2O(l) \end{array} \qquad \textbf{(20.26)}$$

$$E^\circ_{cell} = E^\circ_{O_2/OH^-} - E^\circ_{H_2O/H_2} = 0.401\text{ V} - (-0.828\text{ V}) = 1.229\text{ V}$$

The theoretical maximum energy available as electric energy in any electrochemical cell is the Gibbs energy change for the cell reaction, ΔG°. The maximum energy release when a fuel is burned is the enthalpy change, ΔH°. One of the measures used to evaluate a fuel cell is the *efficiency value*, $\varepsilon = \Delta G^\circ/\Delta H^\circ$. For the hydrogen–oxygen fuel cell, $\varepsilon = -474.4\text{ kJ}/-571.6\text{ kJ} = 0.83$.

The day is fast approaching when fuel cells based on the direct oxidation of common fuels will become a reality. For example, the half-reaction and cell reaction for a fuel cell using methane (natural gas) are

$$\begin{array}{ll} \textit{Reduction:} & 2\{O_2(g) + 4\,H^+ + 4\,e^- \longrightarrow 2\,H_2O(l)\} \\ \textit{Oxidation:} & CH_4(g) + 2\,H_2O(l) \longrightarrow CO_2(g) + 8\,H^+ + 8\,e^- \\ \hline \textit{Overall:} & CH_4(g) + 2\,O_2(g) \longrightarrow CO_2(g) + 2\,H_2O(l) \end{array}$$

$$\Delta H^\circ = -890\text{ kJ} \qquad \Delta G^\circ = -818\text{ kJ} \qquad \varepsilon = 0.92 \qquad \textbf{(20.27)}$$

Although methane fuel cells are still in the research stage, an automobile engine is currently under development in which (1) a liquid hydrocarbon is vaporized; (2) the vaporized fuel is partially oxidized to CO(g); (3) in the presence of a catalyst, steam converts the CO(g) to $CO_2(g)$ and $H_2(g)$; and (4) $H_2(g)$ and air are fed through a fuel cell, producing electric energy.

A fuel cell should actually be called an *energy converter* rather than a battery. As long as fuel and $O_2(g)$ are available, the cell will produce electricity. It does not have the limited capacity of a primary battery or the fixed storage capacity of a secondary battery. Fuel cells based on reaction (20.26) have had their most notable successes as energy sources in space vehicles. (Water produced in the cell reaction is also a valuable product of the fuel cell.)

▲ This Toyota prototype is a fuel-cell-powered electric car producing hydrogen from gasoline.

◀ Fuel cells are environmentally friendly. Oxygen and hydrogen are readily available. Hydrogen, although dangerous, can now be transported safely by the use of special materials that can adsorb large volumes.

Air Batteries

In a fuel cell, $O_2(g)$ is the oxidizing agent that oxidizes a fuel such as $H_2(g)$ or $CH_4(g)$. Another kind of flow battery, because it uses $O_2(g)$ from air, is known as an *air battery*. The substance that is oxidized in an air battery is typically a metal.

One heavily studied battery system is the aluminum–air battery in which oxidation occurs at an aluminum anode and reduction at a carbon–air cathode. The electrolyte circulated through the battery is NaOH(aq). Because it is in the presence of a high concentration of OH^-, Al^{3+} produced at the anode forms the complex ion $[Al(OH)_4]^-$. The operation of the battery is suggested by Figure 20-19. The half-reactions and the overall cell reaction are

$$\begin{array}{ll} \textit{Reduction:} & 3\{O_2(g) + 2\,H_2O(l) + 4\,e^- \longrightarrow 4\,OH^-(aq)\} \\ \textit{Oxidation:} & 4\{Al(s) + 4\,OH^-(aq) \longrightarrow [A1(OH)_4]^-(aq) + 3\,e^-\} \\ \hline \textit{Overall:} & 4\,A1(s) + 3\,O_2(g) + 6\,H_2O(l) + 4\,OH^-(aq) \longrightarrow 4[A1(OH)_4]^-(aq) \qquad \textbf{(20.28)} \end{array}$$

The battery is kept charged by feeding chunks of Al and water into it. A typical air battery can power an automobile several hundred miles before refueling is necessary. The electrolyte is circulated outside the battery, where $Al(OH)_3(s)$ is precipitated from the $[Al(OH)_4]^-(aq)$. This $Al(OH)_3(s)$ is collected and can then be converted back to aluminum metal at an aluminum manufacturing facility.

20-9 CONCEPT ASSESSMENT

Why do dry cells and lead-acid cells "run down" during use? Do you think a fuel cell runs down? Explain.

20-6 Corrosion: Unwanted Voltaic Cells

The reactions occurring in voltaic cells (batteries) are important sources of electricity, but similar reactions also underlie corrosion processes. First, we will consider the electrochemical basis of corrosion, and then we will see how electrochemical principles can be applied to control corrosion.

▶ This and other tests for iron(II) are described more fully in Section 23-5.

Figure 20-20(a) demonstrates the basic processes in the corrosion of an iron nail. The nail is embedded in an agar gel in water. The gel contains the common acid–base indicator phenolphthalein and potassium ferricyanide, $K_3[Fe(CN)_6]$. Within hours of starting the experiment, a deep blue precipitate forms at the head and tip of the nail. Along the body of the nail, the agar gel turns pink. The blue precipitate, Turnbull's blue, establishes the presence of iron(II). The pink color is that of phenolphthalein in basic solution. From these observations, we write two simple half-equations.

$$\begin{aligned} &\textit{Reduction:} && O_2(g) + 2\,H_2O(l) + 4\,e^- \longrightarrow 4\,OH^-(aq) \\ &\textit{Oxidation:} && 2\,Fe(s) \longrightarrow 2\,Fe^{2+}(aq) + 4\,e^- \end{aligned}$$

The potential difference for these two half-reactions is

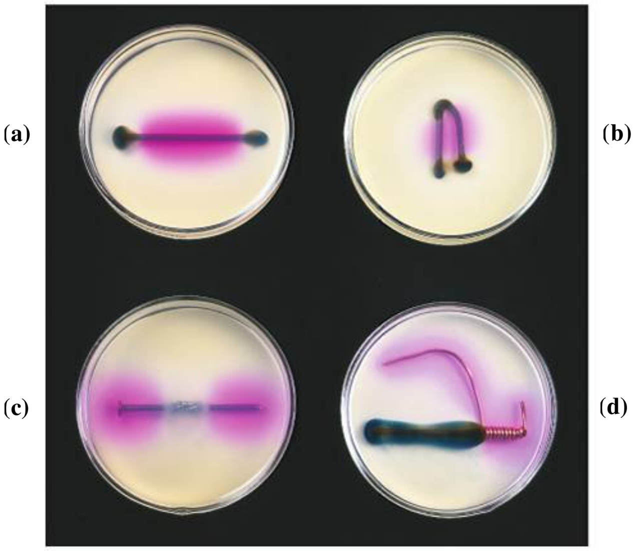
$$E^\circ_{cell} = E^\circ_{O_2/OH^-} - E^\circ_{Fe^{2+}/Fe} = 0.401\ V - (-0.440\ V) = 0.841\ V$$

indicating that the corrosion process should be spontaneous when reactants and products are in their standard states. Typically, the corrosion medium has $[OH^-] \ll 1$ M, the reduction half-reaction is even more favorable, and E_{cell} is even greater than 0.841 V. Corrosion is especially significant in acidic solutions, in which the reduction half-reaction is

$$O_2(g) + 4\,H^+(aq) + 4\,e^- \longrightarrow 2\,H_2O(l) \qquad E^\circ_{O_2/H_2O} = 1.229\ V$$

In the corroding nail of Figure 20-20(a), oxidation occurs at the head and tip. Electrons given up in the oxidation move along the nail and are used to reduce dissolved O_2. The reduction product, OH^-, is detected by the phenolphthalein. In the bent nail in Figure 20-20(b), oxidation occurs at *three* points: the head and tip and also the bend. The nail is preferentially oxidized

▶ FIGURE 20-20
Demonstration of corrosion and methods of corrosion protection
The pink color results from the indicator phenolphthalein in the presence of base; the dark blue color results from the formation of Turnbull's blue $KFe[Fe(CN)_6]$. Corrosion (oxidation) of the nail occurs at strained regions: **(a)** the head and tip and **(b)** a bend in the nail. **(c)** Contact with zinc protects the nail from corrosion. Zinc is oxidized instead of the iron (forming the faint white precipitate of zinc ferricyanide). **(d)** Copper does not protect the nail from corrosion. Electrons lost in the oxidation half-reaction distribute themselves along the copper wire, as seen by the pink color that extends the full length of the wire.



at these points because the strained metal is more active (more anodic) than the unstrained metal. This situation is similar to the preferential rusting of a dented automobile fender.

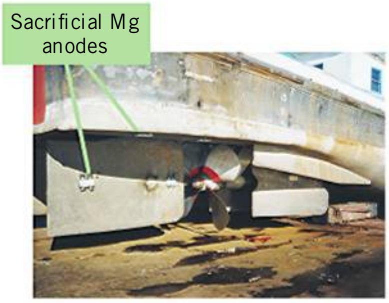
Some metals, such as aluminum, form corrosion products that adhere tightly to the underlying metal and protect it from further corrosion. Iron oxide (rust), however, flakes off and constantly exposes fresh surface. This difference in corrosion behavior explains why cans made of iron deteriorate rapidly in the environment, whereas aluminum cans have an almost unlimited lifetime. The simplest method of protecting a metal from corrosion is to cover it with paint or some other protective coating impervious to water, an important reactant and solvent in corrosion processes.

Another method of protecting an iron surface is to plate it with a thin layer of a second metal. Iron can be plated with copper by electroplating or with tin by dipping the iron into molten tin. In either case, the underlying metal is protected as long as the coating remains intact. If the coating is cracked, as when a "tin" can is dented, the underlying iron is exposed and begins to corrode. Iron, being more active than copper and tin, undergoes oxidation; the reduction half-reaction occurs on the plating (Figs. 20-20d and 20-21).

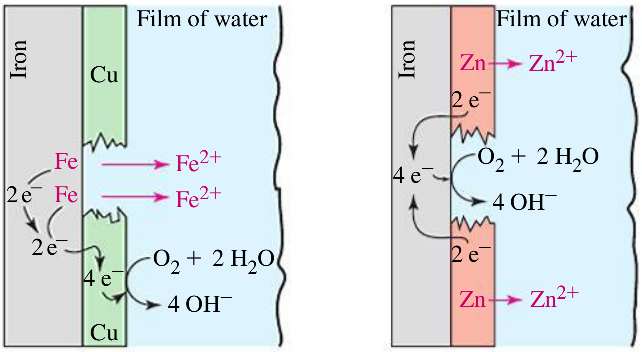
When iron is coated with zinc (galvanized iron), the situation is different. Zinc is more active than iron. If a break occurs in the zinc plating, the iron is still protected because the zinc is oxidized instead of the iron, and corrosion products protect the zinc from further corrosion (Figs. 20-20c and 20-21).

Still another method is used to protect large iron and steel objects in contact with water or moist soils—ships, storage tanks, pipelines, plumbing systems. This method involves connecting a chunk of magnesium or some other active metal to the object, either directly or through a wire. Oxidation occurs at the active metal, which slowly dissolves. The iron surface acquires electrons from the oxidation of the active metal; the iron acts as a cathode and supports a *reduction* half-reaction. As long as some of the active metal remains, the iron is protected. This type of protection is called **cathodic protection**, and the active metal is called, appropriately, a *sacrificial anode*. Millions of pounds of magnesium are used annually in the United States in sacrificial anodes.

▲ **Galvanized nails**



▲ **Magnesium sacrificial anodes** The small cylindrical bars of magnesium attached to the steel ship provide cathodic protection against corrosion.



(a) Copper-plated iron **(b)** Galvanized iron

▲ FIGURE 20-21

Protection of iron against electrolytic corrosion

In the *anodic* reaction, the metal that is more easily oxidized loses electrons to produce metal ions. In **(a)**, this is iron; in **(b)**, it is zinc. In the *cathodic* reaction, oxygen gas, which is dissolved in a thin film of water on the metal, is reduced to OH^-. Rusting of iron occurs in (a), but it does not in (b). When iron corrodes, Fe^{2+} and OH^- ions from the half-reactions initiate these further reactions.

$$\begin{aligned} Fe^{2+} + 2\,OH^- &\longrightarrow Fe(OH)_2(s) \\ 4\,Fe(OH)_2(s) + O_2 + 2\,H_2O &\longrightarrow 4\,Fe(OH)_3(s) \\ 2\,Fe(OH)_3(s) &\longrightarrow \underset{\text{rust}}{Fe_2O_3 \cdot H_2O(s)} + H_2O(l) \end{aligned}$$

20-10 CONCEPT ASSESSMENT

Of the metals Al, Cu, Ni, and Zn, which could act as a sacrificial anode for iron?

20-7 Electrolysis: Causing Nonspontaneous Reactions to Occur

KEEP IN MIND

that voltaic (galvanic) and electrolytic cells are the two categories subsumed under the more general term *electrochemical cell.*

Until now, the emphasis has been on voltaic (galvanic) cells, electrochemical cells in which chemical change is used to produce electricity. Another type of electrochemical cell—the **electrolytic cell**—uses electricity to produce a *nonspontaneous* reaction. The process in which a nonspontaneous reaction is driven by the application of electric energy is called **electrolysis**.

Let's explore the relationship between voltaic and electrolytic cells by returning briefly to the cell shown in Figure 20-4. When the cell functions spontaneously, electrons flow from the zinc to the copper and the overall chemical change in the voltaic cell is

$$\mathrm{Zn(s)} + \mathrm{Cu^{2+}(aq)} \longrightarrow \mathrm{Zn^{2+}(aq)} + \mathrm{Cu(s)} \qquad E^\circ_{\text{cell}} = 1.103\ \mathrm{V}$$

Now suppose the same cell is connected to an external electric source of voltage greater than 1.103 V (Fig. 20-22). That is, the connection is made so that electrons are forced into the zinc electrode (now the cathode) and removed from the copper electrode (now the anode). The overall reaction in this case is the *reverse* of the voltaic cell reaction, and E°_{cell} is *negative*.

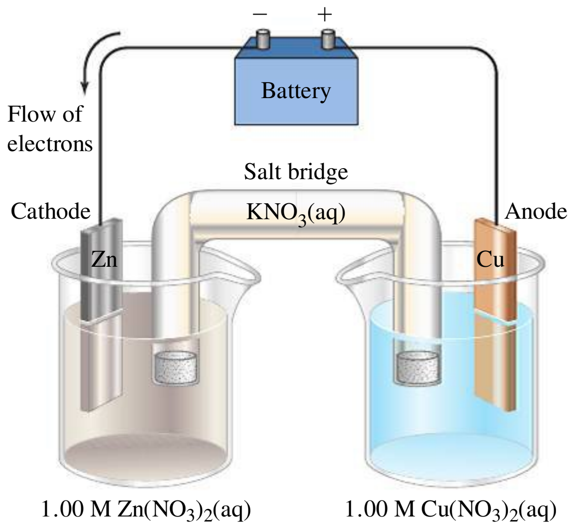
$$\begin{array}{lrcl}
\textit{Reduction:} & \mathrm{Zn^{2+}(aq)} + 2\,\mathrm{e^-} & \longrightarrow & \mathrm{Zn(s)} \\
\textit{Oxidation:} & \mathrm{Cu(s)} & \longrightarrow & \mathrm{Cu^{2+}(aq)} + 2\,\mathrm{e^-} \\
\hline
\textit{Overall:} & \mathrm{Cu(s)} + \mathrm{Zn^{2+}(aq)} & \longrightarrow & \mathrm{Cu^{2+}(aq)} + \mathrm{Zn(s)}
\end{array}$$

$$E^\circ_{\text{cell}} = E^\circ_{\mathrm{Zn^{2+}/Zn}} - E^\circ_{\mathrm{Cu^{2+}/Cu}} = -0.763\ \mathrm{V} - 0.340\ \mathrm{V} = -1.103\ \mathrm{V}$$

Thus, reversing the direction of the electron flow changes the voltaic cell into an electrolytic cell.

Predicting Electrolysis Reactions

For the cell in Figure 20-22 to function as an electrolytic cell with reactants and products in their standard states, the external voltage has to exceed 1.103 V.



▶ FIGURE 20-22
An electrolytic cell
The direction of electron flow is the reverse of that in the voltaic cell of Figure 20-4, and so is the cell reaction. Now the zinc electrode is the *cathode* and the copper electrode, the *anode*. The battery must have a voltage in excess of 1.103 V in order to force electrons to flow in the reverse (nonspontaneous) direction.

20-2 ARE YOU WONDERING...

Why the anode is (+) in an electrolytic cell but (−) in a voltaic cell?

Assigning the terms *anode* and *cathode* is not based on the electrode charges; it is based on the half-reactions at the electrode surfaces. Specifically,

- *Oxidation* always occurs at the *anode* of an electrochemical cell. Because of the buildup of electrons freed in the oxidation half-reaction, the anode of a *voltaic* cell is (−). Because electrons are withdrawn from it, the anode in an *electrolytic* cell is (+). For both cell types, the anode is the electrode from which electrons *exit* the cell.
- *Reduction* always occurs at the cathode of an electrochemical cell. Because of the *removal* of electrons by the reduction half-reaction, the cathode of a *voltaic* cell is (+). Because of the electrons forced onto it, the cathode of an *electrolytic* cell is (−). For both cell types, the cathode is the electrode at which electrons *enter* the cell.

The following table summarizes the relationship between a voltaic cell and an electrolytic cell.

	Voltaic Cell			Electrolytic Cell	
Oxidation:	$A \longrightarrow A^+ + e^-$	Anode (negative)	*Oxidation:*	$B \longrightarrow B^+ + e^-$	Anode (positive)
Reduction:	$B^+ + e^- \longrightarrow B$	Cathode (positive)	*Reduction:*	$A^+ + e^- \longrightarrow A$	Cathode (negative)
Overall:	$A + B^+ \longrightarrow A^+ + B$ $\Delta G < 0$ Spontaneous redox reaction releases energy		*Overall:*	$A^+ + B \longrightarrow A + B^+$ $\Delta G > 0$ Nonspontaneous redox reaction absorbs energy to drive it	
	The system (the cell) does work on the surroundings			The surroundings (the source of energy) do work on the system	

Note that the sign of each electrode in an electrolytic cell is the same as the sign of the battery electrode to which it is attached.

We can make similar calculations for other electrolyses. What actually happens, however, does not always correspond to these calculations. Four complicating factors must be considered:

1. A voltage significantly in excess of the calculated value, an **overpotential**, may be necessary to cause a particular electrode reaction to occur. Overpotentials are needed to overcome interactions at the electrode surface and are particularly common when gases are involved. For example, the overpotential for the discharge of $H_2(g)$ at a mercury cathode is approximately 1.5 V; the overpotential on a platinum cathode is practically zero.
2. Competing electrode reactions may occur. In the electrolysis of *molten* sodium chloride with inert electrodes, only one oxidation and one reduction are possible.

$$\textit{Reduction:} \quad 2\,\mathrm{Na}^+ + 2\,e^- \longrightarrow 2\,\mathrm{Na(l)}$$

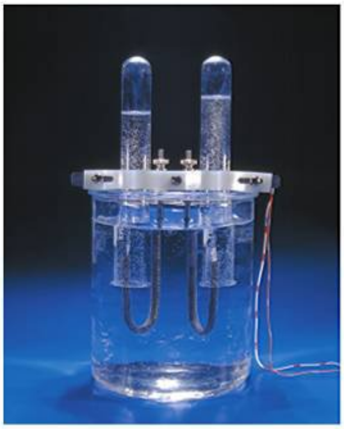
$$\textit{Oxidation:} \quad 2\,\mathrm{Cl}^- \longrightarrow \mathrm{Cl_2(g)} + 2\,e^-$$

In the electrolysis of *aqueous* sodium chloride with inert electrodes, there are *two* possible reduction half-reactions and *two* possible oxidation half-reactions.

$$\begin{array}{llll} \textit{Reduction:} & 2\,Na^+(aq) + 2\,e^- \longrightarrow Na(s) & E^\circ_{Na^+/Na} = -2.71\ V & \textbf{(20.29)} \\ & 2\,H_2O(l) + 2\,e^- \longrightarrow H_2(g) + 2\,OH^-(aq) & E^\circ_{H_2O/H_2} = (-0.83\ V) & \textbf{(20.30)} \\ \textit{Oxidation:} & 2\,Cl^-(aq) \longrightarrow Cl_2(g) + 2\,e^- & -E^\circ_{Cl_2/Cl^-} = -(1.36\ V) & \textbf{(20.31)} \\ & 2\,H_2O(l) \longrightarrow O_2(g) + 4\,H^+(aq) + 4\,e^- & -E^\circ_{O_2/H_2O} = -(1.23\ V) & \textbf{(20.32)} \end{array}$$

▶ We have written a *minus* sign in front of the electrode potentials in (20.31) and (20.32) as a way of emphasizing the *oxidation* rather than the reduction tendency.

Reaction (20.29) can be eliminated as a possible reduction half-reaction: Unless the overpotential for $H_2(g)$ is unusually high, the reduction of Na^+ is far more difficult to accomplish than that of H_2O. This leaves two possibilities for the cell reaction.



▲ The electrolysis of water into $H_2(g)$ and $O_2(g)$, shown by bubbles at the electrodes and the gases collecting in the test tubes—twice the volume of $H_2(g)$ as $O_2(g)$.

Half-reaction (20.30) + half-reaction (20.31):

$$\begin{array}{lll} \textit{Reduction:} & 2\,H_2O(l) + 2\,e^- \longrightarrow H_2(g) + 2\,OH^-(aq) & \\ \textit{Oxidation:} & 2\,Cl^-(aq) \longrightarrow Cl_2(g) + 2\,e^- & \\ \hline \textit{Overall:} & 2\,Cl^-(aq) + 2\,H_2O(l) \longrightarrow Cl_2(g) + H_2(g) + 2\,OH^-(aq) & \textbf{(20.33)} \end{array}$$

$$E^\circ_{cell} = E^\circ_{H_2O/H_2} - E^\circ_{Cl_2/Cl^-} = -0.83\ V - (1.36\ V) = -2.19\ V$$

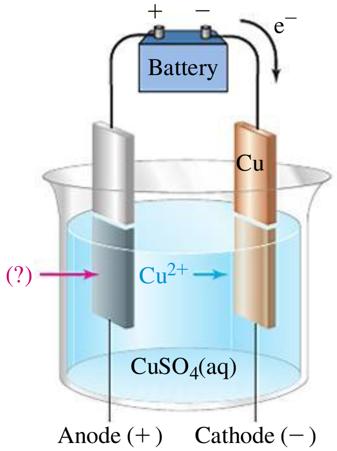
Half-reaction (20.30) + half-reaction (20.32):

$$\begin{array}{lll} \textit{Reduction:} & 2\{2\,H_2O(l) + 2\,e^- \longrightarrow H_2(g) + 2\,OH^-(aq)\} & \\ \textit{Oxidation:} & 2\,H_2O(l) \longrightarrow O_2(g) + 4\,H^+(aq) + 4\,e^- & \\ \hline \textit{Overall:} & 2\,H_2O(l) \longrightarrow 2\,H_2(g) + O_2(g) & \textbf{(20.34)} \end{array}$$

$$E^\circ_{cell} = E^\circ_{H_2O/H_2} - E^\circ_{O_2/H_2O} = -0.83\ V - (1.23\ V) = -2.06\ V$$

In the electrolysis of NaCl(aq), $H_2(g)$ is the product expected at the *cathode*. Because cell reactions (20.33) and (20.34) have E°_{cell} values that are so similar, a mixture of $Cl_2(g)$ and $O_2(g)$ would be the expected product at the *anode*. Actually, because of the high overpotential of $O_2(g)$ compared to $Cl_2(g)$, cell reaction (20.33) predominates; $Cl_2(g)$ is essentially the only product at the anode.

3. The reactants very often are in *nonstandard* states. In the industrial electrolysis of NaCl(aq), $[Cl^-] \approx 5.5$ M, not the unit activity ($[Cl^-] \approx 1$ M) implied in half-reaction (20.31); therefore $E_{Cl_2/Cl^-} = 1.31$ V (*not* 1.36 V). Also, the pH in the anode half-cell is adjusted to 4, not the unit activity ($[H_3O^+] \approx 1$ M) implied in half-reaction (20.32); hence $E_{O_2/H_2O} = 0.99$ V (*not* 1.23 V). The net effect of these nonstandard conditions is to favor the production of O_2 at the anode. In practice, however, the $Cl_2(g)$ obtained contains less than 1% $O_2(g)$, indicating the overpowering effect of the high overpotential of $O_2(g)$. Not surprisingly, the proportion of $O_2(g)$ increases significantly in the electrolysis of very dilute NaCl(aq).
4. The nature of the electrodes matters. An *inert electrode*, such as platinum, provides a surface on which an electrolysis half-reaction occurs, but the reactants themselves must come from the electrolyte solution. An *active electrode* is one that can itself participate in the oxidation or reduction half-reaction. The distinction between inert and active electrodes is explored in Figure 20-23 and Example 20-12.



▲ FIGURE 20-23
Predicting electrode reactions in electrolysis—Example 20-11 illustrated
Electrons are forced onto the copper cathode by the external source (battery). Cu^{2+} ions are attracted to the cathode and are reduced to Cu(s). The oxidation half-reaction depends on the metal used for the anode.

Quantitative Aspects of Electrolysis

We have seen how to calculate the theoretical voltage required for electrolysis. Equally important are calculations of the quantities of reactants consumed and products formed in an electrolysis. For these calculations, we will continue to use stoichiometric factors from the chemical equation, but another

EXAMPLE 20-12 Predicting Electrode Half-Reactions and Overall Reactions in Electrolysis

Refer to Figure 20-23. Predict the electrode reactions and the overall reaction when the anode is made of **(a)** copper and **(b)** platinum.

Analyze

In both cases we have to decide on the likely oxidation and reduction processes. The low reduction potential of $Cu^{2+}(aq)$ makes this the likely reduction process in both cases. What about oxidation processes? The possibilities are in **(a)** oxidation of the copper electrode (anode) ($E° = 0.340$ V), oxidation of sulfate anion (2.01 V), and oxidation of water (1.23 V). Thus, the most easily oxidized is the copper at the anode. In **(b)**, the platinum electrode is inert and is not easily oxidized. Of the other two candidates, sulfate anion and water, water has the lower oxidation potential.

Solve

$$\textit{Reduction:}\quad \mathrm{Cu^{2+}(aq) + 2\,e^- \longrightarrow Cu(s)} \qquad E^\circ_{\mathrm{Cu^{2+}/Cu}} = 0.340\ \mathrm{V}$$

(a) At the cathode we have the reduction of $Cu^{2+}(aq)$. At the anode, Cu(s) can be oxidized to $Cu^{2+}(aq)$, as represented by

$$\textit{Oxidation:}\quad \mathrm{Cu(s) \longrightarrow Cu^{2+}(aq) + 2\,e^-}$$

If the oxidation and reduction half-equations are added, $Cu^{2+}(aq)$ cancels out. The electrolysis reaction is simply

$$\mathrm{Cu(s)[anode] \longrightarrow Cu(s)[cathode]} \qquad \textbf{(20.35)}$$

$$E^\circ_{\mathrm{cell}} = E^\circ_{\mathrm{Cu^{2+}/Cu}} - E^\circ_{\mathrm{Cu^{2+}/Cu}} = 0.340\ \mathrm{V} - 0.340\ \mathrm{V} = 0$$

(b) The oxidation that occurs most readily is that of H_2O, shown in reaction (20.32).

$$\textit{Oxidation:}\quad \mathrm{2\,H_2O(l) \longrightarrow O_2(g) + 4\,H^+(aq) + 4\,e^-}$$

$$-E^\circ_{\mathrm{O_2/H_2O}} = -1.23\ \mathrm{V}$$

The electrolysis reaction and its E°_{cell} are

$$\mathrm{2\,Cu^{2+}(aq) + 2\,H_2O(l) \longrightarrow 2\,Cu(s) + 4\,H^+(aq) + O_2(g)} \qquad \textbf{(20.36)}$$

$$\begin{aligned} E^\circ_{\mathrm{cell}} &= E^\circ(\text{reduction half-cell}) - E^\circ(\text{oxidation half-cell}) \\ &= E^\circ_{\mathrm{Cu^{2+}/Cu}} - E^\circ_{\mathrm{O_2/H_2O}} \\ &= 0.340\ \mathrm{V} - 1.23\ \mathrm{V} = -0.89\ \mathrm{V} \end{aligned}$$

Assess

(a) Only a very small voltage is needed to overcome the resistance in the electric circuit for this electrolysis. For every Cu atom that enters the solution at the anode, an active electrode, one Cu^{2+} ion, deposits as a Cu atom at the cathode. Copper is transferred from the anode to the cathode through the solution as Cu^{2+} and the concentration of $CuSO_4(aq)$ remains unchanged.

(b) A potential greater than 0.89 V is required to electrolyze water and deposit copper. Keep in mind that when calculating E°_{cell} as a *difference* between two $E°$ values, the $E°$ values are reduction potentials. Because $-E°$ corresponds to the half-cell potential for the oxidation process, the *difference* between two reduction potentials is equivalent to the *sum* of a reduction potential and an oxidation potential.

PRACTICE EXAMPLE A: Use data from Table 20.1 to predict the probable products when Pt electrodes are used in the electrolysis of KI(aq).

PRACTICE EXAMPLE B: In the electrolysis of $AgNO_3(aq)$, what are the expected electrolysis products if the anode is silver metal and the cathode is platinum?

factor enters in as well: the quantity of electric charge associated with one mole of electrons. This factor is provided by the Faraday constant, which we can write as

$$1\ \mathrm{mol\ e^-} = 96{,}485\ \mathrm{C}$$

Generally, electric charge is not measured directly; instead, it is the electric current that is measured. One *ampere* (A) of electric current represents the passage of 1 coulomb of charge per second (C/s). The product of current and time yields the total quantity of charge transferred.

$$\text{charge (C)} = \text{current (C/s)} \times \text{time (s)}$$

To determine the number of moles of electrons involved in an electrolysis reaction, we can write

$$\text{number of mol e}^- = \text{current}\left(\frac{\text{C}}{\text{s}}\right) \times \text{time (s)} \times \frac{1 \text{ mol e}^-}{96{,}485 \text{ C}}$$

As illustrated in Example 20-13, to determine the mass of a product in an electrolysis reaction, follow this conversion pathway.

$$\text{C/s} \longrightarrow \text{C} \longrightarrow \text{mol e}^- \longrightarrow \text{mol product} \longrightarrow \text{g product}$$

EXAMPLE 20-13 Calculating Quantities Associated with Electrolysis Reactions

The electrodeposition of copper can be used to determine the copper content of a sample. The sample is dissolved to produce $Cu^{2+}(aq)$, which is electrolyzed. At the cathode, the reduction half-reaction is $Cu^{2+}(aq) + 2\,e^- \longrightarrow Cu(s)$. What mass of copper can be deposited in 1.00 hour by a current of 1.62 A?

Analyze

To find the mass of copper deposited, we first need to determine the number of moles of electrons generated in the given time. Because we know that for each copper(II) ion we need two electrons, we can calculate the mass by using the number of moles of electrons.

Solve

First, we determine the number of moles of electrons involved in the electrolysis in the manner outlined above:

$$1.00 \text{ h} \times \frac{60 \text{ min}}{1 \text{ h}} \times \frac{60 \text{ s}}{1 \text{ min}} \times \frac{1.62 \text{ C}}{1 \text{ s}} \times \frac{1 \text{ mol e}^-}{96{,}485 \text{ C}} = 0.0604 \text{ mol e}^-$$

The mass of Cu(s) produced at the cathode by this number of moles of electrons is calculated as follows:

$$\text{mass of Cu} = 0.0604 \text{ mol e}^- \times \frac{1 \text{ mol Cu}}{2 \text{ mol e}^-} \times \frac{63.5 \text{ g Cu}}{1 \text{ mol Cu}} = 1.92 \text{ g Cu}$$

Assess

The key factor in this calculation, relating moles of copper to moles of electrons, is printed in blue. This type of conversion is very similar to the one you learned when doing stoichiometric problems.

PRACTICE EXAMPLE A: If 12.3 g of Cu is deposited at the cathode of an electrolytic cell after 5.50 h, what was the current used?

PRACTICE EXAMPLE B: For how long would the electrolysis in Example 20-13 have to be carried out, using Pt electrodes and a current of 2.13 A, to produce 2.62 L $O_2(g)$ at 26.2 °C and 738 mmHg pressure at the anode?

20-8 Industrial Electrolysis Processes

Modern industry could not function in its present form without electrolysis reactions. A number of elements are produced almost exclusively by electrolysis—for example, aluminum, magnesium, chlorine, and fluorine. Among chemical compounds produced industrially by electrolysis are NaOH, $K_2Cr_2O_7$, $KMnO_4$, $Na_2S_2O_8$, and a number of organic compounds.

◀ The refining of copper by electrolysis.

Electrorefining

The *electrorefining* of metals involves the deposition of pure metal at a cathode, from a solution containing the metal ion. Copper produced by the smelting of copper ores is of sufficient purity for some uses, such as plumbing, but it is not pure enough for applications in which high electrical conductivity is required. For these applications, the copper must be more than 99.5% pure. The electrolysis reaction (20.35) on page 899 is used to obtain such high-purity copper. A chunk of impure copper is the anode and a thin sheet of pure copper is the cathode. During the electrolysis, Cu^{2+} produced at the anode migrates through an aqueous sulfuric acid–copper(II) sulfate solution to the cathode, where it is reduced to Cu(s). The pure copper cathode increases in size as the impure chunk of copper is consumed. As noted in Example 20-12a, the electrolysis is carried out at a low voltage—from 0.15 to 0.30 V. Under these conditions, Ag, Au, and Pt impurities are not oxidized at the anode, and they drop to the bottom of the tank as a sludge called *anode mud.* Sn, Bi, and Sb are oxidized, but they precipitate as oxides or hydroxides; Pb is oxidized but precipitates as $PbSO_4(s)$. As, Fe, Ni, Co, and Zn are oxidized but form water-soluble species. Recovery of Ag, Au, and Pt from the anode mud helps offset the cost of the electrolysis.

Electroplating

In *electroplating,* one metal is plated onto another, often less expensive, metal by electrolysis. This procedure is done for decorative purposes or to protect the underlying metal from corrosion. Silver-plated flatware, for example, consists of a thin coating of metallic silver on an underlying base of iron. In electroplating, the item to be plated is the cathode in an electrolytic cell. The electrolyte contains ions of the metal to be plated, which are attracted to the cathode, where they are reduced to metal atoms.

In copper plating, the electrolyte is usually copper sulfate. In silver plating, it is commonly $K[Ag(CN)_2](aq)$. The concentration of free silver ion in a solution of the complex ion $[Ag(CN)_2]^-(aq)$ is very low, and electroplating under these conditions promotes a strongly adherent microcrystalline deposit of the metal. Chromium plating is useful for its resistance to corrosion as well as its appearance. Steel can be chromium-plated from an aqueous solution of CrO_3 and H_2SO_4. The plating obtained, however, is thin and porous and tends to develop cracks. In practice, the steel is first plated with a thin coat of copper or nickel, and then the chromium plating is applied. Chromium plating or cadmium plating is used to weatherproof machine parts. Metal plating can even be applied to some plastics. The plastic must first be made electrically conductive—for example, by coating it with graphite powder. Copper plating of plastics has been used to improve the quality of some microelectronic circuit boards. Electroplating is even used, quite literally, to make money. The U.S. penny is no longer copper throughout. A zinc plug is electroplated with a thin coat of copper, and the copper-plated plug is stamped to create a penny.

Electrosynthesis

Electrosynthesis is a method of producing substances through electrolysis reactions. It is useful for certain syntheses in which reaction conditions must be carefully controlled. Manganese dioxide occurs naturally as the mineral *pyrolusite*, but small crystal size and lattice imperfections make this material inadequate for certain modern applications, such as alkaline batteries. The electrosynthesis of MnO_2 is carried out in a solution of $MnSO_4$ in $H_2SO_4(aq)$ Pure $MnO_2(s)$ is formed by the oxidation of Mn^{2+} at an inert anode, such as graphite.

$$\textit{Oxidation:}\quad Mn^{2+}(aq) + 2\,H_2O(l) \longrightarrow MnO_2(s) + 4\,H^+(aq) + 2\,e^-$$

The reaction at the cathode is the reduction of H^+ to $H_2(g)$, and the overall electrolysis reaction is

$$Mn^{2+}(aq) + 2\,H_2O(l) \longrightarrow MnO_2(s) + 2\,H^+(aq) + H_2(g)$$

An example of electrosynthesis in organic chemistry is the reduction of acrylonitrile, $CH_2{=}CH{-}C{\equiv}N$, to adiponitrile, $N{\equiv}C(CH_2)_4C{\equiv}N$, at a lead cathode (chosen because of the high overpotential of H_2 on lead). Oxygen is released at the anode.

$$\textit{Reduction:}\quad 2\,CH_2{=}CH{-}C{\equiv}N + 2\,H_2O + 2\,e^- \longrightarrow N{\equiv}C(CH_2)_4C{\equiv}N + 2\,OH^-$$

The commercial importance of this electrolysis is that adiponitrile can be readily converted to two other compounds: hexamethylenediamine, $H_2NCH_2(CH_2)_4CH_2NH_2$, and adipic acid, $HOOCCH_2(CH_2)_2CH_2COOH$. These two compounds are the monomers used to make the polymer *Nylon-66* (page 1253).

▲ A rack of metal parts being lifted from the electrolyte solution after electroplating.

The Chlor–Alkali Process

On page 898 we described the electrolysis of NaCl(aq) through the reduction half-reaction (20.30) and the oxidation half-reaction (20.31).

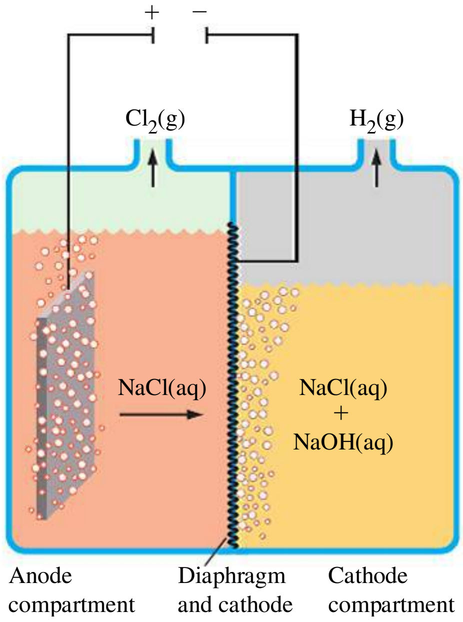
$$2\,Cl^-(aq) + 2\,H_2O(l) \longrightarrow 2\,OH^-(aq) + H_2(g) + Cl_2(g) \qquad E^\circ_{cell} = -2.19\text{ V}$$

When conducted on an industrial scale, this electrolysis is called the *chlor–alkali process*, named after the two principal products: *chlorine* and the *alkali* NaOH(aq). The chlor–alkali process is one of the most important of all electrolytic processes because of the high value of these products.

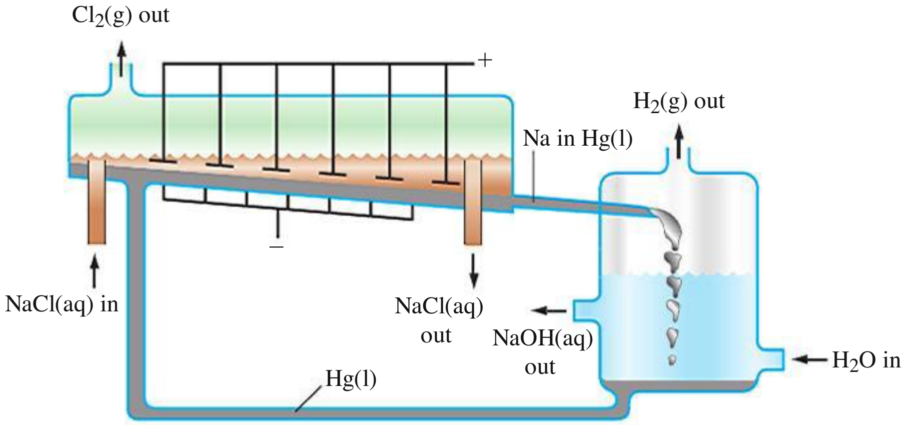
In the *diaphragm cell* depicted in Figure 20-24, $Cl_2(g)$ is produced in the anode compartment, and $H_2(g)$ and NaOH(aq) in the cathode compartment. If $Cl_2(g)$ comes in contact with NaOH(aq), the Cl_2 disproportionates into $ClO^-(aq)$, $ClO_3^-(aq)$, and $Cl^-(aq)$. The purpose of the diaphragm is to prevent this contact. The NaCl(aq) in the anode compartment is kept at a slightly higher level than that in the cathode compartment. This disparity creates a gradual flow of NaCl(aq) between the compartments and reduces the backflow of NaOH(aq) into the anode compartment. The solution in the cathode compartment, about 10%–12% NaOH(aq) and 14%–16% NaCl(aq), is concentrated and purified by evaporating some water and crystallizing the NaCl(s). The final product is 50% NaOH(aq), with up to 1% NaCl(aq).

The theoretical voltage required for this electrolysis is 2.19 V. However, as a result of the internal resistance of the cell and overpotentials at the electrodes, a voltage of about 3.5 V is used. The current is kept very high, typically about 1×10^5 A.

The NaOH(aq) produced in a diaphragm cell is not pure enough for certain uses, such as rayon manufacture. A higher purity is achieved if electrolysis is carried out in a mercury cell, illustrated in Figure 20-25. This cell takes advantage of the high overpotential for the reduction of $H_2O(l)$ to $H_2(g)$ and $OH^-(aq)$ at a



◀ FIGURE 20-24
A diaphragm chlor–alkali cell
The anode may be made of graphite or, in more modern technology, specially treated titanium metal. The diaphragm and cathode are generally fabricated as a composite unit consisting of asbestos or an asbestos–polymer mixture deposited on a steel wire mesh. To avoid the use of asbestos, a more modern development substitutes a fluorocarbon mesh for the asbestos.



▲ FIGURE 20-25
The mercury-cell chlor–alkali process
The cathode is a layer of Hg(l) that flows along the bottom of the tank. Anodes, at which $Cl_2(g)$ forms, are situated in the NaCl(aq) just above the Hg(l). Sodium formed at the cathode dissolves in the Hg(l), and the sodium amalgam is decomposed with water to produce NaOH(aq) and $H_2(g)$. The regenerated Hg(l) is recycled.

mercury cathode. The reduction that occurs instead is that of $Na^+(aq)$ to Na, which dissolves in Hg(l) to form an amalgam (Na–Hg alloy) with about 0.5% Na by mass.

$$2\,Na^+(aq) + 2\,Cl^-(aq) \longrightarrow 2\,Na(\text{in Hg}) + Cl_2(g) \qquad E^\circ_{cell} = -3.20\text{ V}$$

When the Na amalgam is removed from the cell and treated with water, NaOH(aq) forms,

$$2\,Na(\text{in Hg}) + 2\,H_2O(l) \longrightarrow 2\,Na^+(aq) + 2\,OH^-(aq) + H_2(g) + Hg(l)$$

and the liquid mercury is recycled back to the electrolytic cell.

Although the mercury cell has the advantage of producing concentrated high-purity NaOH(aq), it has some disadvantages. The mercury cell requires a higher voltage (about 4.5 V) than does the diaphragm cell (3.5 V) and consumes more electrical energy, about 3400 kWh/ton Cl_2 in a mercury cell, compared with 2500 kWh/ton Cl_2 in a diaphragm cell. Another serious drawback is the need to control mercury effluents to the environment. Mercury losses, which at one time were as high as 200 g Hg per ton Cl_2, have been reduced to about 0.25 g Hg per ton of Cl_2 in older plants and half this amount in new plants.

The ideal chlor–alkali process is one that is energy-efficient and does not use mercury. A type of cell offering these advantages is the *membrane cell*, in which the porous diaphragm of Figure 20-24 is replaced by a cation-exchange membrane, normally made of a fluorocarbon polymer. The membrane permits hydrated cations (Na^+ and H_3O^+) to pass between the anode and cathode compartments but severely restricts the backflow of Cl^- and OH^- ions. As a result, the sodium hydroxide solution produced contains less than 50 ppm chloride ion contaminant.

MasteringCHEMISTRY **www.masteringchemistry.com**

The concepts presented in this chapter can be used to explain the roles played by ions in the generation of biological electric currents. Electric currents in biological systems are generated in muscle contraction and neuron activity, for example. For a discussion of the source of biological electric currents, go to the Focus On feature for Chapter 20, Membrane Potentials, on the MasteringChemistry site.

Summary

20-1 Electrode Potentials and Their Measurement—In an **electrochemical cell** electrons in an oxidation–reduction reaction are transferred at metal strips called **electrodes** and conducted through an external circuit. The oxidation and reduction half-reactions occur in separate regions called **half-cells**. In a half-cell, an electrode is immersed in a solution. The electrodes of the two half-cells are joined by a wire, and an electrical connection between the solutions is also made, as through a **salt bridge** (Fig. 20-3). The cell reaction involves oxidation at one electrode called the **anode** and reduction at the other electrode called the **cathode**. A **voltaic (galvanic) cell** produces electricity from a spontaneous oxidation–reduction reaction. The difference in electric potential between the two electrodes is the **cell voltage**; the unit of cell voltage is the **volt (V)**. The cell voltage is also called the **cell potential** or **electromotive force (emf)** and designated as E_{cell}. A **cell diagram** displays the components of a cell in a symbolic way (expression 20-4).

20-2 Standard Electrode Potentials—The reduction occurring at a **standard hydrogen electrode (SHE)**, $2\,H^+(a = 1) + 2\,e^- \xrightarrow{\text{on Pt}} H_2(g, 1\text{ bar})$, is arbitrarily assigned a potential of zero. A half-cell has a **standard electrode potential**, $E°$, in which all reactants and products are at unit activity. A half-cell reaction with a *positive* standard electrode potential ($E°$) occurs more readily than does reduction of H^+ ions at the SHE. A *negative* standard electrode potential signifies a lesser tendency to undergo reduction. The **standard cell potential** ($E°_{\text{cell}}$) of a voltaic cell is the *difference* between $E°$, of the cathode and $E°$, of the anode; that is, $E°_{\text{cell}} = E°(\text{cathode}) - E°(\text{anode})$.

20-3 E_{cell}, ΔG, and K—Cell voltages based on standard electrode potentials are $E°_{\text{cell}}$ values. The electrical work that can be obtained from a cell depends on the number of electrons involved in the cell reaction, the cell potential, and the **Faraday constant (F)**, which is the number of coulombs of charge per mole of electrons—96,485 C/mol e^-. An important relationship exists between $E°_{\text{cell}}$ and $\Delta G°$, namely, $\Delta G° = -zFE°_{\text{cell}}$. The equilibrium constant of the cell reaction K is related to $E°_{\text{cell}}$ through the expression $\Delta G° = -RT \ln K = -zFE°_{\text{cell}}$.

20-4 E_{cell} as a Function of Concentrations—In the **Nernst equation**, E_{cell} for nonstandard conditions is related to $E°_{\text{cell}}$ and the reaction quotient Q (equation 20.18). If $E_{\text{cell}} > 0$, the cell reaction is spontaneous in the forward direction for the stated conditions; if $E_{\text{cell}} < 0$, the forward reaction is *nonspontaneous* for those conditions. A **concentration cell** consists of two half-cells with identical electrodes but different solution concentrations.

20-5 Batteries: Producing Electricity Through Chemical Reactions—An important application of voltaic cells is found in various battery systems. A **battery** stores chemical energy so that it can be released as energy. Batteries consist of one or more voltaic cells and are divided into three major classes: **primary** (Leclanché), **secondary** (lead–acid, silver–zinc nicad, and lithium-ion), and **flow batteries** or **fuel cells** in which reactants, such as hydrogen and oxygen, are continuously fed into the battery and chemical energy is converted to electric energy.

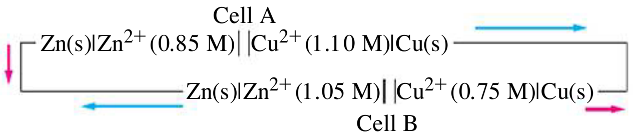
20-6 Corrosion: Unwanted Voltaic Cells—Electrochemistry plays a key role in corrosion and its control. Oxidation half-reactions produce anodic regions and reduction half-reactions, cathodic regions. **Cathodic protection** is achieved when a more active metal is attached to the metal being protected from corrosion. The more active metal, a "sacrificial" anode, is preferentially oxidized while the protected metal is a cathode at which a harmless reduction half-reaction occurs.

20-7 Electrolysis: Causing Nonspontaneous Reactions to Occur—In **electrolysis**, a nonspontaneous chemical reaction occurs as electrons from an external source are forced to flow in a direction opposite that in which they would flow spontaneously. The electrochemical cell in which electrolysis is conducted is called an **electrolytic cell**. $E°$, values are used to establish the theoretical voltage requirements for an electrolysis. Sometimes, particularly when a gas is liberated at an electrode, the voltage requirement for the electrode reaction exceeds the value of $E°$. The additional voltage requirement is called the **overpotential**. The amounts of reactants and products involved in an electrolysis can be calculated from the amount of electric charge passing through the electrolytic cell. The Faraday constant is featured in these calculations.

20-8 Industrial Electrolysis Processes—Electrolysis has many industrial applications, including electroplating, refining of metals, and production of substances such as NaOH(aq), $H_2(g)$, and $Cl_2(g)$.

Integrative Example

Two electrochemical cells are connected as shown.



Cell A
Zn(s)|Zn²⁺(0.85 M)||Cu²⁺(1.10 M)|Cu(s)
Zn(s)|Zn²⁺(1.05 M)||Cu²⁺(0.75 M)|Cu(s)
Cell B

(a) Do electrons flow in the direction of the red arrows or the blue arrows?

(b) What are the ion concentrations in the half-cells at the point at which current ceases to flow?

Analyze

The two cells differ only in their ion concentrations, which means that they have the same $E°_{cell}$ value but different E_{cell} values. In part **(a)**, use the Nernst equation (20.18) to determine which cell has the greater E_{cell} value when functioning as a voltaic cell. This will establish the direction that electrons flow. In part **(b),** write and solve an equation relating ion concentrations to the condition where the two cells have the same voltage but, being connected in opposition to each other, produce no net electric current.

Solve

(a) In each voltaic cell zinc is the anode, copper is the cathode, and the cell reaction is

$$\text{Zn(s)} + \text{Cu}^{2+}\text{(aq)} \longrightarrow \text{Zn}^{2+}\text{(aq)} + \text{Cu(s)}$$

The E_{cell} values are given by the Nernst equation.

$$E_{cell} = E°_{cell} - (0.0592/2)\log[\text{Zn}^{2+}]/[\text{Cu}^{2}] \qquad \textbf{(20.37)}$$

Note that for Cell A,

$$[\text{Zn}^{2+}]/[\text{Cu}^{2+}] = 0.85\text{ M}/1.10\text{ M} < 1$$
$$\log[\text{Zn}^{2+}]/[\text{Cu}^{2+}] < 0, \quad \text{and} \quad E_{cell} > E°_{cell}$$

For Cell B,

$$[\text{Zn}^{2+}]/[\text{Cu}^{2+}] = 1.05\text{ M}/0.75\text{ M} > 1$$
$$\log[\text{Zn}^{2+}]/[\text{Cu}^{2+}] > 0, \text{and } E_{cell} < E°_{cell}$$

The voltage of Cell A is greater than that of Cell B.

In the connection of the two cells shown in the diagram, Cell A is a *voltaic cell* and Cell B is an *electrolytic cell*. There is an emf from Cell B that resists that of Cell A, but on balance, the electron flow is in the direction of the red arrows.

(b) As electrons flow between the two cells, the overall reaction in Cell A causes $[\text{Zn}^{2+}]$ to increase, $[\text{Cu}^{2+}]$ to decrease, and E_{cell} to decrease. The overall reaction in Cell B causes $[\text{Zn}^{2+}]$ to decrease, $[\text{Cu}^{2+}]$ to increase, and the back emf to increase. When the back emf from Cell B equals E_{cell} of Cell A, electrons cease to flow.

The cell diagrams when this condition is reached, with x representing *changes* in concentrations, are

$$\textit{Cell A:} \quad \text{Zn(s)}|\text{Zn}^{2+}(0.85 + x)\text{ M}||\text{Cu}^{2+}(1.10 - x)\text{ M}|\text{Cu(s)}$$
$$\textit{Cell B:} \quad \text{Zn(s)}|\text{Zn}^{2+}(1.05 - x)\text{ M}||\text{Cu}^{2+}(0.75 + x)\text{ M}|\text{Cu(s)}$$

Use equation (20.37) to obtain E_{cell} for each cell.

$$\textit{Cell A:}\quad E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0592\text{ V}}{2}\log\frac{(0.85 + x)}{(1.10 - x)}$$

$$\textit{Cell B:}\quad E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0592\text{ V}}{2}\log\frac{(1.05 - x)}{(0.75 + x)}$$

Set the two expressions equal to one another, cancel the terms E°_{cell} and $(0.0592\text{ V})/2$, to obtain

$$\log\frac{(0.85 + x)}{(1.10 - x)} = \log\frac{(1.05 - x)}{(0.75 + x)}$$

Because the logarithms of the quantities on the two sides are equal, so too are the quantities themselves.

$$\frac{(0.85 + x)}{(1.10 - x)} = \frac{(1.05 - x)}{(0.75 + x)}$$

The expression to be solved is a quadratic equation

$$(0.85 + x)(0.75 + x) = (1.10 - x)(1.05 - x)$$

Cancel x^2 on each side

$$0.64 + 1.60x + \cancel{x^2} = 1.16 - 2.15x + \cancel{x^2}$$

$$0.64 + 1.60x = 1.16 - 2.15x$$

Solve to obtain

$$3.75x = 0.52 \quad \text{and} \quad x = 0.14$$

When electrons no longer flow, the ion concentrations are as follows:

Cell A: $[Zn^{2+}] = 0.99\text{ M}; [Cu^{2+}] = 0.96\text{ M}.$

Cell B: $[Zn^{2+}] = 0.91\text{ M}; [Cu^{2+}] = 0.89\text{ M}.$

Assess

Once the direction of electron flow had been established, it was possible to decide in which cell $[Zn^{2+}]$ would increase and in which cell it would decrease. At equilibrium the two cell potentials became equal. That the calculated equilibrium concentrations are correct can be seen in $0.99/0.96 \approx 0.91/0.89$.

PRACTICE EXAMPLE A: Current fuel cells use the reaction of $H_2(g)$ and $O_2(g)$ to form $H_2O(l)$. Often, the $H_2(g)$ is obtained by the steam reforming of a hydrocarbon, such as $C_3H_8(g) + 3\,H_2O(g) \longrightarrow 3\,CO(g) + 7\,H_2(g)$. A future possibility is a fuel cell that converts a hydrocarbon, such as propane, directly to $CO_2(g)$ and $H_2O(l)$:

$$C_3H_8(g) + 5\,O_2(g) \longrightarrow 3\,CO_2(g) + 4\,H_2O(l)$$

Based on this reaction, use data from Table 20.1 and Appendix D to determine E° for the reduction of $CO_2(g)$ to $C_3H_8(g)$ in an acidic solution.

PRACTICE EXAMPLE B: A battery system that may be used to power automobiles in the future is the aluminum–air battery. This is a *flow battery* in which oxidation occurs at an aluminum anode and reduction at a carbon–air cathode. The electrolyte circulated through the battery is NaOH(aq); the ultimate reaction product is $Al(OH)_3(s)$, which is removed from the battery as it is formed. In operation the battery can be kept charged by feeding Al anode slugs and water into it; oxygen is drawn from the air (see Fig. 20-18). The battery can power an automobile several hundred miles between charges. The $Al(OH)_3(s)$ removed from the battery can be converted back to aluminum in an aluminum manufacturing facility.

(a) In actual practice Al^{3+} produced at the anode does not precipitate as $Al(OH)_3(s)$ but is obtained as the complex ion $[Al(OH)_4]^-$ in the presence of NaOH(aq). $Al(OH)_3$ is precipitated from the circulating NaOH(aq) electrolyte *outside* the battery. Write plausible equations for oxidation and reduction half-reactions, and for the net reaction that occurs in the battery.

(b) The theoretical voltage of the aluminum–air cell is +2.73 V. Use this information and data from Table 20.1 to obtain E° for the reduction

$$[Al(OH)_4]^- + 3\,e^- \longrightarrow Al(s) + 4\,OH^- \quad E^\circ = ?$$

(c) Given that E°_{cell} for the reaction is $+2.73$ V, that $\Delta G^\circ_f[OH^-(aq)] = -157\text{ kJ mol}^{-1}$, and that $\Delta G^\circ_f[H_2O(l)] = -237.2\text{ kJ mol}^{-1}$, determine the Gibbs energy of formation, ΔG°_f, of the aluminate ion, $[Al(OH)_4]^-$.

(d) What mass of aluminum is consumed if 10.0 A of electric current is drawn from the battery for 4.00 h?

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

Exercises

(Use data from Table 20.1 and Appendix D as necessary.)

Standard Electrode Potentials

1. From the observations listed, estimate the value of $E°$ for the half-reaction $M^{2+}(aq) + 2\,e^- \longrightarrow M(s)$.
   (a) The metal M reacts with $HNO_3(aq)$, but not with HCl(aq); M displaces $Ag^+(aq)$, but not $Cu^{2+}(aq)$.
   (b) The metal M reacts with HCl(aq), producing $H_2(g)$, but displaces neither $Zn^{2+}(aq)$ nor $Fe^{2+}(aq)$.
2. You must estimate $E°$ for the half-reaction $In^{3+}(aq) + 3\,e^- \longrightarrow In(s)$. You have no electrical equipment, but you do have all of the metals listed in Table 20.1 and aqueous solutions of their ions, as well as In(s) and $In^{3+}(aq)$. Describe the experiments you would perform and the accuracy you would expect in your result.
3. $E°_{cell} = 0.201$ V for the reaction

$$3\,Pt(s) + 12\,Cl^-(aq) + 2\,NO_3^-(aq) + 8\,H^+(aq) \longrightarrow 3[PtCl_4]^{2-}(aq) + 2\,NO(g) + 4\,H_2O(l)$$

   What is $E°$ for the reduction of $[PtCl_4]^{2-}$ to Pt in acidic solution?
4. Given that $E°_{cell} = 3.20$ V for the reaction

$$2\,Na(\text{in Hg}) + Cl_2(g) \longrightarrow 2\,Na^+(aq) + 2\,Cl^-(aq)$$

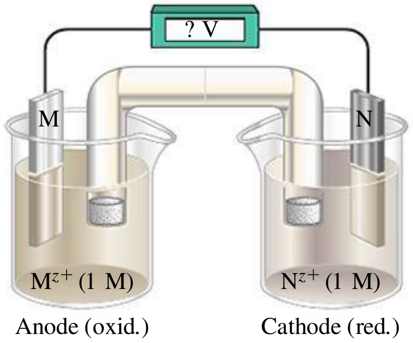
   What is $E°$ for the reduction $2\,Na^+(aq) + 2\,e^- \longrightarrow 2\,Na(\text{in Hg})$?
5. Given that $E°_{cell}$ for the aluminum-air battery is 2.71 V, what is $E°$ for the reduction half-reaction $[Al(OH)_4]^-(aq) + 3\,e^- \longrightarrow Al(s) + 4\,OH^-(aq)$? [*Hint:* Refer to cell reaction (20.28).]
6. The theoretical $E°_{cell}$ for the methane–oxygen fuel cell is 1.06 V. What is $E°$ for the reduction half-reaction $CO_2(g) + 8\,H^+(aq) + 8\,e^- \longrightarrow CH_4(g) + 2\,H_2O(l)$? [*Hint:* Refer to cell reaction (20.27).]
7. The following sketch is of a voltaic cell consisting of two standard electrodes for two metals, M and N:

$$M^{z+}(aq) + z\,e^- \longrightarrow M(s) \qquad E°_{M^{z+}/M}$$
$$N^{z+}(aq) + z\,e^- \longrightarrow N(s) \qquad E°_{N^{z+}/N}$$

   Use the standard reduction potentials of these half-reactions to answer the questions that follow:

$$Ag^+(aq) + e^- \longrightarrow Ag(s)$$
$$Zn^{2+}(aq) + 2\,e^- \longrightarrow Zn(s)$$
$$Cu^{2+}(aq) + 2\,e^- \longrightarrow Cu(s)$$
$$Al^{3+}(aq) + 3\,e^- \longrightarrow Al(s)$$

   (a) Determine which pair of these half-cell reactions leads to a cell reaction with the largest positive cell potential, and calculate its value. Which couple is at the anode and which at the cathode?
   (b) Determine which pair of these half-cell reactions leads to the cell with the smallest positive cell potential, and calculate its value. Which couple is at the anode and which is at the cathode?



8. Given these half-reactions and associated standard reduction potentials, answer the questions that follow:

$$[Zn(NH_3)_4]^{2+}(aq) + 2\,e^- \longrightarrow Zn(s) + 4\,NH_3(aq) \qquad E° = -1.015\text{ V}$$
$$Ti^{3+}(aq) + e^- \longrightarrow Ti^{2+}(aq) \qquad E° = -0.37\text{ V}$$
$$VO^{2+}(aq) + 2\,H^+(aq) + e^- \longrightarrow V^{3+}(aq) + H_2O(l) \qquad E° = 0.340\text{ V}$$
$$Sn^{2+}(aq) + 2\,e^- \longrightarrow Sn(aq) \qquad E° = -0.14\text{ V}$$

   (a) Determine which pair of half-cell reactions leads to a cell reaction with the largest positive cell potential, and calculate its value. Which couple is at the anode and which is at the cathode?
   (b) Determine which pair of these half-cell reactions leads to the cell with the smallest positive cell potential, and calculate its value. Which couple is at the anode and which is at the cathode?

Predicting Oxidation–Reduction Reactions

9. Ni^{2+} has a more positive reduction potential than Cd^{2+}.
   (a) Which ion is more easily reduced to the metal?
   (b) Which metal, Ni or Cd, is more easily oxidized?
10. Refer to standard reduction potentials, and predict which metal in each of the following pairs is the stronger reducing agent:
    (a) sodium or potassium
    (b) magnesium or barium
11. Assume that all reactants and products are in their standard states, and use data from Table 20.1 to predict whether a spontaneous reaction will occur in the forward direction in each case.
    (a) $Sn(s) + Pb^{2+}(aq) \longrightarrow Sn^{2+}(aq) + Pb(s)$
    (b) $Cu^{2+}(aq) + 2\,I^-(aq) \longrightarrow Cu(s) + I_2(s)$
    (c) $4\,NO_3^-(aq) + 4\,H^+(aq) \longrightarrow 3\,O_2(g) + 4\,NO(g) + 2\,H_2O(l)$
    (d) $O_3(g) + Cl^-(aq) \longrightarrow OCl^-(aq) + O_2(g)$ (basic solution)
12. For the reduction half-reaction $Hg_2^{2+}(aq) + 2\,e^- \longrightarrow 2\,Hg(l)$, $E° = 0.797$ V. Will Hg(l) react with and dissolve in HCl(aq)? in $HNO_3(aq)$? Explain.
13. Use data from Table 20.1 to predict whether, to any significant extent,
    (a) Mg(s) will displace Pb^{2+} from aqueous solution;
    (b) Sn(s) will react with and dissolve in 1 M HCl;

(c) SO_4^{2-} will oxidize Sn^{2+} to Sn^{4+} in acidic solution;
(d) $MnO_4^-(aq)$ will oxidize $H_2O_2(aq)$ to $O_2(g)$ in acidic solution;
(e) $I_2(s)$ will displace $Br^-(aq)$ to produce $Br_2(l)$.

14. Consider the reaction $Co(s) + Ni^{2+}(aq) \longrightarrow Co^{2+}(aq) + Ni(s)$, with $E^\circ_{cell} = 0.02\ V$. If Co(s) is added to a solution with $[Ni^{2+}] = 1\ M$, should the reaction go to completion? Explain.

15. Dichromate ion $(Cr_2O_7^{2-})$ in acidic solution is a good oxidizing agent. Which of the following oxidations can be accomplished with dichromate ion in acidic solution? Explain.
(a) $Sn^{2+}(aq)$ to $Sn^{4+}(aq)$
(b) $I_2(s)$ to $IO_3^-(aq)$
(c) $Mn^{2+}(aq)$ to $MnO_4^-(aq)$

16. The standard electrode potential for the reduction of $Eu^{3+}(aq)$ to $Eu^{2+}(aq)$ is $-0.43\ V$. Use the data in Appendix D to determine which of the following is capable of reducing $Eu^{3+}(aq)$ to $Eu^{2+}(aq)$ under standard-state conditions: Al(s), Co(s), $H_2O_2(aq)$, Ag(s), $H_2C_2O_4(aq)$.

17. Predict whether the following metals will react with the acid indicated. If a reaction does occur, write the net ionic equation for the reaction. Assume that reactants and products are in their standard states. **(a)** Ag in $HNO_3(aq)$; **(b)** Zn in HI(aq); **(c)** Au in HNO_3 (for the couple Au^{3+}/Au, $E^\circ = 1.52\ V$).

18. Predict whether, to any significant extent,
(a) Fe(s) will displace $Zn^{2+}(aq)$;
(b) $MnO_4^-(aq)$ will oxidize $Cl^-(aq)$ to $Cl_2(g)$ in acidic solution;
(c) Ag(s) will react with 1 M HCl(aq);
(d) $O_2(g)$ will oxidize $Cl^-(aq)$ to $Cl_2(g)$ in acidic solution.

Galvanic Cells

19. Write cell reactions for the electrochemical cells diagrammed here, and use data from Table 20.1 to calculate E°_{cell} for each reaction.
(a) $Al(s)|Al^{3+}(aq)||Sn^{2+}(aq)|Sn(s)$
(b) $Pt(s)|Fe^{2+}(aq), Fe^{3+}(aq)||Ag^+(aq)|Ag(s)$
(c) $Cr(s)|Cr^{2+}(aq)||Au^{3+}(aq)|Au(s)$
(d) $Pt(s)|O_2(g)|H^+(aq)||OH^-(aq)|O_2(g)|Pt(s)$

20. Write the half-reactions and the balanced chemical equation for the electrochemical cells diagrammed here. Use data from Table 20.1 and Appendix D to calculate E°_{cell} for each reaction.
(a) $Cu(s)|Cu^{2+}(aq)||Cu^+(aq)|Cu(s)$
(b) $Ag(s)|AgI(s)|I^-(aq)||Cl^-(aq)|AgCl(s)|Ag(s)$
(c) $Pt|Ce^{4+}(aq), Ce^{3+}(aq)||I^-(aq), I_2(s)|C(s)$
(d) $U(s)|U^{3+}(aq)||V^{2+}(aq)|V(s)$

21. Use the data in Appendix D to calculate the standard cell potential for each of the following reactions. Which reactions will occur spontaneously?
(a) $H_2(g) + F_2(g) \longrightarrow 2\,H^+(aq) + 2\,F^-(aq)$
(b) $Cu(s) + Ba^{2+}(aq) \longrightarrow Cu^{2+}(aq) + Ba(s)$
(c) $3\,Fe^{2+}(aq) \longrightarrow Fe(s) + 2\,Fe^{3+}(aq)$
(d) $Hg(l) + HgCl_2(aq) \longrightarrow Hg_2Cl_2(s)$

22. In each of the following examples, sketch a voltaic cell that uses the given reaction. Label the anode and cathode; indicate the direction of electron flow; write a balanced equation for the cell reaction; and calculate E°_{cell}.
(a) $Cu(s) + Fe^{3+}(aq) \longrightarrow Cu^{2+}(aq) + Fe^{2+}(aq)$
(b) $Pb^{2+}(aq)$ is displaced from solution by Al(s)
(c) $Cl_2(g) + H_2O(l) \longrightarrow Cl^-(aq) + O_2(g) + H^+(aq)$
(d) $Zn(s) + H^+ + NO_3^- \longrightarrow Zn^{2+} + H_2O(l) + NO(g)$

23. Use the data in Appendix D to calculate the standard cell potential for each of the following reactions. Which reactions will occur spontaneously?
(a) $Fe^{3+}(aq) + Ag(s) \longrightarrow Fe^{2+}(aq) + Ag^+(aq)$
(b) $Sn(s) + Sn^{4+}(aq) \longrightarrow 2\,Sn^{2+}(aq)$
(c) $2\,Hg^{2+}(aq) + 2\,Br^-(aq) \longrightarrow Hg_2^{2+}(aq) + Br_2(l)$
(d) $2\,NO_3^-(aq) + 4\,H^+(aq) + Zn(s) \longrightarrow Zn^{2+}(aq) + 2\,NO_2(g) + 2\,H_2O(l)$

24. Write a cell diagram and calculate the value of E°_{cell} for a voltaic cell in which
(a) $Cl_2(g)$ is reduced to $Cl^-(aq)$ and Fe(s) is oxidized to $Fe^{2+}(aq)$;
(b) $Ag^+(aq)$ is displaced from solution by Zn(s);
(c) The cell reaction is $2\,Cu^+(aq) \longrightarrow Cu^{2+}(aq) + Cu(s)$;
(d) $MgBr_2(aq)$ is produced from Mg(s) and $Br_2(l)$.

ΔG°, E°_{cell}, and K

25. Determine the values of ΔG° for the following reactions carried out in voltaic cells.
(a) $2\,Al(s) + 3\,Cu^{2+}(aq) \longrightarrow 2\,Al^{3+}(aq) + 3\,Cu(s)$
(b) $O_2(g) + 4\,I^-(aq) + 4\,H^+(aq) \longrightarrow 2\,H_2O(l) + 2\,I_2(s)$
(c) $Cr_2O_7^{2-}(aq) + 14\,H^+(aq) + 6\,Ag(s) \longrightarrow 2\,Cr^{3+}(aq) + 6\,Ag^+(aq) + 7\,H_2O(l)$

26. Write the equilibrium constant expression for each of the following reactions, and determine the value of K at 25 °C. Use data from Table 20.1.
(a) $2\,V^{3+}(aq) + Ni(s) \longrightarrow 2\,V^{2+}(aq) + Ni^{2+}(aq)$
(b) $MnO_2(s) + 4\,H^+(aq) + 2\,Cl^-(aq) \longrightarrow Mn^{2+}(aq) + 2\,H_2O(l) + Cl_2(g)$
(c) $2\,OCl^-(aq) \longrightarrow 2\,Cl^-(aq) + O_2(g)$ (basic solution)

27. For the reaction

$$MnO_4^-(aq) + 8\,H^+(aq) + 5\,Ce^{3+}(aq) \longrightarrow 5\,Ce^{4+}(aq) + Mn^{2+}(aq) + 4\,H_2O(l)$$

use data from Table 20.1 to determine **(a)** E°_{cell}; **(b)** ΔG°; **(c)** K; **(d)** whether the reaction goes substantially to completion when the reactants and products are initially in their standard states.

28. For the reaction that occurs in the voltaic cell

$$\text{Pt}|\text{Pb}^{4+}(\text{aq}), \text{Pb}^{2+}(\text{aq})||\text{Sn}^{4+}(\text{aq}), \text{Sn}^{2+}(\text{aq})|\text{C(s)}$$

use data from Appendix D to determine **(a)** the equation for the cell reaction; **(b)** E°_{cell}; **(c)** ΔG°; **(d)** K; **(e)** whether the reaction goes substantially to completion when the reactants and products are initially in their standard states.

29. For the reaction $2\,\text{Cu}^+(\text{aq}) + \text{Sn}^{4+}(\text{aq}) \longrightarrow 2\,\text{Cu}^{2+}(\text{aq}) + \text{Sn}^{2+}(\text{aq})$, $E^\circ_{\text{cell}} = -0.0050$ V,

(a) can a solution be prepared at 298 K that is 0.500 M in each of the four ions?

(b) If not, in which direction will a reaction occur?

30. For the reaction $2\,\text{H}^+(\text{aq}) + \text{BrO}_4{}^-(\text{aq}) + 2\,\text{Ce}^{3+}(\text{aq}) \longrightarrow \text{BrO}_3{}^-(\text{aq}) + 2\,\text{Ce}^{4+}(\text{aq}) + \text{H}_2\text{O(l)}$, $E^\circ_{\text{cell}} = -0.017$ V, answer the following questions:

(a) Can a solution be prepared at 298 K that has $[\text{BrO}_4{}^-] = [\text{Ce}^{4+}] = 0.675$ M, $[\text{BrO}_3{}^-] = [\text{Ce}^{3+}] = 0.600$ M and pH $= 1$?

(b) If not, in which direction will a reaction occur?

31. Use thermodynamic data from Appendix D to calculate a theoretical voltage of the silver–zinc button cell described on page 890.

32. The theoretical voltage of the aluminum–air battery is $E^\circ_{\text{cell}} = 2.71$ V. Use data from Appendix D and equation (20.28) to determine ΔG°_f for $\text{Al}[(\text{OH})_4]^-$.

33. By the method of combining reduction half-equations illustrated on page 875, determine $E^\circ_{\text{IrO}_2/\text{Ir}}$, given that $E^\circ_{\text{Ir}^{3+}/\text{Ir}} = 1.156$ V and $E^\circ_{\text{IrO}_2/\text{Ir}^{3+}} = 0.223$ V.

34. Determine $E^\circ_{\text{MoO}_2/\text{Mo}^{3+}}$, given that $E^\circ_{\text{H}_2\text{MoO}_4/\text{MoO}_2} = 0.646$ V and $E^\circ_{\text{H}_2\text{MoO}_4/\text{Mo}^{3+}} = 0.428$ V. (See page 875).

Concentration Dependence of E_{cell}—The Nernst Equation

35. A voltaic cell represented by the following cell diagram has $E_{\text{cell}} = 1.250$ V. What must be $[\text{Ag}^+]$ in the cell?

$$\text{Zn(s)}|\text{Zn}^{2+}(1.00\text{ M})||\text{Ag}^+(x\text{ M})|\text{Ag(s)}$$

36. For the cell pictured in Figure 20-11, what is E_{cell} if the unknown solution in the half-cell on the left **(a)** has pH $= 5.25$; **(b)** is 0.0103 M HCl; **(c)** is 0.158 M $\text{HC}_2\text{H}_3\text{O}_2$ ($K_a = 1.8 \times 10^{-5}$)?

37. Use the Nernst equation and Table 20.1 to calculate E_{cell} for each of the following cells.

(a) $\text{Al(s)}|\text{Al}^{3+}(0.18\text{ M})||\text{Fe}^{2+}(0.85\text{ M})|\text{Fe(s)}$

(b) $\text{Ag(s)}|\text{Ag}^+(0.34\text{ M})||\text{Cl}^-(0.098\text{ M}), \text{Cl}_2(\text{g}, 0.55\text{ atm})|\text{Pt(s)}$

38. Use the Nernst equation and data from Appendix D to calculate E_{cell} for each of the following cells.

(a) $\text{Mn(s)}|\text{Mn}^{2+}(0.40\text{ M})||\text{Cr}^{3+}(0.35\text{ M}), \text{Cr}^{2+}(0.25\text{ M})|\text{Pt(s)}$

(b) $\text{Mg(s)}|\text{Mg}^{2+}(0.016\text{ M})||[\text{Al(OH)}_4]^-(0.25\text{ M}), \text{OH}^-(0.042\text{ M})|\text{Al(s)}$

39. Consider the reduction half-reactions listed in Appendix D, and give plausible explanations for the following observations:

(a) For some half-reactions, E depends on pH; for others, it does not.

(b) Whenever H^+ appears in a half-equation, it is on the *left* side.

(c) Whenever OH^- appears in a half-equation, it is on the *right* side.

40. Write an equation to represent the oxidation of $\text{Cl}^-(\text{aq})$ to $\text{Cl}_2(\text{g})$ by $\text{PbO}_2(\text{s})$ in an acidic solution. Will this reaction occur spontaneously in the forward direction if all other reactants and products are in their standard states and **(a)** $[\text{H}^+] = 6.0$ M; **(b)** $[\text{H}^+] = 1.2$ M; **(c)** pH $= 4.25$? Explain.

41. If $[\text{Zn}^{2+}]$ is maintained at 1.0 M,

(a) what is the minimum $[\text{Cu}^{2+}]$ for which reaction (20.3) is spontaneous in the forward direction?

(b) Should the displacement of $\text{Cu}^{2+}(\text{aq})$ by Zn(s) go to completion? Explain.

42. Can the displacement of Pb(s) from 1.0 M $\text{Pb(NO}_3)_2$ be carried to completion by tin metal? Explain.

43. A concentration cell is constructed of two hydrogen electrodes: one immersed in a solution with $[\text{H}^+] = 1.0$ M and the other in 0.65 M KOH.

(a) Determine E_{cell} for the reaction that occurs.

(b) Compare this value of E_{cell} with E° for the reduction of H_2O to $\text{H}_2(\text{g})$ in basic solution, and explain the relationship between them.

44. If the 0.65 M KOH of Exercise 43 is replaced by 0.65 M NH_3,

(a) will E_{cell} be higher or lower than in the cell with 0.65 M KOH?

(b) What will be the value of E_{cell}?

45. A voltaic cell is constructed as follows:

$$\text{Ag(s)}|\text{Ag}^+(\text{satd Ag}_2\text{CrO}_4)||\text{Ag}^+(0.125\text{ M})|\text{Ag(s)}$$

What is the value of E_{cell}? For Ag_2CrO_4, $K_{sp} = 1.1 \times 10^{-12}$.

46. A voltaic cell, with $E_{\text{cell}} = 0.180$ V, is constructed as follows:

$$\text{Ag(s)}|\text{Ag}^+(\text{satd Ag}_3\text{PO}_4)||\text{Ag}^+(0.140\text{ M})|\text{Ag(s)}$$

What is the K_{sp} of Ag_3PO_4?

47. For the voltaic cell,

$$\text{Sn(s)}|\text{Sn}^{2+}(0.075\text{ M})||\text{Pb}^{2+}(0.600\text{ M})|\text{Pb(s)}$$

(a) what is E_{cell} initially?

(b) If the cell is allowed to operate spontaneously, will E_{cell} increase, decrease, or remain constant with time? Explain.

(c) What will be E_{cell} when $[\text{Pb}^{2+}]$ has fallen to 0.500 M?

(d) What will be $[\text{Sn}^{2+}]$ at the point at which $E_{\text{cell}} = 0.020$ V?

(e) What are the ion concentrations when $E_{\text{cell}} = 0$?

48. For the voltaic cell,

$$\mathrm{Ag(s)}|\mathrm{Ag^{+}(0.015\ M)}||\mathrm{Fe^{3+}(0.055\ M)},\ \mathrm{Fe^{2+}(0.045\ M)}|\mathrm{Pt(s)}$$

(a) what is E_{cell} initially?
(b) As the cell operates, will E_{cell} increase, decrease, or remain constant with time? Explain.
(c) What will be E_{cell} when $[\mathrm{Ag^{+}}]$ has increased to 0.020 M?
(d) What will be $[\mathrm{Ag^{+}}]$ when $E_{\text{cell}} = 0.010$ V?
(e) What are the ion concentrations when $E_{\text{cell}} = 0$?

49. Show that the oxidation of $\mathrm{Cl^{-}(aq)}$ to $\mathrm{Cl_2(g)}$ by $\mathrm{Cr_2O_7{}^{2-}(aq)}$ in acidic solution, with reactants and products in their standard states, does not occur spontaneously. Explain why it is still possible to use this method to produce $\mathrm{Cl_2(g)}$ in the laboratory. What experimental conditions would you use?

50. Derive a balanced equation for the reaction occurring in the cell:

$$\mathrm{Fe(s)}|\mathrm{Fe^{2+}(aq)}||\mathrm{Fe^{3+}(aq)},\ \mathrm{Fe^{2+}(aq)}|\mathrm{Pt(s)}$$

(a) If $E^{\circ}_{\text{cell}} = 1.21$ V, calculate ΔG° and the equilibrium constant for the reaction.
(b) Use the Nernst equation to determine the potential for the cell:

$$\mathrm{Fe(s)}|\mathrm{Fe^{2+}(aq, 1.0 \times 10^{-3}\ M)}||\mathrm{Fe^{3+}(aq, 1.0 \times 10^{-3}\ M)},\ \mathrm{Fe^{2+}(aq, 0.10\ M)}|\mathrm{Pt(s)}$$

(c) In light of **(a)** and **(b)**, what is the likelihood of being able to observe the disproportionation of $\mathrm{Fe^{2+}}$ into $\mathrm{Fe^{3+}}$ and Fe under standard conditions?

Batteries and Fuel Cells

51. The iron–chromium redox battery makes use of the reaction

$$\mathrm{Cr^{2+}(aq) + Fe^{3+}(aq) \longrightarrow Cr^{3+}(aq) + Fe^{2+}(aq)}$$

occurring at a chromium anode and an iron cathode.
(a) Write a cell diagram for this battery.
(b) Calculate the theoretical voltage of the battery.

52. Refer to the discussion of the Leclanché cell (page 888).
(a) Combine the several equations written for the operation of the Leclanché cell into a single overall equation.
(b) Given that the voltage of the Leclanché cell is 1.55 V, estimate the electrode potentials, E, for each of the half-reactions. Why are your values only estimates?

53. What is the theoretical standard cell voltage, E°_{cell}, of each of the following voltaic cells: **(a)** the hydrogen–oxygen fuel cell described by equation (20.26); **(b)** the zinc–air battery; **(c)** a magnesium–iodine battery?

54. For the alkaline Leclanché cell (page 888)
(a) write the overall cell reaction.
(b) Determine E°_{cell} for that cell reaction.

55. One of the advantages of the aluminum-air battery over the iron–air and zinc–air batteries is the greater quantity of charge transferred per unit mass of metal consumed. Show that this is indeed the case. Assume that zinc and iron are oxidized to oxidation state +2 in air batteries.

56. Describe how you might construct batteries with each of the following voltages: **(a)** 0.10 V; **(b)** 2.5 V; **(c)** 10.0 V. Be as specific as you can about the electrodes and solution concentrations you would use, and indicate whether the battery would consist of a single cell or two or more cells connected in series.

57. A lithium battery, which is different from a lithium-ion battery, uses lithium metal as one electrode and carbon in contact with $\mathrm{MnO_2}$ in a paste of KOH as the other electrode. The electrolyte is lithium perchlorate in a nonaqueous solvent, and the construction is similar to the silver battery. The half-cell reactions involve the oxidation of lithium and the reaction

$$\mathrm{MnO_2(s) + 2\,H_2O(l) + e^{-} \longrightarrow Mn(OH)_3(s) + OH^{-}(aq)} \qquad E^{\circ} = -0.20\ \mathrm{V}$$

Draw a cell diagram for the lithium battery, identify the negative and positive electrodes, and estimate the cell potential under standard conditions.

58. For each of the following potential battery systems, describe the electrode reactions and the net cell reaction you would expect. Determine the theoretical voltage of the battery.
(a) $\mathrm{Zn{-}Br_2}$
(b) $\mathrm{Li{-}F_2}$

Electrochemical Mechanism of Corrosion

59. Refer to Figure 20-20, and describe in words or with a sketch what you would expect to happen in each of the following cases.
(a) Several turns of copper wire are wrapped around the head and tip of an iron nail.
(b) A deep scratch is filed at the center of an iron nail.
(c) A galvanized nail is substituted for the iron nail.

60. When an iron pipe is partly submerged in water, the iron dissolves more readily below the waterline than at the waterline. Explain this observation by relating it to the description of corrosion given in Figure 20-21.

61. Natural gas transmission pipes are sometimes protected against corrosion by the maintenance of a small potential difference between the pipe and an inert electrode buried in the ground. Describe how the method works.

62. In the construction of the Statue of Liberty, a framework of iron ribs was covered with thin sheets of copper less than 2.5 mm thick. A layer of asbestos separated the copper skin and iron framework. Over time, the asbestos wore away and the iron ribs corroded. Some of the ribs lost more than half their mass in the 100 years before the statue was restored. At the same time, the copper skin lost only about 4% of its thickness. Use electrochemical principles to explain these observations.

Electrolysis Reactions

63. How many grams of metal are deposited at the cathode by the passage of 2.15 A of current for 75 min in the electrolysis of an aqueous solution containing **(a)** Zn^{2+}; **(b)** Al^{3+}; **(c)** Ag^{+}; **(d)** Ni^{2+}?

64. A quantity of electric charge brings about the deposition of 3.28 g Cu at a cathode during the electrolysis of a solution containing $Cu^{2+}(aq)$. What volume of $H_2(g)$, measured at 28.2 °C and 763 mmHg, would be produced by this same quantity of electric charge in the reduction of $H^{+}(aq)$ at a cathode?

65. Which of the following reactions occur spontaneously, and which can be brought about only through electrolysis, assuming that all reactants and products are in their standard states? For those requiring electrolysis, what is the *minimum* voltage required?

(a) $2\,H_2O(l) \longrightarrow 2\,H_2(g) + O_2(g)$ [in 1 M $H^{+}(aq)$]

(b) $Zn(s) + Fe^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Fe(s)$

(c) $2\,Fe^{2+}(aq) + I_2(s) \longrightarrow 2\,Fe^{3+}(aq) + 2\,I^{-}(aq)$

(d) $Cu(s) + Sn^{4+}(aq) \longrightarrow Cu^{2+}(aq) + Sn^{2+}(aq)$

66. An aqueous solution of K_2SO_4 is electrolyzed by means of Pt electrodes.

(a) Which of the following gases should form at the *anode:* O_2, H_2, SO_2, SO_3? Explain.

(b) What product should form at the *cathode*? Explain.

(c) What is the *minimum* voltage required? Why is the actual voltage needed likely to be higher than this value?

67. If a lead storage battery is charged at too high a voltage, gases are produced at each electrode. (It is possible to recharge a lead-storage battery only because of the high overpotential for gas formation on the electrodes.)

(a) What are these gases?

(b) Write a cell reaction to describe their formation.

68. A dilute aqueous solution of Na_2SO_4 is electrolyzed between Pt electrodes for 3.75 h with a current of 2.83 A. What volume of gas, saturated with water vapor at 25 °C and at a total pressure of 742 mmHg, would be collected at the *anode*? Use data from Table 12.4, as required.

69. Calculate the quantity indicated for each of the following electrolyses.

(a) the mass of Zn deposited at the cathode in 42.5 min when 1.87 A of current is passed through an aqueous solution of Zn^{2+}

(b) the time required to produce 2.79 g I_2 at the anode if a current of 1.75 A is passed through KI(aq)

70. Calculate the quantity indicated for each of the following electrolyses.

(a) $[Cu^{2+}]$ *remaining* in 425 mL of a solution that was originally 0.366 M $CuSO_4$, after passage of 2.68 A for 282 s and the deposition of Cu at the cathode

(b) the time required to reduce $[Ag^{+}]$ in 255 mL of $AgNO_3(aq)$ from 0.196 to 0.175 M by electrolyzing the solution between Pt electrodes with a current of 1.84 A

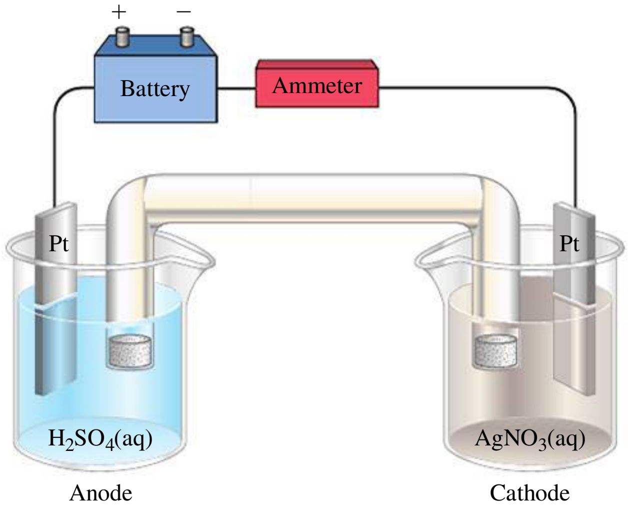
71. A *coulometer* is a device for measuring a quantity of electric charge. In a silver coulometer, $Ag^{+}(aq)$ is reduced to Ag(s) at a Pt cathode. If 1.206 g Ag is deposited in 1412 s by a certain quantity of electricity, **(a)** how much electric charge (in C) must have passed, and **(b)** what was the magnitude (in A) of the electric current?

72. Electrolysis is carried out for 2.00 h in the following cell. The platinum *cathode*, which has a mass of 25.0782 g, weighs 25.8639 g after the electrolysis. The platinum *anode* weighs the same before and after the electrolysis.

(a) Write plausible equations for the half-reactions that occur at the two electrodes.

(b) What must have been the magnitude of the current used in the electrolysis (assuming a constant current throughout)?

(c) A gas is collected at the anode. What is this gas, and what volume should it occupy if (when dry) it is measured at 23 °C and 755 mmHg pressure?



73. A solution containing both Ag^{+} and Cu^{2+} ions is subjected to electrolysis. **(a)** Which metal should plate out first? **(b)** Plating out is finished after a current of 0.75 A is passed through the solution for 2.50 hours. If the total mass of metal is 3.50 g, what is the mass percent of silver in the product?

74. A solution containing a mixture of a platinum(II) salt contaminated by approximately 10 mole % of another oxidation state is electrolyzed at 1.20 A for 32.0 minutes, at which point no more platinum is deposited. **(a)** What is the oxidation state of the contaminant? **(b)** What is the composition of the mixture?

Integrative and Advanced Exercises

75. Two voltaic cells are assembled in which the following reactions occur.

$$V^{2+}(aq) + VO^{2+}(aq) + 2\,H^+(aq) \longrightarrow 2\,V^{3+}(aq) + H_2O(l) \quad E^\circ_{cell} = 0.616\ V$$

$$V^{3+}(aq) + Ag^+(aq) + H_2O(l) \longrightarrow VO^{2+}(aq) + 2\,H^+(aq) + Ag(s) \quad E^\circ_{cell} = 0.439\ V$$

Use these data and other values from Table 20.1 to calculate E° for the half-reaction $V^{3+} + e^- \longrightarrow V^{2+}$.

76. Suppose that a fully charged lead–acid battery contains 1.50 L of 5.00 M H_2SO_4. What will be the concentration of H_2SO_4 in the battery after 2.50 A of current is drawn from the battery for 6.0 h?

77. The energy consumption in electrolysis depends on the product of the charge and the voltage [volt × coulomb = $V \cdot C$ = J(joules)]. Determine the theoretical energy consumption per 1000 kg Cl_2 produced in a diaphragm chlor–alkali cell (page 902) that operates at 3.45 V. Express this energy in **(a)** kJ; **(b)** kilowatt-hours, kWh.

78. For the half-reaction $Cr^{3+} + e^- \longrightarrow Cr^{2+}$, $E^\circ = -0.424$ V. If excess Fe(s) is added to a solution in which $[Cr^{3+}] = 1.00$ M, what will be $[Fe^{2+}]$ when equilibrium is reached at 298 K?

$$Fe(s) + 2\,Cr^{3+} \rightleftharpoons Fe^{2+} + 2\,Cr^{2+}$$

79. A voltaic cell is constructed based on the following reaction and initial concentrations:

$$Fe^{2+}(0.0050\ M) + Ag^+(2.0\ M) \rightleftharpoons Fe^{3+}(0.0050\ M) + Ag(s)$$

Calculate $[Fe^{2+}]$ when the cell reaction reaches equilibrium.

80. To construct a voltaic cell with $E_{cell} = 0.0860$ V, what $[Cl^-]$ must be present in the cathode half-cell to achieve this result?

$$Ag(s)|Ag^+(satd\ AgI)||Ag^+(satd\ AgCl,\ x\ M\ Cl^-)|Ag(s)$$

81. Describe a laboratory experiment that you could perform to evaluate the Faraday constant, *F*, and then show how you could use this value to determine the Avogadro constant.

82. The hydrazine fuel cell is based on the reaction

$$N_2H_4(aq) + O_2(g) \longrightarrow N_2(g) + 2\,H_2O(l)$$

The theoretical E°_{cell} of this fuel cell is 1.559 V. Use this information and data from Appendix D to calculate a value of ΔG°_f for $[N_2H_4(aq)]$.

83. It is sometimes possible to separate two metal ions through electrolysis. One ion is reduced to the free metal at the cathode, and the other remains in solution. In which of these cases would you expect complete or nearly complete separation: **(a)** Cu^{2+} and K^+; **(b)** Cu^{2+} and Ag^+; **(c)** Pb^{2+} and Sn^{2+}? Explain.

84. Show that for some fuel cells the efficiency value, $\varepsilon = \Delta G^\circ/\Delta H^\circ$, can have a value greater than 1.00. Can you identify one such reaction? [*Hint:* Use data from Appendix D.]

85. In one type of Breathalyzer (alcohol meter), the quantity of ethanol in a sample is related to the amount of electric current produced by an ethanol–oxygen fuel cell. Use data from Table 20.1 and Appendix D to determine **(a)** E°_{cell} and **(b)** E° for the reduction of $CO_2(g)$ to $CH_3CH_2OH(g)$.

86. You prepare 1.00 L of a buffer solution that is 1.00 M NaH_2PO_4 and 1.00 M Na_2HPO_4. The solution is divided in half between the two compartments of an electrolytic cell. Both electrodes used are Pt. Assume that the only electrolysis is that of water. If 1.25 A of current is passed for 212 min, what will be the pH in each cell compartment at the end of the electrolysis?

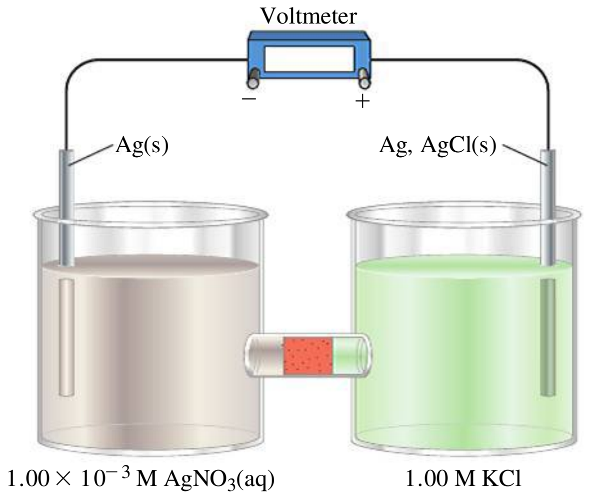
87. Assume that the volume of each solution in Figure 20-22 is 100.0 mL. The cell is operated as an electrolytic cell, using a current of 0.500 A. Electrolysis is stopped after 10.00 h, and the cell is allowed to function as a voltaic cell. What is E_{cell} at this point?

88. A common reference electrode consists of a silver wire coated with AgCl(s) and immersed in 1 M KCl.

$$AgCl(s) + e^- \longrightarrow Ag(s) + Cl^-(1\ M) \quad E^\circ = 0.2223\ V$$

(a) What is E°_{cell} when this electrode is a cathode in combination with a standard zinc electrode as an anode?
(b) Cite several reasons why this electrode should be easier to use than a standard hydrogen electrode.
(c) By comparing the potential of this silver–silver chloride electrode with that of the silver–silver ion electrode, determine K_{sp} for AgCl.

89. The electrodes in the following electrochemical cell are connected to a voltmeter as shown. The half-cell on the right contains a standard silver–silver chloride electrode (see Exercise 88). The half-cell on the left contains a silver electrode immersed in 100.0 mL of 1.00×10^{-3} M $AgNO_3(aq)$. A porous plug through which ions can migrate separates the half-cells.
(a) What is the initial reading on the voltmeter?
(b) What is the voltmeter reading after 10.00 mL of 0.0100 M K_2CrO_4 has been added to the half-cell on the left and the mixture has been thoroughly stirred?
(c) What is the voltmeter reading after 10.00 mL of 10.0 M NH_3 has been added to the half-cell described in part (b) and the mixture has been thoroughly stirred?



90. An important source of Ag is recovery as a by-product in the metallurgy of lead. The percentage of Ag in lead was determined as follows. A 1.050-g sample was dissolved in nitric acid to produce $Pb^{2+}(aq)$ and $Ag^{+}(aq)$. The solution was then diluted to 500.0 mL with water, a Ag electrode was immersed in the solution, and the potential difference between this electrode and a SHE was found to be 0.503 V. What was the percent Ag by mass in the lead metal?

91. A test for completeness of electrodeposition of Cu from a solution of $Cu^{2+}(aq)$ is to add $NH_3(aq)$. A blue color signifies the formation of the complex ion $[Cu(NH_3)_4]^{2+}$ ($K_f = 1.1 \times 10^{13}$). Let 250.0 mL of 0.1000 M $CuSO_4(aq)$ be electrolyzed with a 3.512 A current for 1368 s. At this time, add a sufficient quantity of $NH_3(aq)$ to complex any remaining Cu^{2+} and to maintain a free $[NH_3] = 0.10$ M. If $[Cu(NH_3)_4]^{2+}$ is detectable at concentrations as low as 1×10^{-5} M, should the blue color appear?

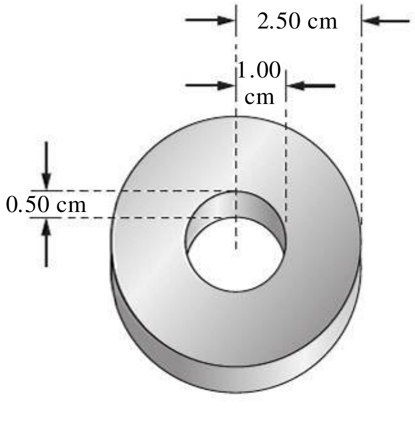
92. A solution is prepared by saturating 100.0 mL of 1.00 M $NH_3(aq)$ with AgBr. A silver electrode is immersed in this solution, which is joined by a salt bridge to a standard hydrogen electrode. What will be the measured E_{cell}? Is the standard hydrogen electrode the anode or the cathode?

93. The electrolysis of $Na_2SO_4(aq)$ is conducted in two separate half-cells joined by a salt bridge, as suggested by the cell diagram $Pt|Na_2SO_4(aq)||Na_2SO_4(aq)|Pt$.

(a) In one experiment, the solution in the anode compartment becomes more acidic and that in the cathode compartment, more basic during the electrolysis. When the electrolysis is discontinued and the two solutions are mixed, the resulting solution has pH = 7. Write half-equations and the overall electrolysis equation.

(b) In a second experiment, a 10.00-mL sample of an unknown concentration of $H_2SO_4(aq)$ and a few drops of phenolphthalein indicator are added to the $Na_2SO_4(aq)$ in the cathode compartment. Electrolysis is carried out with a current of 21.5 mA (milliamperes) for 683 s, at which point, the solution in the cathode compartment acquires a lasting pink color. What is the molarity of the unknown $H_2SO_4(aq)$?

94. A Ni anode and an Fe cathode are placed in a solution with $[Ni^{2+}] = 1.0$ M and then connected to a battery. The Fe cathode has the shape shown. How long must electrolysis be continued with a current of 1.50 A to build a 0.050-mm-thick deposit of nickel on the iron? (Density of nickel = 8.90 g/cm^3.)



95. Initially, each of the half-cells in Figure 20-21 contained a 100.0-mL sample of solution with an ion concentration of 1.000 M. The cell was operated as an electrolytic cell, with copper as the anode and zinc as the cathode. A current of 0.500 A was used. Assume that the only electrode reactions occurring were those involving Cu/Cu^{2+} and Zn/Zn^{2+}. Electrolysis was stopped after 10.00 h, and the cell was allowed to function as a voltaic cell. What was E_{cell} at that point?

96. Silver tarnish is mainly Ag_2S:

$$Ag_2S(s) + 2\,e^- \longrightarrow 2\,Ag(s) + S^{2-}(aq) \qquad E^\circ = -0.691\text{ V}$$

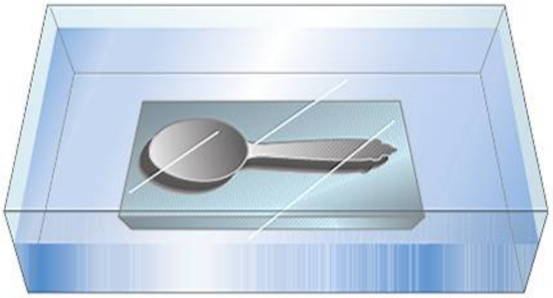
A tarnished silver spoon is placed in contact with a commercially available metallic product in a glass baking dish. Boiling water, to which some $NaHCO_3$ has been added, is poured into the dish, and the product and spoon are completely covered. Within a short time, the removal of tarnish from the spoon begins.

(a) What metal or metals are in the product?

(b) What is the probable reaction that occurs?

(c) What do you suppose is the function of the $NaHCO_3$?

(d) An advertisement for the product appears to make two claims: (1) No chemicals are involved, and (2) the product will never need to be replaced. How valid are these claims? Explain.



97. Your task is to determine E° for the reduction of $CO_2(g)$ to $C_3H_8(g)$ in two different ways and to explain why each gives the same result. **(a)** Consider a fuel cell in which the cell reaction corresponds to the complete combustion of propane gas. Write the half-cell reactions and the overall reaction. Determine ΔG° and E°_{cell} for the reaction, then obtain $E^\circ_{CO_2/C_3H_8}$. **(b)** Without considering the oxidation that occurs simultaneously, obtain $E^\circ_{CO_2/C_3H_8}$ directly from tabulated thermodynamic data for the reduction half-reaction.

98. Equation (20.15) gives the relationship between the standard Gibbs energy of a reaction and the standard cell potential. We know how the Gibbs energy varies with temperature.

(a) Making the assumption that ΔH° and ΔS° do not vary significantly over a small temperature range, derive an equation for the temperature variation of E°_{cell}.

(b) Calculate the cell potential of a Daniell cell at 50 °C under standard conditions. The overall cell reaction for a Daniell cell is $Zn(s) + Cu^{2+}(aq) \rightarrow Zn^{2+}(aq) + Cu(s)$.

99. Show that for nonstandard conditions the temperature variation of a cell potential is

$$E(T_1) - E(T_2) = (T_1 - T_2)\frac{(\Delta S^\circ - R\ln Q)}{zF}$$

where $E(T_1)$ and $E(T_2)$ are the cell potentials at T_1 and T_2, respectively. We have assumed that the value of Q is maintained at a constant value. For the nonstandard cell below, the potential drops from 0.394 V at 50.0 °C to 0.370 V at 25.0 °C. Calculate Q, $\Delta H°$, and $\Delta S°$ for the reaction, and calculate K for the two temperatures.

$$Cu(s)|Cu^{2+}(aq)||Fe^{3+}(aq), Fe^{2+}(aq)|Pt(s)$$

Choose concentrations of the species involved in the cell reaction that give the value of Q that you have calculated, and then determine the equilibrium concentrations of the species at 50.0 °C.

100. Show that for a combination of half-cell reactions that produce a standard reduction potential for a half-cell that is not directly observable, the standard reduction potential is

$$E° = \frac{\Sigma n_i E_i^\circ}{\Sigma n_i}$$

where n_i is the number of electrons in each half-reaction of potential E_i°. Use the following half-reactions:

$$H_5IO_6(aq) + H^+(aq) + 2\,e^- \longrightarrow IO_3^-(aq) + 3H_2O(l) \qquad E° = 1.60\text{ V}$$

$$IO_3^-(aq) + 6\,H^+(aq) + 5\,e^- \longrightarrow \frac{1}{2}I_2(s) + 3\,H_2O(l) \qquad E° = 1.19\text{ V}$$

$$2\,HIO(aq) + 2\,H^+(aq) + 2\,e^- \longrightarrow I_2(s) + 2\,H_2O(l) \qquad E° = 1.45\text{ V}$$

$$I_2(s) + 2\,e^- \longrightarrow 2\,I^-(aq) \qquad E° = 0.535\text{ V}$$

Calculate the standard reduction potential for

$$H_6IO_6 + 5\,H^+ + 2\,I^- + 3\,e^- \longrightarrow \frac{1}{2}I_2 + 4\,H_2O + 2\,HIO$$

Feature Problems

101. Consider the following electrochemical cell:

$$Pt(s)|H_2(g, 1\text{ atm})|H^+(1\text{ M})||Ag^+(x\text{ M})|Ag(s)$$

(a) What is E_{cell}°—that is, the cell potential when $[Ag^+] = 1$ M?
(b) Use the Nernst equation to write an equation for E_{cell} when $[Ag^+] = x$.
(c) Now imagine titrating 50.0 mL of 0.0100 M $AgNO_3$ in the cathode half-cell compartment with 0.0100 M KI. The titration reaction is

$$Ag^+(aq) + I^-(aq) \longrightarrow AgI(s)$$

Calculate $[Ag^+]$ and then E_{cell} after addition of the following volumes of 0.0100 M KI: (i) 0.0 mL; (ii) 20.0 mL; (iii) 49.0 mL; (iv) 50.0 mL; (v) 51.0 mL; (vi) 60.0 mL.
(d) Use the results of part (c) to sketch the titration curve of E_{cell} versus volume of titrant.

102. Ultimately, ΔG_f° values must be based on experimental results; in many cases, these experimental results are themselves obtained from $E°$ values. Early in the twentieth century, G. N. Lewis conceived of an experimental approach for obtaining standard potentials of the alkali metals. This approach involved using a solvent with which the alkali metals do not react. Ethylamine was the solvent chosen. In the following cell diagram, Na(amalg, 0.206%) represents a solution of 0.206% Na in liquid mercury.

1. $Na(s)|Na^+(\text{in ethylamine})|Na(\text{amalg}, 0.206\%) \qquad E_{cell} = 0.8453\text{ V}$

Although Na(s) reacts violently with water to produce $H_2(g)$, at least for a short time, a sodium amalgam electrode does not react with water. This makes it possible to determine E_{cell} for the following voltaic cell.

2. $Na(\text{amalg}, 0.206\%)|Na^+(1\text{ M})||H^+(1\text{ M})|H_2(g, 1\text{ atm}) \qquad E_{cell} = 1.8673\text{ V}$

(a) Write equations for the cell reactions that occur in the voltaic cells (1) and (2).
(b) Use equation (20.14) to establish ΔG for the cell reactions written in part (a).
(c) Write the overall equation obtained by combining the equations of part (a), and establish $\Delta G°$ for this overall reaction.
(d) Use the $\Delta G°$ value from part (c) to obtain E_{cell}° for the overall reaction. From this result, obtain $E_{Na^+/Na}^\circ$. Compare your result with the value listed in Appendix D.

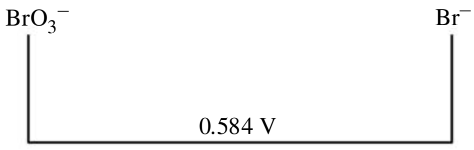
103. The following sketch is called an electrode potential diagram. Such diagrams summarize electrode potential data more efficiently than do listings such as that in Appendix D. In this diagram for bromine and its ions in basic solution,

$$BrO_4^- \xrightarrow{1.025\text{ V}} BrO_3^-$$

signifies

$$BrO_4^-(aq) + H_2O(l) + 2\,e^- \longrightarrow BrO_3^-(aq) + 2\,OH^-(aq), \; E_{BrO_4^-/BrO_3^-}^\circ = 1.025\text{ V}$$

Similarly,

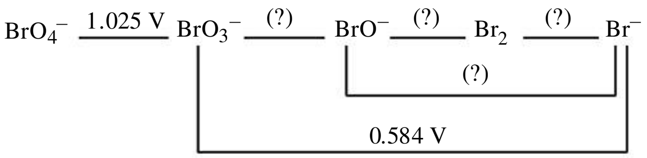


signifies

$$BrO_3^-(aq) + 3\,H_2O(l) + 6\,e^- \longrightarrow Br^-(aq) + 6\,OH^-(aq), \; E_{BrO_3^-/Br^-}^\circ = 0.584\text{ V}$$

With reference to Appendix D and to the method of determining $E°$ values outlined on page 875, supply the missing data in the following diagram.

Basic solution ($[OH^-] = 1$ M):



104. Only a tiny fraction of the diffusible ions move across a cell membrane in establishing a Nernst potential (see Focus On 20: Membrane Potentials), so there is no detectable concentration change. Consider a typical cell with a volume of 10^{-8} cm^3, a surface area (A) of 10^{-6} cm^2, and a membrane thickness (l) of 10^{-6} cm. Suppose that $[K^+] = 155$ mM inside the cell and $[K^+] = 4$ mM outside the cell and that the observed Nernst potential across the cell wall is 0.085 V. The membrane acts as a charge-storing device called a *capacitor*, with a *capacitance*, C, given by

$$C = \frac{\varepsilon_0 \varepsilon A}{l}$$

where ε_0 is the *dielectric constant* of a vacuum and the product $\varepsilon_0\varepsilon$ is the dielectric constant of the membrane, having a typical value of $3 \times 8.854 \times 10^{-12}$ $C^2\,N^{-1}m^{-2}$ for a biological membrane. The SI unit of capacitance is the *farad*, $1\ F = 1$ coulomb per volt $= 1\ C\ V^{-1} = 1 \times C^2\,N^{-1}\,m^{-1}$.

(a) Determine the capacitance of the membrane for the typical cell described.
(b) What is the net charge required to maintain the observed membrane potential?
(c) How many K^+ ions must flow through the cell membrane to produce the membrane potential?
(d) How many K^+ ions are in the typical cell?
(e) Show that the fraction of the intracellular K^+ ions transferred through the cell membrane to produce the membrane potential is so small that it does not change $[K^+]$ within the cell.

105. When deciding whether a particular reaction corresponds to a cell with a positive standard cell potential, which of the following thermodynamic properties would you use to get your answer without performing any calculations? Which would you not use? Explain. **(a)** $\Delta G°$; **(b)** $\Delta S°$; **(c)** $\Delta H°$; **(d)** $\Delta U°$; **(e)** K.

106. Consider two cells involving two metals X and Y

$$X(s)|X^+(aq)||H^+(aq), H_2(g, 1\ bar)|Pt(s)$$

$$X(s)|X^+(aq)||Y^{2+}(aq)|Y(s)$$

In the first cell electrons flow from the metal X to the standard hydrogen electrode. In the second cell electrons flow from metal X to metal Y. Is $E°_{X^+/X}$ greater or less than zero? Is $E°_{X^+/X} > E_{Y^{2+}/Y}$? Explain.

107. Describe in words how you would calculate the standard potential of the $Fe^{2+}/Fe(s)$ couple from those of Fe^{3+}/Fe^{2+} and $Fe^{3+}/Fe(s)$.

Self-Assessment Exercises

108. In your own words, define the following symbols or terms: **(a)** $E°$; **(b)** F; **(c)** anode; **(d)** cathode.

109. Briefly describe each of the following ideas, methods, or devices: **(a)** salt bridge; **(b)** standard hydrogen electrode (SHE); **(c)** cathodic protection; **(d)** fuel cell.

110. Explain the important distinctions between each pair of terms: **(a)** half-reaction and overall cell reaction; **(b)** voltaic cell and electrolytic cell; **(c)** primary battery and secondary battery; **(d)** E_{cell} and $E°_{cell}$.

111. Of the following statements concerning electrochemical cells, the correct ones are: **(a)** The cathode is the negative electrode in both voltaic and electrolytic cells. **(b)** The function of a salt bridge is to permit the migration of electrons between the half-cell compartments of an electrochemical cell. **(c)** The anode is the negative electrode in a voltaic cell. **(d)** Electrons leave the cell from either the cathode or the anode, depending on what electrodes are used. **(e)** Reduction occurs at the cathode in both voltaic and electrolytic cells. **(f)** If electric current is drawn from a voltaic cell long enough, the cell becomes an electrolytic cell. **(g)** The cell reaction is an oxidation-reduction reaction.

112. For the half-reaction $Hg^{2+}(aq) + 2\,e^- \longrightarrow Hg(l)$, $E° = 0.854$ V. This means that **(a)** Hg(l) is more readily oxidized than $H_2(g)$; **(b)** $Hg^{2+}(aq)$ is more readily reduced than $H^+(aq)$; **(c)** Hg(l) will dissolve in 1 M HCl; **(d)** Hg(l) will displace Zn(s) from an aqueous solution of Zn^{2+} ion.

113. The value of $E°_{cell}$ for the reaction $Zn(s) + Pb^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Pb(s)$ is 0.66 V. This means that for the reaction $Zn(s) + Pb^{2+}(0.01\ M) \longrightarrow Zn^{2+}(0.10\ M) + Pb(s)$, E_{cell} equals **(a)** 0.72 V; **(b)** 0.69 V; **(c)** 0.66 V; **(d)** 0.63 V.

114. For the reaction $Co(s) + Ni^{2+}(aq) \longrightarrow Co^{2+}(aq) + Ni(s)$, $E°_{cell} = 0.03$ V. If cobalt metal is added to an aqueous solution in which $[Ni^{2+}] = 1.0$ M, **(a)** the reaction will not proceed in the forward direction at all; **(b)** the displacement of Ni(s) from the $Ni^{2+}(aq)$ will go to completion; **(c)** the displacement of Ni(s) from the solution will proceed to a considerable extent, but the reaction will not go to completion; **(d)** there is no way to predict how far the reaction will proceed.

115. The gas evolved at the *anode* when $K_2SO_4(aq)$ is electrolyzed between Pt electrodes is most likely to be **(a)** O_2; **(b)** H_2; **(c)** SO_2; **(d)** SO_3; **(e)** a mixture of sulfur oxides.

116. The quantity of electric charge that will deposit 4.5 g Al at a cathode will also produce the following volume at STP of $H_2(g)$ from $H^+(aq)$ at a cathode: **(a)** 44.8 L; **(b)** 22.4 L; **(c)** 11.2 L; **(d)** 5.6 L.

117. If a chemical reaction is carried out in a fuel cell, the maximum amount of useful work that can be obtained is **(a)** ΔG; **(b)** ΔH; **(c)** $\Delta G/\Delta H$; **(d)** $T\,\Delta S$.

118. For the reaction $Zn(s) + H^+(aq) + NO_3^-(aq) \longrightarrow Zn^{2+}(aq) + H_2O(l) + NO(g)$, describe the voltaic cell in which it occurs, label the anode and cathode, use a table of standard electrode potentials to evaluate E°_{cell}, and balance the equation for the cell reaction.

119. The following voltaic cell registers an $E_{\text{cell}} = 0.108$ V. What is the pH of the unknown solution?

$$\text{Pt}|\text{H}_2(\text{g}, 1\text{ atm})|\text{H}^+(x\text{ M})||\text{H}^+(1.00\text{ M})|\text{H}_2(\text{g}, 1\text{ atm})|\text{Pt}$$

120. $E^\circ_{\text{cell}} = -0.0050$ V for the reaction, $2\,\text{Cu}^+(\text{aq}) + \text{Sn}^{4+}(\text{aq}) \longrightarrow 2\,\text{Cu}^{2+}(\text{aq}) + \text{Sn}^{2+}(\text{aq})$.

(a) Can a solution be prepared that is 0.500 M in each of the four ions at 298 K?

(b) If not, in what direction must a net reaction occur?

121. For each of the following combinations of electrodes (A and B) and solutions, indicate

- the overall cell reaction
- the direction in which electrons flow spontaneously (from A to B, or from B to A)
- the magnitude of the voltage read on the voltmeter, V

	A	Solution A	B	Solution B
(a)	Cu	1.0 M Cu^{2+}	Fe	1.0 M Fe^{2+}
(b)	Pt	1.0 M Sn^{2+}/1.0 M Sn^{4+}	Ag	1.0 M Ag^+
(c)	Zn	0.10 M Zn^{2+}	Fe	1.0×10^{-3} M Fe^{2+}

122. Use data from Table 20.1, as necessary, to predict the probable products when Pt electrodes are used in the electrolysis of **(a)** $\text{CuCl}_2(\text{aq})$; **(b)** $\text{Na}_2\text{SO}_4(\text{aq})$; **(c)** $\text{BaCl}_2(\text{l})$; **(d)** KOH(aq).

123. Using the method presented in Appendix E, construct a concept map showing the relationship between electrochemical cells and thermodynamic properties.

124. Construct a concept map illustrating the relationship between batteries and electrochemical ideas.

125. Construct a concept map illustrating the principles of electrolysis and its industrial applications.

21

Chemistry of the Main-Group Elements I: Groups 1, 2, 13, and 14

CONTENTS

21-1 Periodic Trends and Charge Density
21-2 Group 1: The Alkali Metals
21-3 Group 2: The Alkaline Earth Metals
21-4 Group 13: The Boron Family
21-5 Group 14: The Carbon Family

Some of the dramatic colors seen in fireworks displays are the flame colors of some of the groups 1 and 2 metals. These colors, as we will see, are related to the electronic structures of those metal atoms.

The chemistry of the elements is best described by using the periodic table as a basis. The trends within the groups and across the periods allow us to organize our thinking about the chemistry of the elements by using patterns. The chemistry of each group has both similarities and differences that can be understood in terms of the underlying principles that organize the periodic table. As we explore the chemistry of these groups, we will discover that the first member of a group is often markedly different from the others in its physical and chemical properties. Typically, the second member of the group exhibits properties that are most representative of the group.

In this chapter, our focus is on groups 1, 2, 13, and 14—the first four groups of the main group of elements. We will start with the chemistry of the group 1 metals: the alkali metals. They are the first members of the *s*-block elements. Atoms of the group 1 elements have ground state valence configurations that consist of a single electron in an *s* orbital.

KEEP IN MIND

that hydrogen is often placed in group 1 of the periodic table, but this element is not an alkali metal. Francium is an alkali metal, but this highly radioactive metal is so rare that few of its properties have been measured.

As discussed in Chapter 9, the group 1 atom in a given period is always the largest (having the largest atomic radius) and is the most easily ionized (having the lowest first ionization energy). As a result, the group 1 elements have low densities (some have densities of less than 1 g cm^{-3}), are easily oxidized, and are highly reactive. The reactivity of the alkali metals is evident in their violent reactions with water.

Next, we will discuss the group 2 metals: the alkaline earth metals. The group 2 metals are considered *s*-block elements because atoms of these metals have valence configurations that consist of two electrons in an *s* orbital. Like their group 1 neighbors, the metals of group 2 are highly reactive and less dense than a typical metal, though they are less reactive and denser than the alkali metals. Unlike the group 1 metals, the group 2 metals react only slowly, or not at all, with water, and all of them have densities greater than that of water.

Atoms of the *p*-block elements are characterized by valence configurations involving electrons in *p*-orbitals. In this chapter we will discuss groups 13 and 14. Atoms of these elements have the configurations ns^2np^1 and ns^2np^2, respectively. These are the first groups in which both metals and nonmetals are encountered. Boron is the only nonmetal in group 13 and has interesting chemistry because it tends to form molecules with incomplete octets around the central boron atoms. Aluminum is the most abundant of the metals and one of the most widely used. Aluminum metal is obtained from its compounds by using electrolysis. Because aluminum production requires prodigious quantities of electricity, aluminum-production plants are often located near plentiful sources of hydroelectricity.

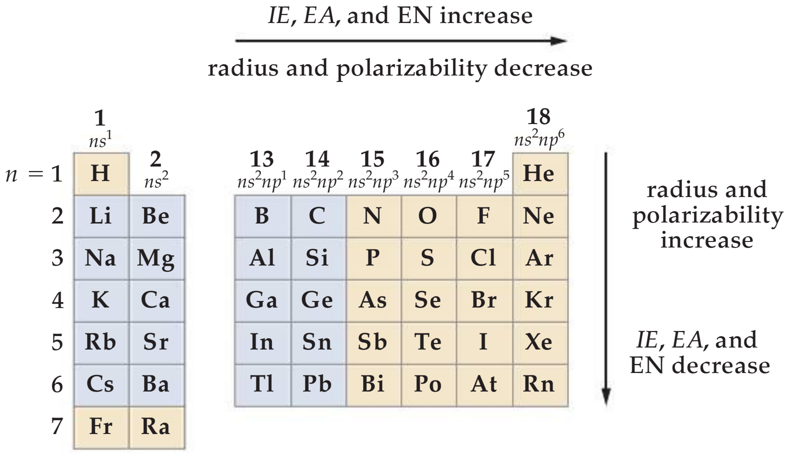
The remaining elements of group 13—gallium, indium, and thallium—are all metals. The chemistry of group 13 is dominated by boron and aluminum, and we will mention the heavier elements only briefly in this chapter. Group 14 contains a nonmetal (carbon), two metalloids (silicon and germanium), and two metals (tin and lead). Carbon has the most important chemistry of the group since it occurs in all living systems and we devote three chapters (26, 27 and 28) to the chemistry of carbon. Silicon is found in numerous minerals, forming many different and interesting oxoanions. In contrast to aluminum, tin and lead can be obtained by chemical reduction, using methods known since ancient times.

This chapter and the remaining chapters offer many opportunities to relate new information to principles presented earlier in the text. Ideas of atomic structure, periodic trends in atomic and ionic radii, chemical bonding, and thermodynamics will help us to understand the chemical behavior of the elements.

21-1 Periodic Trends and Charge Density

The chemistry of the elements can, to some extent, be rationalized in terms of the periodic trends that we have covered previously in this text. The atoms of each group of the periodic table have similar electronic configurations and consequently, the elements in a given group have similar—but not exactly the same—chemical properties. The first member of a group is the lightest and often has features that are different from the remaining members of the group. In this section we will briefly review trends in atomic properties and introduce a new ionic property. With these ideas as a basis we will begin to understand the trends in the chemistry of the elements.

The atomic properties that are responsible for the chemistry of an element are atomic radius, ionization energy, electron affinity, and polarizability. The electronegativity of an atom is also an important consideration. Before we attempt to explain the chemistry of the elements in terms of atomic properties, it will be helpful to examine Figure 21-1, which summarizes the periodic



▲ FIGURE 21-1

A summary of trends in atomic radius, first ionization energy, electron affinity, electronegativity, and atomic polarizability

Atomic radius and polarizability decrease from left to right in a given period and increase from top to bottom in a given group. Ionization energy (*IE*), electron affinity (*EA*) and electronegativity (EN) increase from left to right in a given period and decrease from top to bottom in a given group. The shaded elements are the focus of this chapter. Atomic radii, ionization energies, and electron affinities were discussed in Chapter 9. Electronegativities were discussed in Chapter 10 and polarizabilities in Chapter 12.

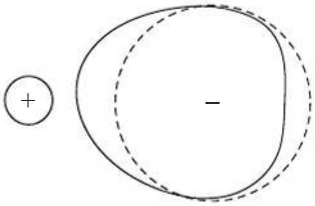
trends we have discussed previously in this text. The figure shows that atomic radii and polarizabilities decrease from left to right in a period and increase from top to bottom in a group. First ionization energies, electron affinities, and electronegativities show the opposite trend: these quantities increase across a period and decrease down a group. It is also important to remember that ionic radii follow the same trend as atomic radii and that cations are smaller than the parent atoms while anions are larger. Explanations for these trends have been given elsewhere in the text (see Chapters 9 and 10).

Most of the elements we consider in this chapter are metals, and when a metal combines with a nonmetallic element to form a compound, a metal atom is converted into a cation. When a cation interacts with an anion, the electron cloud of the anion is distorted into the internuclear region toward the cation, as suggested by Figure 21-2. As a result of this distortion, the bond between the cation and the anion has some covalent character in addition to its ionic character; the greater the distortion, the greater the covalent character.

The polarizability of the anion and the polarizing power of the cation determine the extent to which the electron cloud of the anion is distorted. It is generally true that anions derived from atoms that are lower down in a group are larger and more polarizable. For example, the I^- ion is much more polarizable than F^-. The polarizing power of a cation is related to its **charge density**. The charge density, ρ, can be defined as charge per unit volume. For a metal cation, M^{z+}, with ionic radius r, the charge density is calculated by using the formula below:

$$\rho = \frac{(1.60 \times 10^{-19}\ \text{C})(z)}{\frac{4}{3}\pi r^3} \qquad \textbf{(21.1)}$$

In equation (21.1), the numerator represents the total charge, in coulombs, of the cation; the denominator represents the volume of the cation, which is assumed to be spherical. If the ionic radius is expressed in millimeters, then



▲ FIGURE 21-2

Polarization of the electron cloud of an anion by a cation

A cation with a high charge density distorts the electron cloud around the anion. The undistorted electron cloud is shown with a dashed line and the distorted electron cloud is shown with a solid line. The greater the distortion of the electron cloud, the greater the degree of covalency of the bond.

KEEP IN MIND

that a variety of different definitions have been used for charge density. For example, some authors have defined charge density as the amount of charge distributed over the *surface* of the cation and thus, they calculate the charge density as $ze/(4\pi r^2)$, with $e = 1.60 \times 10^{-19}$ C. Both definitions provide a measure of the charge-to-size ratio for ions. The use of charge-to-size ratios can be traced back to at least 1928, when G. H. Cartledge introduced the *ionic potential*, z/r, in an attempt to explain variations in the properties of compounds.

the charge density is typically a number between 1 and 1000. As an example, consider the lithium cation, which has a charge of 1+ and an ionic radius of 73 pm:

$$\rho_{\text{Li}^+} = \frac{(1.60 \times 10^{-19}\ \text{C})(1)}{\frac{4}{3}\pi(73 \times 10^{-9}\ \text{mm})^3} = 98\ \text{C mm}^{-3}$$

The ionic radius decreases dramatically, and the charge density increases, as the charge on the cation increases. For example, the charge density of the Al^{3+} ion is much greater than that of the Li^+ ion (770 C mm^{-3} for Al^{3+} versus 98 C mm^{-3} for Li^+) because the charge number is much greater (+3 for Al^{3+} versus +1 for Li^+) and the ionic radius is much smaller (53 for Al^{3+} versus 73 pm for Li^+).

We anticipate that the higher the charge density, the greater the polarizing power of the cation and the greater the ability of a cation to distort the electron cloud of an anion toward itself. For example, because the charge density of the Al^{3+} ion is much greater than that of the Li^+ ion, we expect the interaction between Al^{3+} and I^- to have a greater degree of covalency than does the interaction between Li^+ and I^-.

Throughout this chapter, we will use the charge density concept to rationalize certain observations. For example, we will use it to help us understand why sometimes there are dramatic differences in the properties of elements in the same group and interesting similarities in the properties of elements in different groups. However, a single quantity—such as charge density—cannot be used to rationalize all things and it should never be used as a substitute for careful consideration of all contributing factors.

TABLE 21.1 Abundances of Group 1 Elements

Elements	Abundances, ppm[a]	Rank
Li	18	35
Na	22,700	7
K	18,400	8
Rb	78	23
Cs	2.6	46
Fr	Trace	—

[a] Grams per 1000 kg of solid crust.

21-1 CONCEPT ASSESSMENT

One way of distinguishing ionic behavior from covalent behavior is by comparing melting points. Ionic compounds tend to have higher melting points than covalent compounds. Which of the two halides of aluminium, AlF_3 and AlI_3, is expected to have the lowest melting point?

21-2 Group 1: The Alkali Metals

As Table 21.1 indicates, the group 1 elements, the **alkali metals**, are relatively abundant. Some of their compounds have been known and used since prehistoric times. Yet these elements were not isolated in pure form until about 200 years ago. The compounds of the alkali metals are difficult to decompose by ordinary chemical means, so discovery of the elements had to await new scientific developments. Sodium (1807) and potassium (1807) were discovered through electrolysis. Lithium was discovered in 1817. Cesium (1860) and rubidium (1861) were identified as new elements through their emission spectra. Francium (1939) was isolated in the radioactive decay products of actinium.

Because most alkali metal compounds are water soluble, a number of Li, Na, and K compounds, including chlorides, carbonates, and sulfates, can be obtained from natural brines. A few alkali metal compounds, such as NaCl, KCl, and Na_2CO_3, can be mined as solid deposits. Sodium chloride is also obtained from seawater. An important source of lithium is the mineral *spodumene*, $LiAl(SiO_3)_2$, shown in the margin. Rubidium and cesium are obtained as by-products in the processing of lithium ores.

▲ The mineral spodumene, $LiAl(SiO_3)_2$.

Physical Properties of the Alkali Metals

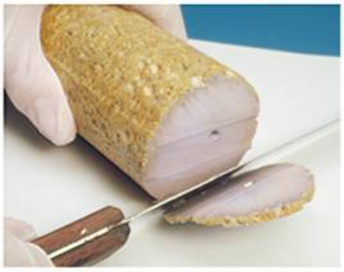
By any measure, the group 1 elements are the most active metals. Table 21.2 lists several of their properties, and a few of these properties are discussed next.

Flame Colors The energy differences between the valence-shell *s* and *p* orbitals of the group 1 atoms match those of certain wavelengths of visible light. As a result, when heated in a flame, group 1 compounds produce characteristic flame colors, as was shown in Figure 8.8. For example, when NaCl is vaporized in a flame, ion pairs are converted to gaseous atoms. Sodium atoms, Na(g), are excited to higher energies, and light with a wavelength of 589 nm (yellow) is emitted as the excited atoms (Na*) revert to their ground-state electron configurations.

$$\begin{aligned} \mathrm{Na^+Cl^-(g)} &\longrightarrow \mathrm{Na(g)} + \mathrm{Cl(g)} \\ \mathrm{Na(g)} &\longrightarrow \mathrm{Na^*(g)} \\ [\mathrm{Ne}]3s^1 \quad & \qquad [\mathrm{Ne}]3p^1 \\ \mathrm{Na^*(g)} &\longrightarrow \mathrm{Na(g)} + h\nu \text{ (589 nm; yellow)} \end{aligned}$$

Alkali metal compounds are used in pyrotechnic displays—fireworks.

Densities and Melting Points Atoms of the group 1 elements are the largest in their respective periods, and the atomic radii increase from the top to the bottom within this group, as was described in Chapter 9. These large atoms make for a relatively low mass per unit volume—that is, low density. The lighter of the alkali metals (Li, Na, and K) will float on water. The large atomic sizes, together with the fact that each of these atoms has only one valence electron, leads to rather weak metallic bonding. This property, in turn, leads to soft metals with low melting points. A bar of sodium has the consistency of a stick of butter and is easily cut with a knife, as shown in the photo in the margin.



▲ **The cutting of metallic sodium**
The sodium, an active metal, is covered with a thick oxide coating.

TABLE 21.2 Some Properties of the Group 1 (Alkali) Metals

	Li	Na	K	Rb	Cs
Atomic number	3	11	19	37	55
Valence-shell electron configuration	$2s^1$	$3s^1$	$4s^1$	$5s^1$	$6s^1$

Principal visible emission lines, nm	610,671	589	405,767	780,795	456,459

[a] The values given here assume a coordination number of 4 for Li^+ and 6 for the others.

[b] For the reduction $\mathrm{M^+(aq) + e^- \longrightarrow M(s)}$.

[c] Hardness measures the ability of substances to scratch, abrade, or indent one another. On the Mohs scale, ten minerals are ranked by hardness, ranging from that of talc (0) to diamond (10). Other values: wax (0 °C), 0.2; asphalt, 1–2; fingernail, 2.5; copper, 2.5–3; iron, 4–5; chromium, 9. Each substance can scratch only other substances with hardness values lower than its own.

[d] On a scale relative to silver as 100.

Electrode Potentials A good indicator of the extreme metallic character of the group 1 elements is their electrode potentials, which are large, negative quantities. The ions $M^+(aq)$ are very difficult to reduce to the metals M(s), and in turn, the metals are very easily oxidized to $M^+(aq)$. All the alkali metals easily displace $H_2(g)$ from water.

$$2\,M(s) + 2\,H_2O(l) \longrightarrow 2\,M^+(aq) + 2\,OH^-(aq) + H_2(g) \tag{21.2}$$

$$\begin{aligned} E^\circ_{cell} &= E^\circ_{H_2O/H_2} - E^\circ_{M^+/M} \\ &= -0.828\text{ V} - E^\circ_{M^+/M} \end{aligned}$$

Using the standard reduction potentials given in Table 21.2, we can calculate the following E°_{cell} values.

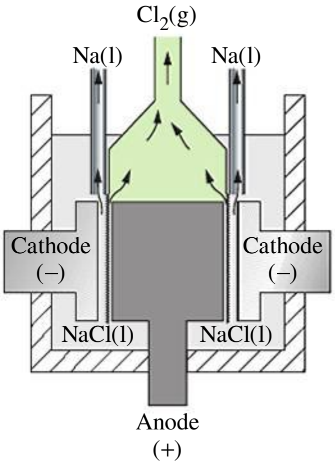
$$E^\circ_{cell} = 2.212\text{ V (for Li)} \qquad 1.885\text{ V (for Na)} \qquad 2.096\text{ V (for K)}$$
$$2.096\text{ V (for Rb)} \qquad 2.095\text{ V (for Cs)}$$

The E°_{cell} values indicate that of the alkali metals, lithium is the strongest reducing agent in aqueous solution. However, all the alkali metals are strong reducing agents in aqueous solution. If we convert the E°_{cell} values given above to equilibrium constants (K) by using the equation $K = nE^\circ_{cell}/(0.0592\text{ V})$, we find that the values of K range from 7×10^{31} for the reaction of Na(s) and water to 2×10^{37} for the reaction of Li(s) and water. The equilibrium position for reaction (21.2) is always very far to the right, and so reaction (21.2) goes essentially to completion regardless of which alkali metal is involved.

KEEP IN MIND

that the equilibrium position for a reaction is controlled by thermodynamic factors—such as E°_{cell} and K. The rate of a reaction, and the time it takes to reach equilibrium, is controlled by kinetic factors.

Experiments show that lithium reacts more slowly and less vigorously with water than do any of the other alkali metals. To explain this observation, it is necessary to consider what happens to the energy that is released by the reaction as the metal is oxidized by water. As the metal reacts, energy released by the reaction is used to heat the system, including unreacted metal. For all the alkali metals except lithium, energy released by the reaction is sufficient to melt the unreacted metal. The melting of the metal increases the rate of reaction because it causes more metal atoms to come into contact with water molecules. Because lithium metal does not melt as the reaction proceeds, the reaction of lithium and water is neither as fast nor as vigorous as it is for the other alkali metals.



▲ FIGURE 21-3
The Downs cell used for the production of sodium
The electrolysis cell shown here is the Downs cell. The electrolyte is molten NaCl(l) to which $CaCl_2$ has been added to lower the melting point of NaCl(s). Liquid sodium metal forms at the steel cathode and $Cl_2(g)$ forms at the graphite anode. The chlorine and sodium are kept apart by a steel gauze diaphragm.

Production and Uses of the Alkali Metals

Lithium and sodium are produced from their molten chlorides by electrolysis, Figure 21-3. The electrolysis of NaCl(l), for example, is carried out at about 600 °C.

$$2\,NaCl(l) \xrightarrow{\text{electrolysis}} 2\,Na(l) + Cl_2(g) \tag{21.3}$$

The melting point of NaCl is 801 °C, which is too high a temperature to carry out this electrolysis economically. Adding $CaCl_2$ to the mixture reduces the melting point. (Calcium metal, also produced in the electrolysis, precipitates out from the Na(l) as the liquid metal is cooled. The final product is 99.95% Na.)

Potassium metal is produced by the reduction of molten KCl by liquid sodium.

$$KCl(l) + Na(l) \xrightarrow{850\,°C} NaCl(l) + K(g) \tag{21.4}$$

Reaction (21.4) is reversible; at low temperatures, most of the KCl(l) remains unreacted. At 850 °C, however, the equilibrium is displaced far to the right as K(g) escapes from the molten mixture (an application of Le Châtelier's principle). The K(g) is freed of any Na(g) present by condensation of the vapor, followed by fractional distillation of the liquid metals. Rb and Cs can be produced in much the same way, with Ca metal as the reducing agent.

Because sodium metal is so easily oxidized, its most important use is as a reducing agent—for example, in obtaining such metals as titanium, zirconium, and hafnium.

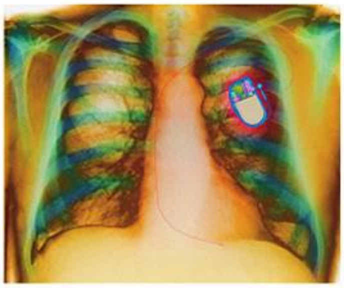
For example, titanium metal can be obtained from the reduction of $TiCl_4$ by Na, as shown below.

$$TiCl_4 + 4\,Na \xrightarrow{\Delta} Ti + 4\,NaCl$$

◀ We introduced the symbol $\xrightarrow{\Delta}$ in Chapter 4 (page 116) to indicate that a reaction is carried out at an elevated temperature.

Sodium is also used as a heat-transfer medium in nuclear reactors. Liquid sodium is especially good for this purpose because it has a low melting point, a high boiling point, and a low vapor pressure. Also, it has better thermal conductivity and a higher specific heat than do most liquid metals. Finally, its low density and low viscosity make it easy to pump. Sodium is also used in sodium vapor lamps, which are very popular for outdoor lighting. Because each lamp uses only a few milligrams of Na, however, the total quantity consumed in this application is rather small.

Lithium metal is used as an alloying agent to make high-strength, low-density alloys with aluminum and with magnesium. These alloys are used in the aerospace and aircraft industries. The use of lithium as an anode material in batteries is on the increase, in part because of its ease of oxidation and in part because a small mass of lithium produces a large number of electrons. Only 6.94 g Li (1 mol) needs to be consumed to produce one mole of electrons. Lithium batteries are particularly useful where the installed battery must have high reliability and a long lifetime, as in cardiac pacemakers. An X-ray photograph of a pacemaker is shown in the margin.



▲ An X-ray photograph showing a heart pacemaker powered by a lithium battery.

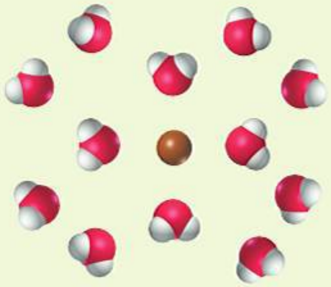
21-1 ARE YOU WONDERING...

Why lithium is the most easily oxidized of the group 1 elements on the basis of $E°$ values but not on the basis of ionization energies?

Being the smallest of the alkali metal atoms, Li has the highest first ionization energy. It is the most difficult to oxidize in the reaction $M(g) \longrightarrow M^+(g) + e^-$. However, oxidation to produce $M^+(aq)$ is a different matter. We can think of it as the overall result of a hypothetical three-step process.

$$\begin{array}{llcl}
\textit{Sublimation:} & M(s) & \longrightarrow & \cancel{M(g)} \\
\textit{Ionization:} & \cancel{M(g)} & \longrightarrow & \cancel{M^+(g)} + e^- \\
\textit{Hydration:} & \cancel{M^+(g)} & \longrightarrow & M^+(aq). \\
\hline
\textit{Overall:} & M(s) & \longrightarrow & M^+(aq) + e^-
\end{array}$$

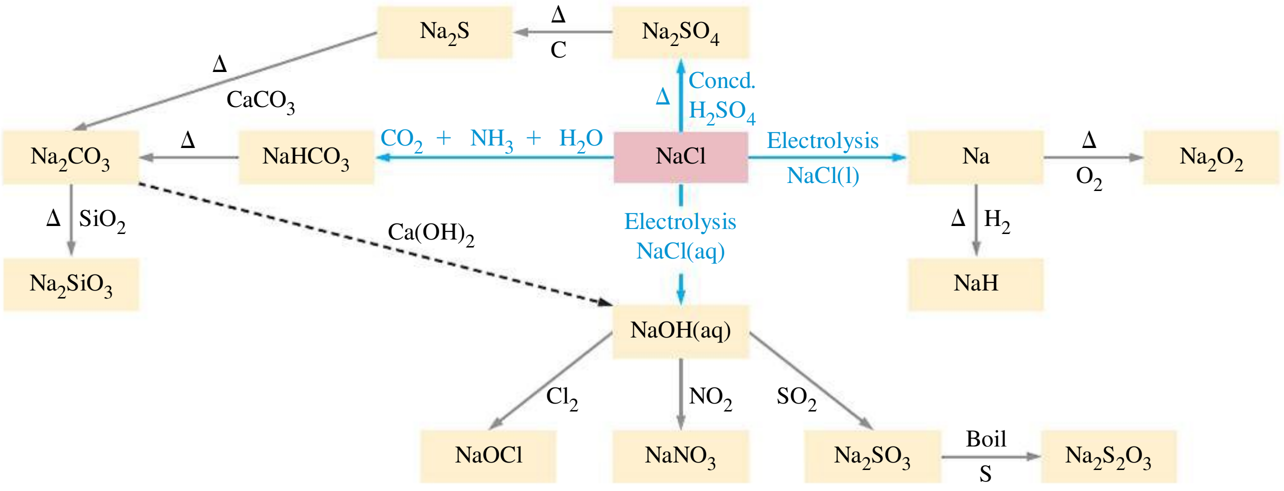
Thus, to compare tendencies to form $M^+(aq)$ by oxidation of the metals, we must compare tendencies in each of these three steps. The data given in Exercise 59 reveal that Li^+ has an unusually large hydration energy—enough to make $Li^+(aq)$ especially hard to reduce and Li(s) especially easy to oxidize. The large hydration energy is a consequence of the small size of the Li^+ ion, which allows a close approach to surrounding water molecules and strong attractive ion–dipole forces between them, as shown in Figure 21-4.



◀ FIGURE 21-4
Hydration of a Li^+ ion
Electrostatic forces hold a small number of H_2O molecules around a Li^+ ion in a primary hydration sphere. These molecules, in turn, hold other molecules, but more weakly, in a secondary hydration sphere.

KEEP IN MIND

that the more negative the value of $E°$, the more difficult is the reduction but the more easily does the reverse process—the oxidation half-reaction—occur. The value of $E°_{Li^+/Li}$, −3.040 V, comes at the very bottom of a listing of electrode potentials (recall Table 20-1), making Li(s) the easiest substance to oxidize.



▲ FIGURE 21-5
Preparation and reactions of sodium compounds
This is a simple and common method of summarizing important reactions, starting from a compound of control importance. Most of these reactions are described in this section. A number of these compounds may be prepared by alternative methods. The conversion of Na_2CO_3 to NaOH (dashed arrow) is no longer of commercial importance.

Group 1 Compounds

Group 1 metals, Li–Fr, have a valence configuration of ns^1 and occur exclusively in the +1 oxidation state. Most of the compounds of group 1 metals are stable, ionic solids. When studying the chemistry of the elements we are faced with a large amount of information that is challenging to organize. Figure 21-5 introduces a useful diagrammatic format for summarizing reaction chemistry. Although this diagram deals with sodium compounds, some of which are discussed in this section, similar diagrams can be constructed for other compounds. Such diagrams note a compound of central importance (NaCl in Figure 21-5) and show how several other compounds can be obtained from it. Some of these conversions occur in one step, such as the reaction of NaCl with H_2SO_4 to form Na_2SO_4 (discussed on page 930). Other conversions involve two or more consecutive reactions, such as the preparation of sodium silicate, Na_2SiO_3. The principal reactants required for the conversions are written near the connecting arrows. If a reaction mixture must be heated, a Δ symbol is used to indicate this requirement. The reactions may also produce by-products that are not noted in the diagram.

Hydration of Salts When salts are dissolved in water, the cations are hydrated, as suggested by Figure 21-4. The anions are similarly hydrated but with the slightly positive hydrogen atoms of the water molecules directed toward the anion. When a salt crystallizes from an aqueous solution, the salt that is obtained may or may not contain water molecules—called water of crystallization—as part of the solid structure. No simple rule exists for predicting with certainty whether the ions will retain all or part of their hydration spheres in the solid state because a number of factors must be considered. That being said, cations with high charge densities tend to retain all or part of their hydration spheres in the solid state. When the cations have low charge densities, the cations tend to lose their hydration spheres; thus, they tend to form anhydrous salts.

The charge densities of the alkali metals are shown in Table 21.2 and, with the exception of lithium and perhaps sodium, the charge densities are rather low; consequently, the majority of alkali metal salts are anhydrous. With lithium and sodium, salts are most likely to exist as hydrated salts. The

EXAMPLE 21-1 Writing Chemical Equations from a Summary Diagram of Reaction Chemistry

Use the information provided in Figure 21-5 to write balanced chemical equations for the reactions involved in synthesizing sodium carbonate from sodium chloride.

Analyze

Consult Figure 21-5 to find a route from NaCl to Na_2CO_3. One possible route involves the conversions NaCl $\longrightarrow Na_2SO_4 \longrightarrow Na_2S \longrightarrow Na_2CO_3$. For each conversion, the other necessary reactants (H_2SO_4, C, $CaCO_3$) are noted. Use this information to write balanced chemical equations for each conversion, keeping in mind that other reaction products (such as HCl, CO and CaS) must be included.

Solve

First, $Na_2SO_4(s)$ is produced from NaCl(s) and concentrated sulfuric acid.

$$2\,NaCl(s) + H_2SO_4(\text{concd aq}) \xrightarrow{\Delta} Na_2SO_4(s) + 2\,HCl(g)$$

Next, the Na_2SO_4 is reduced to Na_2S with carbon.

$$Na_2SO_4(s) + 4\,C(s) \xrightarrow{\Delta} Na_2S(s) + 4\,CO(g)$$

The final step is a reaction between Na_2S and $CaCO_3$.

$$Na_2S(s) + CaCO_3(s) \xrightarrow{\Delta} CaS(s) + Na_2CO_3(s)$$

Assess

There are three conversions and thus three separate chemical equations. Each chemical equation is balanced and produces one of the sodium compounds on the route chosen.

PRACTICE EXAMPLE A: Write chemical equations for the reactions involved in synthesizing sodium nitrate from sodium chloride.

PRACTICE EXAMPLE B: Write chemical equations for the reactions involved in synthesizing sodium thiosulfate from sodium chloride.

empirical formulas of the alkali metal perchlorates illustrate nicely the greater tendency of Li and Na to form hydrated salts: $LiClO_4 \cdot 3\,H_2O$, $NaClO_4 \cdot H_2O$, $KClO_4$, $RbClO_4$, $CsClO_4$.

Halides All alkali metals react vigorously, sometimes explosively, with halogens to produce ionic halides, the most important of which are NaCl and KCl. Sodium chloride—salt—is the most used of all minerals for the production of chemicals. It is not listed among the top chemicals, however, because it is considered a raw material, not a manufactured chemical. Large quantities of NaCl can be obtained by evaporation of seawater, as shown in the photograph. Annual use of NaCl in the United States amounts to about 50 million metric tons. Salt is used to preserve meat and fish, control ice on roads, and regenerate water softeners. In the chemical industry, NaCl is a source of many chemicals, including sodium metal, chlorine gas, hydrochloric acid, and sodium hydroxide.

Potassium chloride, KCl, is obtained from naturally occurring brines (concentrated solutions of salts). It is most extensively used in plant fertilizers because potassium is a major essential element for plant growth. Potassium

◀ Sea salt (sodium chloride) stacks that have been harvested by evaporation of seawater.

chloride is also used as a raw material in the manufacture of KOH, KNO_3, and other industrially important potassium compounds.

Alkali Metal Hydrides When an alkali metal (M) is heated in the presence of hydrogen gas, an ionic hydride is formed:

$$2\,M(s) + H_2(g) \xrightarrow{\Delta} 2\,MH(s)$$

Alkali metal hydrides contain the hydride ion, H^-, and have the sodium chloride structure. All the alkali metal hydrides are very reactive. For example, they react readily with water to give a hydroxide salt and hydrogen gas:

$$MH(s) + H_2O(l) \longrightarrow MOH(aq) + H_2(g)$$

Alkali metal hydrides also react with metal halides. An important example is the reaction of lithium hydride and aluminum chloride, $AlCl_3$, which produces lithium aluminum hydride, $LiAlH_4$, and lithium chloride. Lithium aluminum hydride (LAH) is a powerful reducing agent used in organic chemistry. $LiAlH_4$ can be made using the following reaction:

$$4LiH + AlCl_3 \xrightarrow{(C_2H_5)_2O} LiAlH_4 + 3\,LiCl$$

The reaction is carried out by adding finely divided LiH(s) to a solution of $AlCl_3$ in a nonaqueous solvent, such as diethyl ether, $(C_2H_5)_2O$. A nonaqueous solvent is used because both $LiAlH_4$ and LiH react vigorously with water. $LiAlH_4$ is obtained as a white solid by careful and controlled evaporation of the solvent.

Oxides and Hydroxides The alkali metals react rapidly with oxygen to produce several different ionic oxides. Under appropriate conditions—generally by carefully controlling the supply of oxygen—the oxide M_2O can be prepared for each of the alkali metals. Lithium reacts with excess oxygen to give Li_2O and a small amount of lithium *peroxide*, Li_2O_2. Sodium reacts with excess oxygen to give mostly the peroxide Na_2O_2 and a small amount of Na_2O. Potassium, rubidium, and cesium react to form the *superoxides*, MO_2. The oxides, peroxides, and superoxides are ionic compounds. The Lewis symbol for the O^{2-} ion and the Lewis structures for the $O_2{}^{2-}$ and $O_2{}^{-}$ ions are shown below:

Oxide ion

Peroxide ion

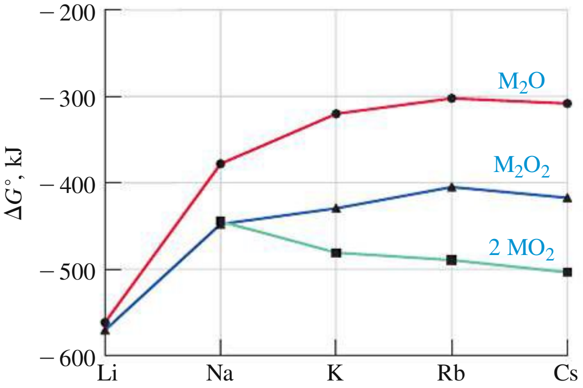
Superoxide ion

The principal products of the reactions of the alkali metals with excess oxygen are summarized in the following table.

▶ These are not the only oxides formed by the alkali metals. About nine different cesium oxides are known.

Principal Combustion Product			
Akali Metal	Oxide	Peroxide	Superoxide
Li	Li_2O		
Na		Na_2O_2	
K			KO_2
Rb			RbO_2
Cs			CsO_2

Notice that the principal combustion product shifts from the oxide (M_2O) to the superoxide (MO_2) as we move down the group from Li to Cs. If we assume that the principal combustion product is the compound that is *most stable with respect to the starting materials*, then we conclude that $Li_2O(s)$ is more stable than $Li_2O_2(s)$ or $LiO_2(s)$, but for the larger alkali metal ions, $MO_2(s)$ is more stable than $M_2O(s)$ or $M_2O_2(s)$. In Figure 21-6, we use ΔG_f° values to compare the stabilities of the various oxides, relative to the elements M(s) and $O_2(g)$.



◀ FIGURE 21-6
Relative stabilities of M_2O, M_2O_2, and $2MO_2$ for the alkali metals
The values of ΔG° at 298 K for forming $M_2O(s)$, $M_2O_2(s)$, and 2 $MO_2(s)$ from M(s) and $O_2(g)$ are plotted for the alkali metals. For K, Rb, and Cs, the superoxides are more stable relative to M(s) and $O_2(g)$ than are the peroxides and monoxides. The ΔG° values for $Li_2O(s)$ and $Li_2O_2(s)$ are very similar at 298 K. At higher temperatures, ΔG_f° for $Li_2O(s)$ is more negative than that of $Li_2O_2(s)$.

▲ The data in Figure 21-6 show that the ΔG_f° values for $Li_2O(s)$ and $Li_2O_2(s)$ are almost the same at 298 K. In a combustion reaction, heat is not dissipated immediately, and the system will be heated temporarily to a very high temperature. At high temperatures, ΔG_f° for $Li_2O(s)$ is more negative than it is for $Li_2O_2(s)$—see exercise 59—and the formation of $Li_2O(s)$ is thermodynamically favored.

For K, Rb, and Cs, the superoxide is most stable (lowest in energy) and for Li and Na, the oxides (M_2O) and peroxides (M_2O_2) are most stable.

Perhaps it comes as a surprise that the principal combustion product in these reactions is MO_2 (or M_2O_2) and not M_2O. Because the O^{2-} ion has a complete octet, it is tempting to jump to the conclusion that O^{2-} is a very stable ion. However, stability can be measured only relative to some set of reference conditions. Compared with oxygen molecules, the O^{2-} ion is not very stable. The formation of the O^{2-} ion from O_2 is a very endothermic process because the O═O bond must be broken and two electrons must be added to an O atom. The formation of one mole of O^{2-} ions from O_2 molecules requires 852 kJ of energy, as shown below:

$$\begin{array}{rll}
\frac{1}{2}O_2(g) \longrightarrow O(g) & \Delta H = \frac{1}{2}(498\ \text{kJ}) \\
O(g) + e^- \longrightarrow O^-(g) & \Delta H = -141\ \text{kJ} \\
O^-(g) + e^- \longrightarrow O^{2-}(g) & \Delta H = +744\ \text{kJ} \\
\hline
\frac{1}{2}O_2(g) + 2e^- \longrightarrow O^{2-}(g) & \Delta H = 852\ \text{kJ}
\end{array}$$

The formation of $O_2{}^-$ or $O_2{}^{2-}$ ions requires much less energy because the O═O bond does not have to be broken. Because the energy requirement for forming O^{2-} ions is so large, it is somewhat surprising that $M_2O(s)$ is formed at all.

The energy consumed in the formation of M^+ and O^{2-} ions is offset by the energy released when M^+ and O^{2-} ions combine to give $M_2O(s)$, as shown below.

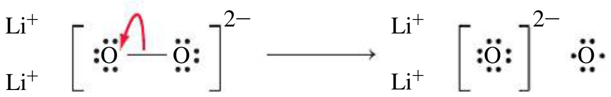
$$2\,M^+(g) + O^{2-}(g) \longrightarrow M_2O(s) \qquad \Delta H < 0$$

The enthalpy change for the process above is the lattice energy (see Chapter 12). The formation of $Li_2O(s)$ starting from Li(s) and $O_2(s)$ is very favorable because the lattice energy of Li_2O is very large (very negative). The lattice energy of Li_2O is large because the Li^+ ion is small and can pack around the O^{2-} ions very efficiently. The lattice energies of Na_2O, K_2O, Rb_2O, and Cs_2O are much smaller (less negative) than that of Li_2O, and so the formation of the M_2O lattice is much less favorable. The larger alkali metal ions pack more efficiently around the larger anions ($O_2{}^{2-}$ or $O_2{}^-$), and thus the heavier alkali metals react with excess oxygen to give either M_2O_2 or MO_2.

The combustion of Li(s) in excess oxygen produces some $Li_2O_2(s)$ as a minor product, and this suggests that $Li_2O_2(s)$ is a reasonably stable compound. Solid Li_2O_2 decomposes to Li_2O, as shown below, when heated to about 300 °C:

$$Li_2O_2(s) \xrightarrow{\Delta} Li_2O(s) + \frac{1}{2}O_2(g)$$

The other alkali metal peroxides must be heated to higher temperatures ($>500\ ^\circ\mathrm{C}$) before decomposition occurs. The decomposition of $\mathrm{Li_2O_2(s)}$ to $\mathrm{Li_2O(s)}$ is thermodynamically favorable because of large differences in the lattice energies of the two solids, but the decomposition may also be assisted kinetically, as suggested below:



Because of the high polarizing power of the $\mathrm{Li^+}$ ion, electrons in the $\mathrm{O_2{}^{2-}}$ bond are dragged from the bond to one of the oxygen atoms, yielding an $\mathrm{O^{2-}}$ ion and an oxygen atom. The oxygen atom combines with another oxygen atom to form an $\mathrm{O_2}$ molecule.

The peroxides have many important uses. For example, sodium peroxide is used as a bleaching agent and a powerful oxidant. Lithium peroxide or sodium peroxide are sometimes used in emergency breathing devices in submarines and spacecraft because these compounds react with carbon dioxide to produce oxygen, as shown below:

$$2\,\mathrm{M_2O_2(s)} + 2\,\mathrm{CO_2(s)} \longrightarrow 2\,\mathrm{M_2CO_3(s)} + \mathrm{O_2(s)} \qquad (\mathrm{M} = \mathrm{Li, Na}) \qquad \mathbf{(21.5)}$$

Potassium superoxide, $\mathrm{KO_2}$, can also be used for this purpose. The oxides, peroxides, and superoxides of the alkali metals react with water to form basic solutions. The reaction of an alkali metal oxide with water is an acid–base reaction that produces the alkali metal hydroxide.

The chemical equation and net ionic equation for the reaction are given below:

$$\mathrm{M_2O(s)} + \mathrm{H_2O(l)} \longrightarrow 2\,\mathrm{MOH(aq)}$$
$$\mathrm{O^{2-}(aq)} + \mathrm{H_2O(l)} \longrightarrow 2\,\mathrm{OH^-(aq)}$$

The resulting solution is quite basic because one mole of the oxide produces two moles of hydroxide ions.

The peroxide ion reacts with water in a similar manner to produce hydroxide ion and hydrogen peroxide.

$$\mathrm{O_2{}^{2-}(aq)} + 2\,\mathrm{H_2O(l)} \longrightarrow 2\,\mathrm{OH^-(aq)} + \mathrm{H_2O_2(aq)}$$

Hydrogen peroxide then slowly disproportionates into water and oxygen (page 174).

The superoxide ion reacts with water to give hydroxide ions, hydrogen peroxide, and oxygen.

$$2\,\mathrm{O_2{}^-(aq)} + 2\,\mathrm{H_2O(l)} \longrightarrow 2\,\mathrm{OH^-(aq)} + \mathrm{H_2O_2(aq)} + \mathrm{O_2(g)}$$

The hydroxides of the group 1 metals are strong bases because they dissociate to release hydroxide ions in aqueous solution. As we learned in Section 20-8, sodium hydroxide is produced commercially by the electrolysis of NaCl(aq). $\mathrm{Na^+(aq)}$ goes through the electrolysis unchanged; $\mathrm{Cl^-(aq)}$ is oxidized to $\mathrm{Cl_2(g)}$; and $\mathrm{H_2O}$ is reduced to $\mathrm{H_2(g)}$. Potassium hydroxide and lithium hydroxide are made in a similar fashion. Alkali metal hydroxides can also be prepared by the reaction of the group 1 metals with water (equation 21.2). Alkali hydroxides are important in the manufacture of soaps and detergents, described later in this section.

Carbonates and Sulfates Except for $\mathrm{Li_2CO_3}$, all the alkali metal carbonates ($\mathrm{M_2CO_3}$) are soluble in water and can be heated to very high temperatures ($>800\ ^\circ\mathrm{C}$) before decomposing to $\mathrm{M_2O(s)}$ and $\mathrm{CO_2(g)}$. The lower aqueous solubility of $\mathrm{Li_2CO_3}$ and its lower stability with respect to the oxide are specific examples of a more general observation: *compounds derived from the first member of a group are often markedly different from compounds derived from the other members of the group.* Typically, the second member of the group exhibits chemistry most representative of the group. No single explanation accounts for the fact that the first member is not representative of the group. However, in many cases, the distinctive chemistry of the first member of the group can be attributed to the small atomic size, inability to expand the valence shell and especially for the *p*-block elements, extensive $\pi-$ bonding.

Lithium carbonate is used in the treatment of individuals who have bipolar disorder. Daily dosages of 1–2 g Li_2CO_3 maintain a level of Li^+ in the blood of about one millimole per liter. This treatment apparently influences the balance of Na^+ and K^+, that of Mg^{2+} and Ca^{2+}, or both, across cell membranes.

Sodium carbonate (soda ash) is used primarily in the manufacture of glass. The Na_2CO_3 produced in the United States now comes mostly from natural sources, such as the mineral *trona*, $Na_2CO_3 \cdot NaHCO_3 \cdot nH_2O$, found in dry lakes in California and in immense deposits in western Wyoming. In the past, sodium carbonate was manufactured mostly from NaCl, $CaCO_3$, and NH_3, using a process introduced by the Belgian chemist Ernest Solvay in 1863.

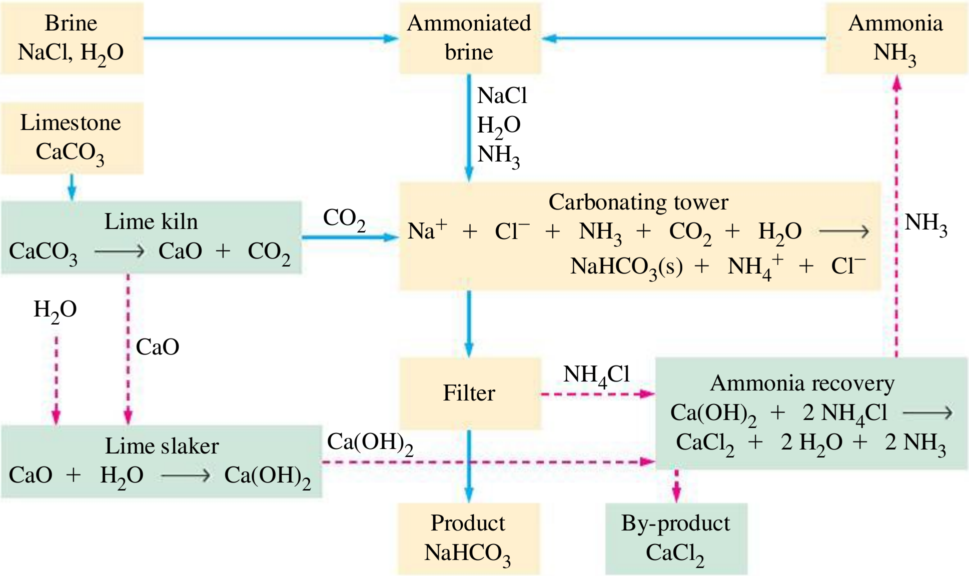
The great success of the *Solvay process* over the synthetic method outlined in Example 21-1 lies in the efficient use of certain raw materials through recycling. An outline of the process is shown in Figure 21-7. The key step involves the reaction of $NH_3(g)$ and $CO_2(g)$ in saturated NaCl(aq). Of the possible ionic compounds that could precipitate from such a mixture (NaCl, NH_4Cl, $NaHCO_3$, and NH_4HCO_3), the least soluble is *sodium hydrogen carbonate* (sodium bicarbonate). The following equation gives a simplified description of the process.

$$Na^+(aq) + Cl^-(aq) + NH_3(g) + CO_2(g) + H_2O(l) \longrightarrow NaHCO_3(s) + NH_4^+(aq) + Cl^-(aq) \qquad \textbf{(21.6)}$$

In industry, the reaction above is actually carried out in two stages. In the first stage, ammonia is bubbled into a concentrated brine (NaCl) solution, and in

◀ The term *ash* signifies a product obtained by heating or burning. The earliest alkaline materials (notably, potassium carbonate, *potash*) were extracted from the ashes of burned plants. The first commercial source of *soda ash* was the Leblanc process, featured in Example 21-1.

▲ The mineral *trona*, from Green River, Wyoming, is currently the principal source of Na_2CO_3 in the United States.



▲ FIGURE 21-7
The Solvay process for the manufacture of $NaHCO_3$
The main reaction sequence is traced by solid arrows. Recycling reactions are shown by dashed arrows.

the second stage, CO_2 is bubbled through the ammoniated brine. The sodium bicarbonate is isolated and sold, or it is converted to sodium carbonate by heating, as shown below in reaction (21.7).

$$2\,NaHCO_3(s) \xrightarrow{\Delta} Na_2CO_3(s) + H_2O(g) + CO_2(g) \qquad \textbf{(21.7)}$$

One noteworthy feature of the Solvay process is that it involves only simple precipitation and acid–base reactions. Another feature is that materials produced in one step are efficiently recycled into a subsequent step. Recycling makes good economic sense: A process that recycles materials minimizes the use of raw materials (an expense in purchasing) and cuts down on the production of by-products (an expense in disposal). Thus, when limestone ($CaCO_3$) is heated to produce the reactant CO_2, the other reaction product, CaO, is also used. It is converted to $Ca(OH)_2$, which is then used to convert NH_4Cl (another reaction by-product) to $NH_3(g)$. The $NH_3(g)$ is recycled into the production of ammoniated brine.

The Solvay process has ultimately only one by-product—$CaCl_2$—for which the demand is very limited. In the past, some $CaCl_2$ was used for deicing roads in the winter (page 584) and for dust control on dirt roads in the summer (by means of the deliquescence of $CaCl_2 \cdot 6\,H_2O$, page 578). The bulk of the $CaCl_2$, however, was dumped into local lakes and streams (notably, Onondaga Lake, near Solvay, New York), resulting in extensive environmental contamination. Environmental regulations no longer permit such dumping. Partly because of these regulations, but mainly for economic reasons, natural sources of sodium carbonate have supplanted the Solvay process in the United States. The process is still widely used elsewhere in the world, however.

Sodium sulfate, Na_2SO_4, is obtained partly from natural sources, partly from neutralization reactions, and partly through a process discovered by Johann Rudolf Glauber in 1625. Glauber's process is based on the following reactions.

▶ Equations (21.8) are often replaced by the overall equation, $H_2SO_4(\text{concd aq}) + 2\,NaCl(s) \longrightarrow Na_2SO_4(s) + 2\,HCl(g)$

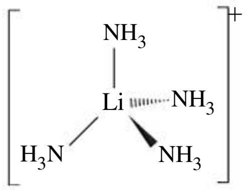
$$\begin{aligned} H_2SO_4(\text{concd aq}) + NaCl(s) &\xrightarrow{\Delta} NaHSO_4(s) + HCl(g) \\ NaHSO_4(s) + NaCl(s) &\xrightarrow{\Delta} Na_2SO_4(s) + HCl(g) \end{aligned} \qquad \textbf{(21.8)}$$

The strategy behind reactions (21.8) is the production of a *volatile* acid (HCl) by heating one of its salts (NaCl) with a *nonvolatile* acid (H_2SO_4). Several other acids can be produced by similar reactions. The major use of Na_2SO_4 is in the paper industry. For instance, in the kraft process for papermaking, undesirable lignin is removed from wood by digesting the wood in an alkaline solution of Na_2S. The Na_2S required for this step is produced by the reduction of Na_2SO_4 with carbon.

$$Na_2SO_4(s) + 4\,C(s) \xrightarrow{\Delta} Na_2S(s) + 4\,CO(g)$$

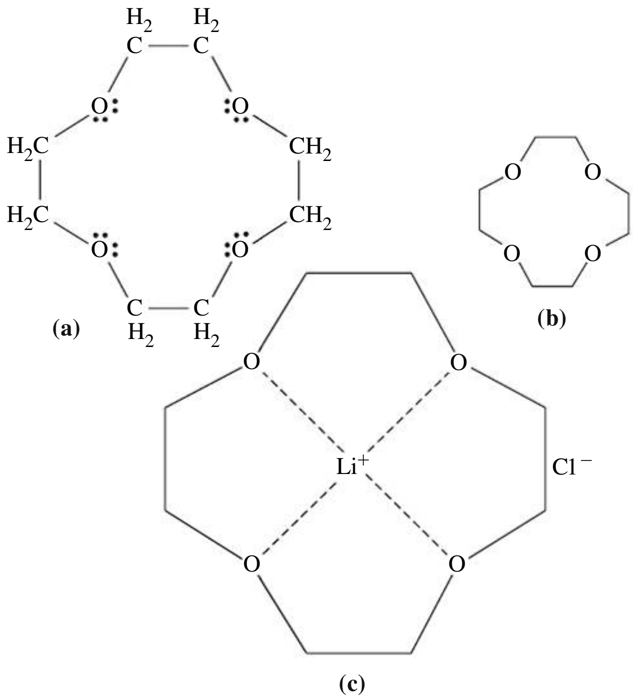
About 45 kilograms of Na_2SO_4 is required for every metric ton of paper produced.

Alkali Metal Complexes Most alkali metals show little or no tendency to form complexes with neutral Lewis bases, such as NH_3, because most of them have relatively low charge densities. However, the Li^+ ion has an unusually high charge density and shows a greater tendency to form complexes with simple Lewis bases. For example, in the presence of ammonia, the lithium ion forms a tetrahedral complex, $[Li(NH_3)_4]^+$, which is shown in the margin.



▲ The $[Li(NH_3)_4]^+$ complex

In 1967, Charles J. Pedersen reported the discovery of a type of Lewis base that could coordinate the "recalcitrant alkali metal ions," a quote from his 1987 Nobel lecture. The structure of the Lewis base is that of a ring of oxygen atoms connected by $—CH_2CH_2—$ units, as shown in Figure 21-8(a). The ring structures were called *crown ethers* by Pedersen because they resemble a monarch's crown. Crown ethers are given a name that reflects its structure in



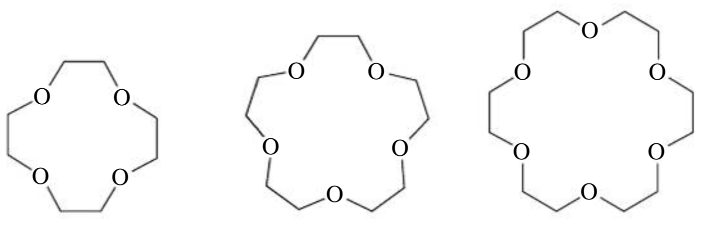
◀ FIGURE 21-8
12-crown-4 ether and the [Li(12-crown-4)]$^+$ complex
(a) The 12-crown-4 ether consists of a ring of 12 atoms, of which 4 are oxygen atoms. **(b)** A simplified illustration of 12-crown-4. **(c)** In the [Li(12-crown-4)]$^+$ complex, electron density is donated from the oxygen atoms to the Li$^+$ ion.

a very intuitive way. For example, the crown ether shown in Figure 21-8 is called 12-crown-4 because the ring consists of 12 carbon and oxygen atoms, and of those 12 ring atoms, 4 are oxygen. A line-angle formula of 12-crown-4 is shown in Figure 21-8(b). When a crown ether forms a complex with a metal ion, it encapsulates the metal ion, as shown in Figure 21-8(c). The metal ion is held in place by the donation of electron density from the oxygen atoms.

The cavity size of a crown ether depends on the number of $—OCH_2CH_2—$ units in the ring. This is illustrated in Figure 21-9. Cavity size is one of the factors that determine which cations will bind to a particular crown ether. The diameter of a K$^+$ ion is about 304 pm, and thus a K$^+$ ion fits nicely in the cavity of the 18-crown-6 ether. Thus, the K$^+$ ion binds preferentially to 18-crown-6, whereas Li$^+$ and Na$^+$ bind less effectively. A chemical equation representing the binding of a metal cation and 18-crown-6 is given below:

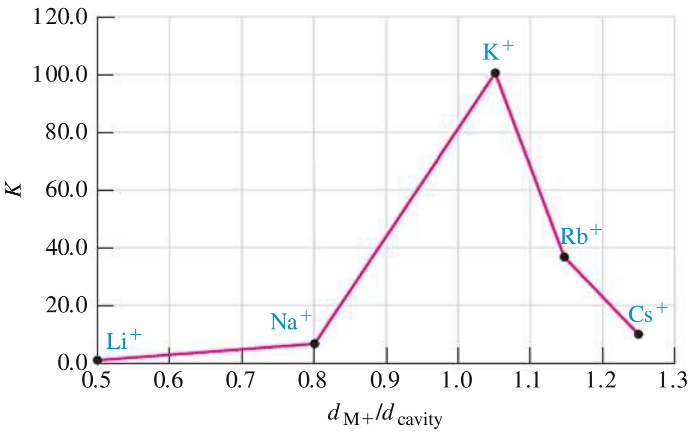
$$\mathrm{M^+ + 18\text{-}crown\text{-}6 \rightleftharpoons [M(18\text{-}crown\text{-}6)]^+}$$

Equilibrium constants for the reaction of the alkali metal ions with 18-crown-6 are plotted in Figure 21-10. The figure shows that the equilibrium constant is greatest when the cation is K$^+$, partly because K$^+$ fits best into the cavity of 18-crown-6. However, the values of the equilibrium constants are not



12-crown-4 15-crown-5 18-crown-6

◀ FIGURE 21-9
Three different crown ethers
The cavity size of a crown ether increases with the number of atoms in the ring.



▶ FIGURE 21-10
Selectivity of 18-crown-6
The $\log_{10}K$ values for the reaction of alkali metal ions (M^+) with 18-crown-6 in water at 25 °C are plotted against the ratio of diameters, d_{M^+}/d_{cavity}. The equilibrium constant is largest for K^+ because the radius of this cation most closely matches that of the cavity.

different enough to make 18-crown-6 selective for just K^+; the other alkali metal ions also form complexes with 18-crown-6 to varying degrees.

The formation of crown ether complexes has been exploited in synthetic organic chemistry to dissolve ionic reagents in nonpolar solvents, such as benzene. For example, $KMnO_4$ is not soluble in pure benzene but $[K(18\text{-crown-}6)][MnO_4]$ is soluble. The $[K(18\text{-crown-}6)]^+$ complex is soluble in nonpolar solvents because most of the complex is made up of a hydrocarbon skeleton, which is compatible with other nonpolar molecules. The MnO_4^- ion remains in the vicinity of the complexed cation, because of electrostatic attraction to the positive charge on the complex. However, the MnO_4^- ion does not interact strongly with the nonpolar benzene molecules, and thus it is hardly solvated by benzene molecules. Consequently, MnO_4^- is much more reactive in benzene than it is in water.

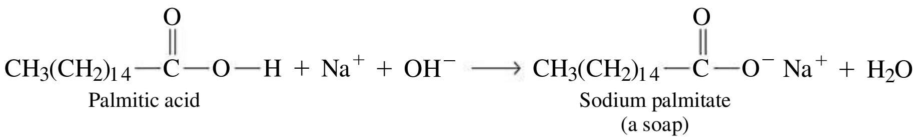
▶ An emulsion is a suspension of one liquid in another (see Table 13.4). Soap is an emulsifier because it facilitates the formation of an emulsion of oil droplets in water.

Alkali Metal Detergents and Soaps A **detergent** is a cleansing agent used primarily because it can emulsify oils. Although the term *detergent* includes common soaps, it is used primarily to describe certain synthetic products, such as sodium lauryl sulfate, whose manufacture involves the following conversions.

$$\underset{\text{Lauryl alcohol}}{CH_3(CH_2)_{10}CH_2OH} \longrightarrow \underset{\text{Lauryl hydrogen sulfate}}{CH_3(CH_2)_{10}CH_2OSO_3H} \longrightarrow \underset{\text{Sodium lauryl sulfate}}{CH_3(CH_2)_{10}CH_2OSO_3^-\ Na^+}$$

Notice that the lauryl sulfate anion has a long, nonpolar tail and a highly polar (negatively charged) head. These structural features are common to all detergents and soaps, as described in more detail below.

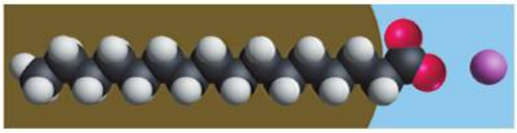
A **soap** is a specific kind of detergent that is the salt of a metal hydroxide and a fatty acid. An example is sodium palmitate, which is the product of the reaction of palmitic acid and NaOH.



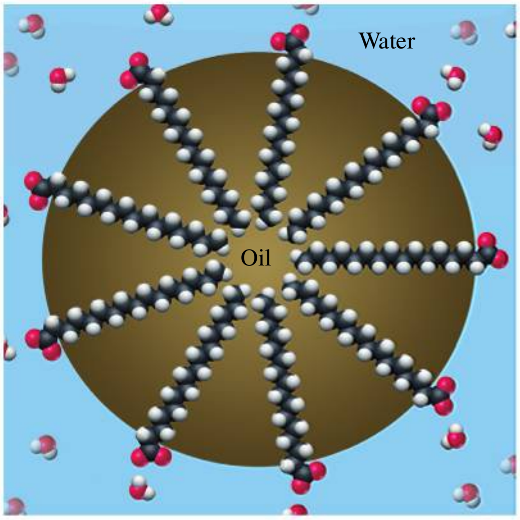
$$\underset{\text{Palmitic acid}}{CH_3(CH_2)_{14}-\overset{\overset{\displaystyle O}{\|}}{C}-O-H} + Na^+ + OH^- \longrightarrow \underset{\substack{\text{Sodium palmitate}\\ \text{(a soap)}}}{CH_3(CH_2)_{14}-\overset{\overset{\displaystyle O}{\|}}{C}-O^-\ Na^+} + H_2O \qquad \textbf{(21.9)}$$

Again, notice that the anion of the soap has a long, nonpolar tail and a polar head. Figure 21-11 illustrates the detergent action of sodium palmitate.

Sodium soaps are the familiar hard (bar) soaps. Potassium soaps have low melting points and are soft soaps. Lithium stearate ($C_{17}H_{35}CO_2Li$), a soap not seen in ordinary household use, is used to thicken some oils into greases. These greases have excellent water-repellent and lubricating properties at both high and low temperatures. The greases remain in contact with moving metal parts under conditions in which oil by itself would run off.



(a)



(b)

▲ FIGURE 21-11
Illustration of soap molecules and their cleaning action
(a) The sodium palmitate molecule has a long nonpolar portion buried in a droplet of oil and a polar head projecting into an aqueous medium. **(b)** Electrostatic attractions between these polar heads and water molecules cause the droplet to be emulsified, or solubilized.

21-2 CONCEPT ASSESSMENT

The nitrates MNO_3 ($M = Na, K, Rb, Cs$) decompose to the nitrites (MNO_2) on heating; while in contrast, $LiNO_3$ decomposes to Li_2O. Suggest a reason for this difference in behavior. Write balanced equations for both reactions.

21-3 Group 2: The Alkaline Earth Metals

As a group, the alkaline earth metals of group 2 are as common as the elements of group 1. Table 21.3 shows that calcium and magnesium are particularly abundant. Even beryllium, the least abundant member of group 2, is accessible because it occurs in deposits of the mineral *beryl*, $Be_3Al_2Si_6O_{18}$, which is shown in the margin. The other group 2 elements are found primarily as carbonates, sulfates, and silicates. Radium, like its group 1 neighbor, francium, is a radioactive element found only in trace amounts. Radium is more interesting for its radioactive properties than for its chemical similarities to the other group 2 elements.

Even though the group 2 metal oxides and hydroxides are only very slightly soluble in water, they are basic, or *alkaline*. At one time, insoluble substances that do not decompose on heating were called "earths." This term is the basis of the group 2 name: **alkaline earth metals**.

From a chemical standpoint (for example, in their abilities to react with water and acids and to form ionic compounds), the heavier group 2 metals—Ca, Sr, Ba, and Ra—are nearly as active as the group 1 metals. In terms of certain physical properties (for example, density, hardness, and melting point), all the group 2 elements are more typically metallic than the group 1 elements, as we can see by comparing Tables 21.2 and 21.4.

Table 21.4 shows that beryllium is out of step with the other group 2 elements in some of its physical properties. For instance, it has a higher melting point and is much harder than the others. Its chemical properties also differ significantly. For example,

- Be is quite unreactive with air and water;
- BeO does not react with water, whereas the other MO oxides form $M(OH)_2$;

TABLE 21.3 Abundances of Group 2 Elements

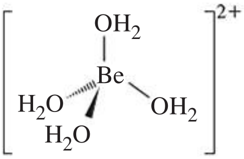
- Be and BeO dissolve in strongly basic solutions to form the ion $[Be(OH)_4]^{2-}$;
- $BeCl_2$ and BeF_2 in the molten state are poor conductors of electricity; they are covalent substances.

The unusual chemical behavior of beryllium is related to the high charge density of the beryllium cation. Beryllium shows only a limited tendency to form ionic compounds because the small Be^{2+} ion polarizes any nearby anion, drawing electron density toward itself, creating a bond with significant covalent character. Thus, compounds of beryllium show some properties that are more typical of covalent solids. For example, while the other oxides of group 2 are basic, BeO is an *amphoteric* oxide, reacting with both strong acids and bases to yield complex ions:

$$BeO(s) + H_2O(l) + 2\,H_3O^+(aq) \longrightarrow [Be(H_2O)_4]^{2+}(aq)$$

$$BeO(s) + H_2O(l) + 2\,OH^-(aq) \longrightarrow [Be(OH)_4]^{2-}(aq)$$



▲ Tetrahedral shape of the $[Be(OH_2)_4]^{2+}$ ion.

In these complex ions, electron density is donated from H_2O or OH^- to Be^{2+} because of the high polarizing power of the Be^{2+} ion and the resulting complex has a well-defined structure. The figure in the margin shows that the $[Be(H_2O)_4]^{2+}$ ion, for example, has a tetrahedral structure.

The reaction of beryllium metal with aqueous acids yields hydrogen and ionic compounds, such as $BeCl_2 \cdot 4\,H_2O$. In $BeCl_2 \cdot 4\,H_2O$, water molecules are covalently bonded to Be^{2+} ions, producing the complex cations $[Be(OH_2)_4]^{2+}$ that, together with the anions Cl^-, form the crystal lattice. In covalent compounds, Be atoms appear to use hybrid orbitals—*sp* orbitals in $BeCl_2(g)$ and sp^3 orbitals in $BeCl_2(s)$ (Fig. 21-12).

21-3 CONCEPT ASSESSMENT

Why, on going from monomeric $BeCl_2$ to dimeric $(BeCl_2)_2$ to polymeric $(BeCl_2)_n$, does the atomic arrangement around the beryllium change from linear to trigonal planar to tetrahedral?

Two other Cl atoms are bonded by coordinate covalent bonds, using lone-pair electrons on the Cl atoms. Once formed, these two types of bonds are indistinguishable. $BeCl_2$ units are linked into long, chain-like polymeric molecules as $(BeCl_2)_n$.

Production and Uses of the Alkaline Earth Metals

The preferred method of producing the group 2 metals (except Mg) is by reducing their salts with other active metals. Beryl, $Be_3Al_2Si_6O_{18}$, is the natural source of beryllium compounds. This mineral is processed to produce BeF_2, which is then reduced with Mg to give Be(s). Beryllium metal is used as an alloying agent when low density is a primary requirement. Because Be can withstand metal fatigue, an alloy of copper with about 2% Be is used in springs, clips, and electrical contacts. The Be atom does not readily absorb X-rays or neutrons, so beryllium is also used to make windows for X-ray tubes and for various components in nuclear reactors. Beryllium and its compounds are limited in their use, however, because they are toxic. In addition, they are suspected of being carcinogens even at a level as low as 0.002 ppm in air.

Calcium, strontium, and barium are obtained by the reduction of their oxides with aluminum; Ca and Sr also can be obtained by electrolysis of their molten chlorides. Calcium metal is used primarily as a reducing agent to prepare, from their oxides or fluorides, other metals such as U, Pu, and most of the lanthanides. Strontium and barium have limited use in alloys, but some of their compounds (discussed later) are quite important. Some salts of Sr and Ba provide vivid colors for pyrotechnic displays.

Magnesium metal is obtained by electrolysis of the molten chloride in the *Dow process.* The Dow process is outlined in Figure 21-13, and the electrolysis of

▶ FIGURE 21-14

The electrolysis of molten $MgCl_2$

The electrolyte is a mixture of molten NaCl, $CaCl_2$, and $MgCl_2$. This mixture has a lower melting point and higher electrical conductivity than $MgCl_2$ alone, but if the voltage is carefully controlled, only Mg^{2+} is reduced in the electrolysis.

$MgCl_2(l)$ is pictured in Figure 21-14. Like the Solvay process for making $NaHCO_3$, the Dow process takes advantage of simple chemistry and recycling.

▶ In Example 18-6, we demonstrated that this precipitation goes to completion.

The source of magnesium is seawater or natural brines. The abundance of Mg^{2+} in seawater is about 1350 mg/L. The first step in the Dow process is the precipitation of $Mg(OH)_2(s)$ with slaked lime, $Ca(OH)_2$, as the source of OH^-. Slaked lime is formed by the reaction of quicklime (CaO) with water. The precipitated $Mg(OH)_2(s)$ is washed, filtered, and dissolved in HCl(aq). The resulting concentrated $MgCl_2(aq)$ is dried by evaporation, melted, and electrolyzed, yielding pure Mg metal and $Cl_2(g)$. The $Cl_2(g)$ is converted to HCl, which is recycled.

Magnesium has a lower density than that of any other metal used for structural purposes. Lightweight objects, such as aircraft parts, are manufactured from magnesium alloyed with aluminum and other metals. Magnesium is a good reducing agent and is used in a number of metallurgical processes, such as the production of beryllium, as mentioned earlier. The ease with which magnesium is oxidized also underlies its use in sacrificial anodes for corrosion protection (page 895). Magnesium's most spectacular use may be in firework, as it burns in air with a brilliant white light.

21-4 CONCEPT ASSESSMENT

The good reducing properties of magnesium are illustrated by the fact that the metal burns in an atmosphere of pure carbon dioxide. Write a plausible equation(s) for this reaction.

Group 2 Compounds

The alkaline earth metals always exist in the +2 oxidation state in their compounds. Recall that atoms of the group 2 metals have an ns^2 valence configuration and it is the ns^2 electrons that are lost by these atoms when they combine with nonmetals to form compounds. The alkaline earth metals form primarily ionic compounds, but covalent bonding is evident in magnesium compounds and especially in beryllium compounds.

The properties of group 2 compounds differ from those of group 1 compounds. In some cases, this difference is attributable to the smaller ionic size and the larger ionic charge of group 2 cations. For example, the lattice energy of $Mg(OH)_2$ is about $-3000\ \text{kJ mol}^{-1}$, compared with about $-900\ \text{kJ mol}^{-1}$ for

NaOH. This difference in lattice energy helps explain why NaOH is very soluble in water—up to about 20 M NaOH(aq)—while $Mg(OH)_2$ is only sparingly soluble, with $K_{sp} = 1.8 \times 10^{-11}$. The heavier group 2 hydroxides are somewhat more soluble than $Mg(OH)_2$. Other alkaline earth compounds that are only slightly soluble include the carbonates, fluorides, and oxides.

Halides The group 2 metals react directly with the halogens to form halides:

$$M(s) + X_2 \longrightarrow MX_2(s) \qquad \textbf{(21.10)}$$

$$(M = \text{a group 2 metal, and } X = F, Cl, Br, \text{or } I)$$

However, the standard method for preparing $MX_2(s)$ in anhydrous form is to dehydrate the hydrates obtained from the reaction of the metal and aqueous hydrohalic acid, HX(aq). However, this method of preparation cannot be used to prepare beryllium halides because the hydrates of beryllium halides decompose to $Be(OH)_2(s)$ on heating. For example, when $[Be(H_2O)_4]Cl_2(s)$ is heated, the following reaction occurs:

$$[Be(H_2O)_4]Cl_2(s) \xrightarrow{\Delta} Be(OH)_2(s) + 2H_2O(g) + 2HCl(g)$$

Instead anhydrous $BeCl_2$ is prepared from BeO and CCl_4, as shown below.

$$2\,BeO + CCl_4 \xrightarrow{1070\text{ K}} 2\,BeCl_2 + CO_2$$

The halides have varied uses. For example, $MgCl_2$ is used in the preparation of magnesium metal, in fireproofing wood, in special cements, in ceramics, in treating fabrics, and as a refrigeration brine.

Oxides and Hydroxides All the group 2 metals burn in air to produce oxides, MO(s):

$$2\,M(s) + O_2(g) \longrightarrow 2\,MO(s)$$

In the presence of excess oxygen, the heavier group 2 metals—such as barium—form peroxides:

$$Ba(s) + O_2(g) \longrightarrow BaO_2(s)$$

The peroxides of Mg, Ca, and Sr are also known but they are less stable, presumably because the charge densities of Mg^{2+}, Ca^{2+}, and $Sr^{2+}$are high enough to assist the decomposition of $O_2{}^{2-}$, as suggested on page 928. On heating, the peroxides decompose to give MO(s) and $O_2(g)$:

$$MO_2(s) \xrightarrow{\Delta} MO(s) + \frac{1}{2}O_2(g)$$

Although oxides of the group 2 metals can be obtained from burning the metals in air or oxygen (or by thermal decomposition of the peroxides), the chief method of preparing them, except for BeO(s), is the thermal decomposition of the respective carbonate:

$$MCO_3(s) \xrightarrow{\Delta} MO(s) + CO_2(g) \quad (M = Mg, Ca, Sr, \text{and } Ba) \qquad \textbf{(21.11)}$$

A particularly useful oxide is calcium oxide, CaO(s), also known as **quicklime**. It is used in water treatment, in the removal of $SO_2(g)$ from the smokestack gases in electric power plants, and in the making of $Ca(OH)_2$—an important and inexpensive strong base. The conversion of CaO to $Ca(OH)_2$ is a specific example of the reaction that converts a group 2 oxide into a hydroxide:

$$MO(s) + H_2O(l) \longrightarrow M(OH)_2(aq) \qquad \textbf{(21.12)}$$

All the hydroxides of the group 2 metals are strong bases. Calcium hydroxide, $Ca(OH)_2$, also known as **slaked lime**, is the cheapest commercial strong base. It is not very soluble in water, but it is used in a variety of applications, such as the Solvay and Dow processes.

A mixture of slaked lime, sand, and water composes the mortar used in bricklaying. Excess water in the mortar is absorbed by the bricks and then lost by evaporation. In the final setting of the mortar, $CO_2(g)$ from the air reacts with $Ca(OH)_2(s)$ and converts it to $CaCO_3(s)$, as shown below:

$$Ca(OH)_2(s) + CO_2(g) \longrightarrow CaCO_3(s) + H_2O(g) \qquad \textbf{(21.13)}$$

The final form of the mortar is a complex mixture of hydrated calcium carbonate and silicate (from the sand).

Reaction (21.13) is general for all group 2 hydroxides. Art conservators have used this reaction to preserve art objects. For example, an aqueous solution of $Ba(NO_3)_2$ is sprayed onto cracking frescos (paintings embedded in plaster). When the solution has had time to fill small cracks and spaces, an aqueous ammonia solution is applied to the surface of the fresco. The ammonia raises the pH of the solution, resulting in formation of $Ba(OH)_2$. As excess water evaporates, carbon dioxide from the air reacts with the barium hydroxide. Insoluble barium carbonate is produced, binding the cracking fresco together and strengthening it without affecting the delicate colors.

21-5 CONCEPT ASSESSMENT

Comment on the statement "The best way to way to prepare BeO is to heat the compound $BeCO_3(s)$." If you disagree with this statement suggest an alternative.

Hydration of Salts Another common characteristic of alkaline earth compounds is the formation of hydrates. Typical hydrates are $MX_2 \cdot 6\,H_2O$, where $M = Mg$, Ca, or Sr, and $X = Cl$ or Br. The Ba^{2+} ion has a low charge density and shows little or no tendency to retain its hydration sphere in the solid state. The formulas for the hydrates of the alkaline earth nitrates illustrate that the degree of hydration typically decreases as the charge density of the metal ion decreases: $Mg(NO_3)_2 \cdot 6\,H_2O$, $Ca(NO_3)_2 \cdot 4\,H_2O$, $Sr(NO_3)_2 \cdot 4\,H_2O$, $Ba(NO_3)_2$.

Carbonates and Sulfates The group 2 carbonates are insoluble in water, as are the sulfates of Ca, Sr, and Ba. Because of this insolubility, these compounds are the most important minerals of the group 2 metals. The most familiar is $CaCO_3$, the principal component of the rock *limestone*. If a limestone contains more than 5% $MgCO_3$, it is usually called dolomite limestone, or *dolomite*. Some clay, sand, or quartz may also be present in limestone. The primary use of limestone (about 70%) is as a building stone. Among other applications, limestone is used in the manufacture of quicklime and slaked lime, as an ingredient in glass, and as a flux in metallurgical processes. A *flux* is a material that combines with impurities and removes them as a free-flowing liquid—a *slag*—during production of a metal (page 1044).

Portland cement, another important product of limestone, is a complex mixture of calcium silicates and aluminates. It is produced in long rotary kilns like the one shown in the photograph in the margin. In the kiln, mixtures of limestone, clay, and sand are heated to progressively higher temperatures as they slowly move down the inclined kiln. First, moisture and then chemically bound water are driven off. This process is followed by decomposition (calcination) of the limestone to $CaO(s)$ and $CO_2(g)$. Finally, CaO combines with silica (SiO_2) and alumina (Al_2O_3) from the sand and clay to form silicates and aluminates. Pure cement does not have much strength. When mixed with sand, gravel, and water, however, it sets into the familiar rock-like mass called *concrete*. Portland cement is an especially valuable material for building bridge piers and other underwater structures because it hardens even when underwater—it is a *hydraulic* cement.

▲ The decomposition (calcination) of limestone is carried out in a long rotary kiln, whether for the production of quicklime, CaO, or for the manufacture of Portland cement.

Pure, white $CaCO_3$ is used in a wide variety of products. For example, it is used in papermaking to impart brightness, opacity, smoothness, and good ink-absorbing qualities to paper. It is particularly suited to newer papermaking processes that produce acid-free (alkaline) paper with an expected shelf life of 300 years or more. $CaCO_3$ is used as a filler in plastics, rubber, floor tiles, putties, and adhesives, as well as in foods and cosmetics. It is also used as an antacid and as a dietary supplement for the prevention of osteoporosis, a condition in which the bones become porous and brittle and break easily.

Three steps are required to obtain pure $CaCO_3$ from limestone: (1) thermal decomposition of limestone (called **calcination**), (2) reaction of CaO with water (slaking), and (3) conversion of an aqueous suspension of $Ca(OH)_2(s)$ to precipitated $CaCO_3$ (carbonation).

$$\textit{Calcination:}\quad CaCO_3(s) \xrightarrow{\Delta} CaO(s) + CO_2(g) \tag{21.14}$$

$$\textit{Slaking:}\quad CaO(s) + H_2O(l) \longrightarrow Ca(OH)_2(s) \tag{21.15}$$

$$\textit{Carbonation:}\quad Ca(OH)_2(s) + CO_2(aq) \xrightarrow{aq} CaCO_3(s) + H_2O(l) \tag{21.16}$$

The calcination of limestone, reaction (21.14), is highly reversible at room temperature. Thus, a high temperature must be used and $CO_2(g)$ must be continuously removed from the kiln to prevent the reverse reaction.

Limestone ($CaCO_3$) is also responsible for the beautiful natural formations found in limestone caves. Natural groundwater is slightly acidic because of dissolved $CO_2(g)$ and is essentially a solution of carbonic acid, H_2CO_3.

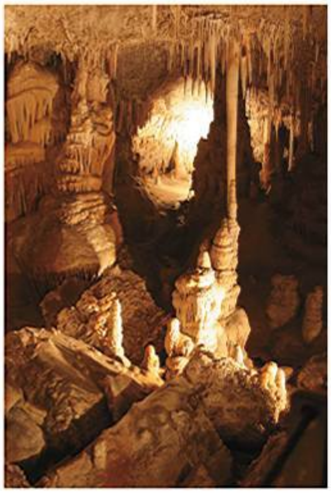
$$CO_2(aq) + 2\,H_2O(l) \rightleftharpoons H_3O(aq)^+ + HCO_3^-(aq) \quad K_{a_1} = 4.4 \times 10^{-7} \tag{21.17}$$

$$HCO_3^-(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + CO_3^{2-}(aq) \quad K_{a_2} = 4.7 \times 10^{-11} \tag{21.18}$$

Although the carbonates are not very soluble in water, they are bases; thus, they dissolve readily in acidic solutions. As mildly acidic groundwater seeps through limestone beds, insoluble $CaCO_3$ is converted to soluble $Ca(HCO_3)_2$.

$$CaCO_3(s) + H_2O(l) + CO_2(aq) \rightleftharpoons Ca(HCO_3)_2(aq) \quad K = 2.6 \times 10^{-5} \tag{21.19}$$

Over time, this dissolving action can produce a large cavity in the limestone bed—a limestone cave. Reaction (21.19) is reversible, however, and evaporation of the solution causes a loss of both water and CO_2 and conversion of $Ca(HCO_3)_2(aq)$ back to $CaCO_3(s)$. This process occurs very slowly. Yet over a period of many years, as $Ca(HCO_3)_2(aq)$ drips from the ceiling of a cave, $CaCO_3(s)$ remains as icicle-like deposits called **stalactites**. Some of the dripping solution may hit the floor of the cave before decomposition occurs; in this way, limestone deposits build up from the floor in formations called **stalagmites**. Eventually, some stalactites and stalagmites grow together into limestone columns, as shown in Figure 21-15.



▲ FIGURE 21-15
Stalactites and stalagmites
Stalactites hang from the top; stalagmites rise from the ground.

Another important calcium-containing mineral is *gypsum*, $CaSO_4 \cdot 2\,H_2O$. In the United States, about 50 million metric tons of gypsum are consumed annually. About half of this is converted to **plaster of Paris**, $CaSO_4 \cdot \frac{1}{2}H_2O$, a hemihydrate.

$$CaSO_4 \cdot 2\,H_2O(s) \xrightarrow{\Delta} CaSO_4 \cdot \tfrac{1}{2}H_2O(s) + \tfrac{3}{2}H_2O(g) \tag{21.20}$$

When mixed with water, plaster of Paris reverts to gypsum. Because it expands as it sets, a mixture of plaster of Paris and water is useful in making castings where sharp details of an object must be retained. Plaster of Paris is used extensively in jewelry making and in dental work. The most important application, though, is in producing gypsum wallboard (drywall), which has all but supplanted other interior wall coverings in the construction industry.

Barium sulfate has had important applications in medical imaging because barium is opaque to X-rays. Although barium ion is toxic, the compound $BaSO_4$ is so insoluble as to be safe to use as a "barium milkshake" to coat the stomach or upper gastrointestinal tract or in a "barium enema" for the lower tract.

▲ Plaster of Paris castings and the molds used to form them.

21-6 CONCEPT ASSESSMENT

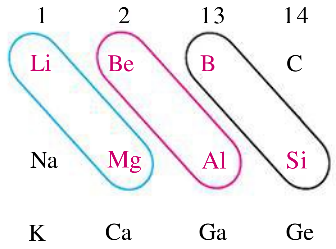
Suggest a reason why the hydrated beryllium ion is $[Be(H_2O)_4]^{2+}$, whereas the hydrated magnesium ion is $[Mg(H_2O)_6]^{2+}$.

Diagonal Relationship of Lithium and Magnesium

We have described trends in the periodic table either vertically (down a group) or horizontally (across periods), but an investigation of the chemistry of lithium and magnesium reveals a **diagonal relationship**. Let us look at these similarities.

The following list contains some of the chemical similarities between lithium and magnesium that lead to the diagonal relationship between them.

- Lithium and magnesium combine with O_2 to give the oxide rather than the peroxide.
- The carbonates of lithium and magnesium can be decomposed thermally to give the oxide and carbon dioxide. The carbonates of the remaining group 1 metals are stable to thermal decomposition.
- As mentioned earlier the salts of lithium and magnesium are strongly hydrated.
- The fluorides of lithium and magnesium are sparingly soluble in water, whereas the later group 1 fluorides are soluble.
- LiOH is the least soluble of the group 1 hydroxides and $Mg(OH)_2$ is only sparingly soluble in water.



▲ FIGURE 21-16
Diagonal relationships
The two elements in each encircled pair exhibit many similar properties.

The diagonal relationship between lithium and magnesium can be understood in terms of charge densities. The similarities in charge density arises from the increase in size of the Mg^{2+} relative to Li^+, which is counterbalanced by the increase in charge. Both Li^+ and Mg^{2+} have high polarizing power and their compounds exhibit a high degree of covalency. Diagonal relationships also exist between Be and Al and between B and Si also. These relationships are emphasized in Figure 21-16.

21-7 CONCEPT ASSESSMENT

Lithium and magnesium combine with N_2 to give the nitrides Li_3N and Mg_3N_2, respectively. Suggest a reason for this and write balanced chemical equations for the reactions.

EXAMPLE 21-2 Identifying Elements and Compounds from a Description of Reaction Chemistry

In an experiment, 0.1 moles of M, a group 1 metal, react with sufficient oxygen to give 0.05 moles of compound X. Compound X is then allowed to react with water, and a hydroxide is the only product. In a separate experiment, 0.1 moles of the metal reacts with water to give 0.1 moles of a hydroxide and 0.05 moles of a gas, Y. Identify the metal and compounds X and Y. Write balanced chemical equations for the reactions described.

Analyze

Three reactions are described and some information is provided for each reaction. One way to tackle this problem is to write partial chemical equations for these reactions, and then use the information provided to complete the equations.

Solve

We are told that M is a group 1 metal, so the hydroxide has the formula MOH. The partial chemical equations are as follows:

$$\begin{aligned} M + O_2 &\longrightarrow X \\ X + H_2O &\longrightarrow MOH \\ M + H_2O &\longrightarrow MOH + \frac{1}{2}Y \end{aligned}$$

All the alkali metals react with water to give MOH and H_2. Thus, Y must be H_2. In the first reaction, X could be M_2O, M_2O_2, or MO_2. However, the second reaction has only one product. Because M_2O_2 and MO_2 react with water to give MOH and other products, we know that X cannot be M_2O_2 or MO_2. Thus, X must be M_2O. The only alkali metal that reacts with oxygen to give M_2O as the principal product is lithium, so M must be Li. The complete chemical equations are

$$\begin{aligned} 2\,Li(s) + \frac{1}{2}O_2(g) &\longrightarrow Li_2O(s) \\ Li_2O(s) + H_2O(l) &\longrightarrow 2\,LiOH(s) \\ Li(s) + H_2O(l) &\longrightarrow LiH(aq) + \frac{1}{2}H_2(g) \end{aligned}$$

Assess

The key to solving this problem was in recognizing that only the normal oxide, M_2O, reacts with water to give MOH as the only product and that lithium is the only alkali metal that gives M_2O.

PRACTICE EXAMPLE A: Sodium nitrite (0.1 mol) reacts with sodium metal (0.3 mol) to give compound X (0.2 mol) and nitrogen gas (0.05 mol). Compound X (0.1 mol) reacts with oxygen (0.05 mol) to give compound Y (0.1 mol) only. Identify X and Y, and write balanced chemical equations for the reactions described.

PRACTICE EXAMPLE B: A group 2 metal (0.1 mol) is heated with carbon (0.2 mol) at 1100 °C to produce a single compound X (0.1 mol). When compound X (0.1 mol) is heated in excess $N_2(g)$ at 1100 °C solid carbon (0.1 mol) is produced along with compound Y (0.1 mol). The group 2 metal sulfate is used in plaster of Paris and the anion in compound Y is isoelectronic with CO_2. Identify compounds X and Y, write balanced chemical equations for the reactions described and describe the shape of the anion in Y.

21-4 Group 13: The Boron Family

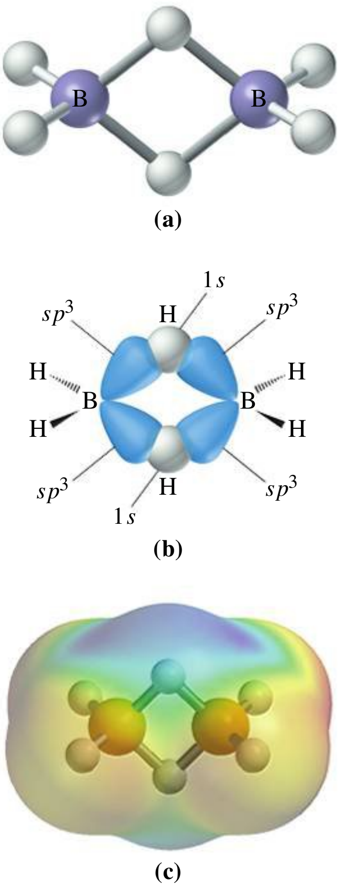
The only group 13 element that is almost exclusively nonmetallic in its physical and chemical properties is boron. The remaining members of group 13—Al, Ga, In, and Tl—are metals and will be discussed later in this section. In group 13 we find for the first time elements possessing more than one oxidation state. All the elements of this group exhibit both the +1 and +3 oxidation states. Boron is a nonmetal and forms primarily covalent bonds. The other members of the group, despite being metals, commonly form covalent bonds. The tendency for forming covalent bonds can be attributed to the high charge densities (Table 21.5) of the group 13 ions. The high charge density means that the group 13 ions have a high polarizing power that leads to covalent bonding between cation and an anion.

TABLE 21.5 Charge Densities of Group 13 Elements in the +3 Oxidation State

Element	Charge Density, C mm^{-3}
B	1663
Al	364
Ga	261
In	138
Tl	105

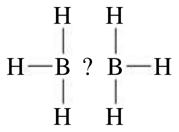
Boron and Its Compounds

Many boron compounds lack an octet of electrons about the central boron atom, which makes the compounds *electron deficient*. This deficiency also makes them strong Lewis acids. The electron deficiency of some boron compounds leads to bonding of a type that we have not previously encountered. This type of bonding occurs in the boron hydrides.



▲ FIGURE 21-17
Structure of diborane, B_2H_6
(a) The molecular structure.
(b) Bonding.
(c) Electrostatic potential map.

Boron Hydrides The molecule BH_3 (borane) may exist as a reaction intermediate, but it has not been isolated as a stable compound. The B atom in BH_3 lacks a complete octet—it has only six electrons in its valence shell. The simplest boron hydride that has been isolated is diborane, B_2H_6, but this molecule defies simple description. In the following structural formula, what holds the two borane units together?



$$\begin{array}{ccccccc} & & H & & H & & \\ & & | & & | & & \\ H & - & B & ? & B & - & H \\ & & | & & | & & \\ & & H & & H & & \end{array}$$

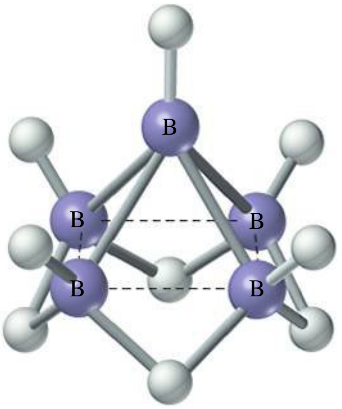
To explain the structure and bonding in B_2H_6, we need to use molecular orbital theory because simpler bonding theories fail for this molecule. The problem is this: The B_2H_6 molecule has only *12* valence electrons (three each from the two B atoms, and one each from the six H atoms). The minimum number of valence-shell atomic orbitals required to make a Lewis structure for B_2H_6 resembling that of C_2H_6, however, is *14* (four each from the two B atoms, and one each from the six H atoms).

The structure of diborane is illustrated in Figure 21-17. The two B atoms and four of the H atoms lie in the same plane (a plane perpendicular to the plane of the page). The orbitals used by the B atoms to bond these particular four H atoms can be viewed as sp^3. Eight electrons are involved in these four bonds. Four electrons are left to bond the two remaining H atoms to the two B atoms and also to bond the B atoms together. This is accomplished if each of the two H atoms simultaneously bonds to *both* B atoms.

Atom bridges are actually fairly common, although we have not had much occasion to deal with them before. (See the discussion of Al_2Cl_6, page 949.) The B—H—B bridges are unusual, however, in having only *two* electrons shared among *three* atoms. For this reason, these bonds are referred to as *three-center* two-electron bonds.

We can rationalize the bonding in these three-center bonds with molecular orbital theory. The *six* atomic orbitals shown in Figure 21-17(b)—two sp^3 orbitals from each B atom and an *s* orbital from each bridging H atom—are combined into *six* molecular orbitals in these two bridge bonds. Of these six molecular orbitals, *two* are bonding orbitals, and these are the orbitals into which the four electrons are placed. The concept of bridge bonds can be extended to B—B—B bonds to describe the structure of higher boranes, such as B_5H_9 (Fig. 21-18).

Boron hydrides are widely used in reactions for synthesizing organic compounds. They continue to provide new and exciting developments in chemistry.

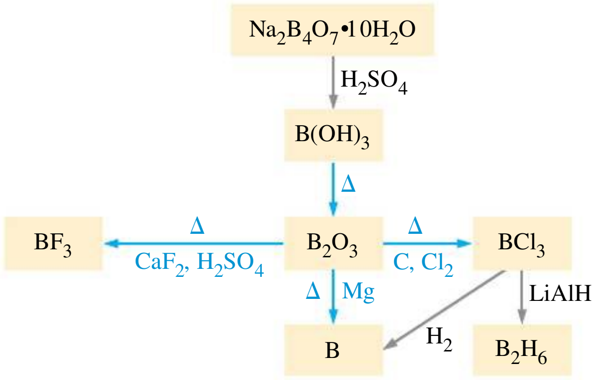


▲ FIGURE 21-18
Structure of pentaborane, B_5H_9
The boron atoms are joined by multicenter B—B—B bonds. Five of the H atoms are bonded to one B atom each. The other four H atoms bridge pairs of B atoms.

Other Boron Compounds Boron compounds are widely distributed in Earth's crust, but concentrated ores are found in only a few locations—in Italy, Russia, Tibet, Turkey, and the desert regions of California. Typical of these ores is the hydrated borate *borax*, $Na_2B_4O_7 \cdot 10\,H_2O$. Figure 21-19 illustrates how borax can be converted to a variety of boron compounds.

One useful compound that can be obtained by crystallization from a solution of borax and hydrogen peroxide is *sodium perborate*, $NaBO_3 \cdot 4\,H_2O$. This formula is deceptively simple; a more precise formula is $Na_2[B_2(O_2)_2(OH)_4] \cdot 6\,H_2O$. Sodium perborate contains the perborate ion, $[B_2(O_2)_2(OH)_4]^{2-}$, the structure of which is shown in Figure 21-20. Sodium perborate is a bleach alternative used in many color-safe bleaches. The key to the bleaching action is the presence of the two peroxo groups (—O—O—) bridging the boron atoms in the $[B_2(O_2)_2(OH)_4]^{2-}$ ion.

One of the key compounds from which other boron compounds can be synthesized is *boric acid*, $B(OH)_3$. The weakly acidic nature of boric acid comes about in a rather unusual way. The electron-deficient $B(OH)_3$ molecule accepts a



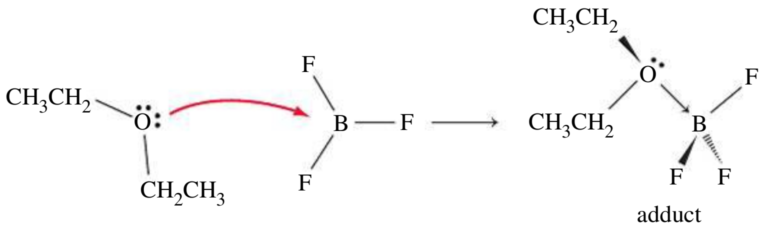
▲ FIGURE 21-19
Preparation of some boron compounds
$Na_2B_4O_7 \cdot 10\,H_2O$ (borax) is converted to $B(OH)_3$ by reaction with H_2SO_4. When heated strongly, $B(OH)_3$ is converted to B_2O_3. A variety of boron-containing compounds and boron itself can be prepared from B_2O_3.

OH^- ion from the self-ionization of water, forming the complex ion $[B(OH)_4]^-$. Thus, the source of the H_3O^+ in $B(OH)_3(aq)$ is the water itself. This ionization scheme, together with the fact that $B(OH)_3$ is a *mono*protic, not *tri*protic, acid suggests that the best formula of boric acid is $B(OH)_3$, not H_3BO_3.

$$B(OH)_3(aq) + 2\,H_2O(l) \longrightarrow H_3O^+(aq) + B(OH)_4^-(aq) \qquad K_a = 5.6 \times 10^{-10}$$

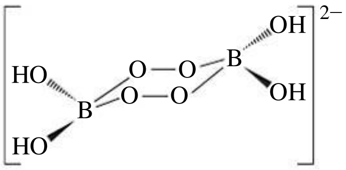
Borate salts, as expected of the salts of a weak acid, produce basic solutions by hydrolysis, which accounts for their use in cleaning agents. Boric acid also acts as an insecticide, particularly to kill roaches, and as an antiseptic in eyewash solutions. Boron compounds are used in products as varied as adhesives, cement, disinfectants, fertilizers, fire retardants, glass, herbicides, metallurgical fluxes, and textile bleaches and dyes.

The halides of boron, particularly BF_3 and BCl_3, provide examples of the Lewis acid behavior of boron compounds. For example, BF_3 can react with diethyl ether, $(C_2H_5)_2O$, to form an **adduct**:

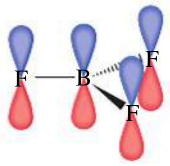


In the formation of an adduct, a coordinate covalent bond is formed between a Lewis acid and a Lewis base, with the pair of electrons for the bond coming from the Lewis base. In the reaction above, the transfer of electron density from the Lewis base to the Lewis acid is shown by the red arrow. Although a coordinate covalent bond, once formed, is indistinguishable from a regular covalent bond, we sometimes use an arrow, rather than a straight line, to identify a coordinate covalent bond. Notice that the hybridization of the boron atom changes from sp^2 to sp^3 when BF_3 and $(C_2H_5)_2O$ form an adduct.

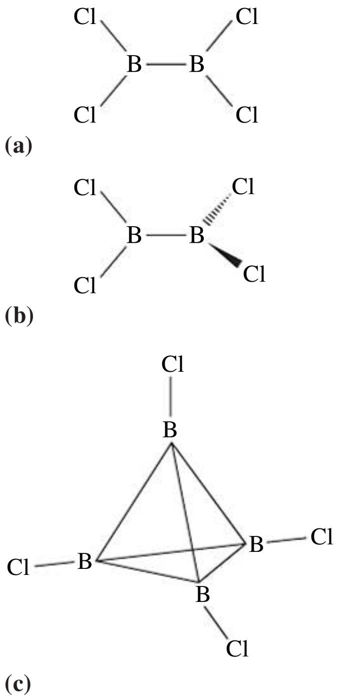
Unlike BH_3, BF_3 does not dimerize, and the boron–fluorine bond energy in BF_3 is extremely high (646 kJ mol^{-1}) and is comparable to the bond energies of many double bonds. A possible explanation for these observations is that in a BF_3 molecule, some π bonding occurs in addition to σ bonding. A delocalized π system involving the empty $2p$ orbital on the boron atom and one full $2p$ orbital on each of the fluorine atoms can be formed (Figure 21-21).



▲ FIGURE 21-20
Perborate ion



▲ FIGURE 21-21
Delocalized π system in BF_3
The $2p$ orbitals on the B and F atoms overlap to form a delocalized π system.



▲ FIGURE 21-22
Structures of (a) planar B_2Cl_4, (b) nonplanar B_2Cl_4, (c) tetrahetral B_4Cl_4

Evidence for π bonding in BF_3 is that the B—F bond length increases (from 130 pm to 145 pm) when BF_3 reacts with F^- to form the BF_4^-, ion. In BF_4^-, the 2*s* and 2*p* orbitals on the B atom are used in σ bonding and are not available for π bonding. In the other boron trihalides, such as BCl_3, π bonding also occurs but to a lesser extent. Evidence that supports less π bonding in BCl_3 is that BCl_3 is a stronger Lewis acid than BF_3 and shows a greater tendency than BF_3 to form adducts.

Boron forms a variety of halides, many of which contain B—B bonds. A few such compounds are shown in Figure 21-22. One of these compounds, B_2Cl_4, is obtained from the reaction of BCl_3 and Cu:

$$2\,BCl_3 + 2\,Cu \longrightarrow B_2Cl_4 + 2\,CuCl$$

B_2Cl_4 is an interesting compound because, in the solid phase (mp −92.6 °C), the B_2Cl_4 molecule adopts a planar geometry (Fig. 21-22a) but in the gas phase (mp 65.5 °C), it is nonplanar (Fig. 21-22b).

Another interesting chloride of boron is B_4Cl_4, which consists of a tetrahedral arrangement of boron atoms with a chlorine atom bonded to each B atom (Fig. 21-22c). The B_4Cl_4 molecule is highly electron deficient and the bonding is usually described in terms of three-center two-electron bonds.

21-8 CONCEPT ASSESSMENT

Boron forms a compound with the formula $B_2H_2(CH_3)_4$. Suggest a probable structure.

EXAMPLE 21-3 Writing Chemical Equations from a Summary Diagram of Reaction Chemistry

Using Figure 21-19, write chemical equations for the successive conversions of borax to **(a)** boric acid, **(b)** B_2O_3, and **(c)** impure boron metal.

Analyze

Figure 21-19 lists the key substances involved in each reaction. We can write an incomplete chemical equation for each reaction and then identify other plausible reactants and products.

Solve

(a) The conversion of a borax, a salt, to boric acid, $B(OH)_3$, requires H_2SO_4. An incomplete chemical equation for the reaction is as follows:

$$Na_2B_4O_7 \cdot 10\,H_2O(aq) + H_2SO_4(aq) \longrightarrow B(OH)_3(aq)$$

This is an acid–base reaction. The other products of the reaction are Na_2SO_4 and H_2O. The reaction does not involve changes in oxidation states, and thus the equation can be balanced by inspection. The balanced chemical equation is given below:

$$Na_2B_4O_7 \cdot 10\,H_2O(aq) + H_2SO_4(aq) \longrightarrow 4\,B(OH)_3(aq) + Na_2SO_4(aq) + 5\,H_2O(l)$$

(b) $B(OH)_3$ can be converted to B_2O_3 by heating. The conversion of a hydroxide to an oxide requires that H_2O be driven off. The balanced chemical equation for the conversion of $B(OH)_3$ to B_2O_3 is given below:

$$2\,B(OH)_3(s) \xrightarrow{\Delta} B_2O_3(s) + 3\,H_2O(g)$$

(c) B is obtained when B_2O_3 is heated with Mg. An incomplete chemical equation for the reaction is as follows:

$$B_2O_3(s) + Mg(s) \xrightarrow{\Delta} B(s)$$

The other product must be MgO. The balanced chemical equation is given below.

$$B_2O_3(s) + 3\,Mg(s) \xrightarrow{\Delta} 2\,B(s) + 3\,MgO(s)$$

Assess

The reaction summary diagram identifies only some of the substances involved in the various reaction pathways. Writing down an incomplete chemical equation for a reaction can often make it easier to identify other reactants and products that are involved.

PRACTICE EXAMPLE A: Using Figure 21-19, write chemical equations for the sequence of reactions by which borax is converted to diborane.

PRACTICE EXAMPLE B: Using Figure 21-19, write chemical equations for the sequence of reactions by which borax is converted to BF_3.

Properties and Uses of Group 13 Metals

In their appearance and physical properties and in most of their chemical behaviors, aluminum, gallium, indium, and thallium are metallic. Some properties of the group 13 metals are listed in Table 21.6.

The most important of the group 13 metals is aluminum, which is used mainly in lightweight alloys. Aluminum, like most of the other main-group metals, is an active metal. Because it is easily oxidized to the 3+ ion, aluminum is an excellent reducing agent—for example, reacting with acids to reduce $H^+(aq)$ to $H_2(g)$.

$$2\,Al(s) + 6\,H^+(aq) \longrightarrow 2\,Al^{3+}(aq) + 3\,H_2(g) \qquad \textbf{(21.21)}$$

Aluminum also reacts in basic solutions as shown below:

$$2\,Al(s) + 2\,OH^-(aq) + 6\,H_2O(l) \longrightarrow 2[Al(OH)_4]^-(aq) + 3\,H_2(g) \qquad \textbf{(21.22)}$$

Air or other oxidants easily oxidize powdered aluminum in highly exothermic reactions. The reaction of Al and O_2 yields Al_2O_3:

$$2\,Al(s) + \tfrac{3}{2}O_2(g) \longrightarrow Al_2O_3(s) \qquad \Delta H = -1676\text{ kJ} \qquad \textbf{(21.23)}$$

Aluminum is such a good reducing agent that it will extract oxygen from other metal oxides, producing aluminum oxide while liberating the other metal in its free state. The following reaction, known as the **thermite reaction**, produces liquid iron and is used in the on-site welding of large metal objects.

$$Fe_2O_3(s) + 2\,Al(s) \longrightarrow Al_2O_3(s) + 2\,Fe(l) \qquad \textbf{(21.24)}$$

◀ Certain drain cleaners are a mixture of NaOH and Al(s). When they are added to water, reaction (21.22) occurs. The evolved $H_2(g)$ helps unplug a stopped-up drain. The heat of reaction melts fats and grease, and the NaOH(aq) solubilizes them.

TABLE 21.6 Some Properties of the Group 13 Metals

	Al	Ga	In	Tl
Atomic number	13	31	49	81
Atomic (metallic) radius, pm	143	122	163	170
Ionic (M^{3+}) radius, pm	53	62	79	88
Electronegativity	1.5	1.6	1.7	1.8
First ionization energy, kJ mol^{-1}	577.6	578.8	558.3	589.3
Electrode potential $E°$, V[a]	−1.676	−0.56	−0.34	+0.72
Melting point, °C	660.37	29.78	156.17	303.55
Boiling point, °C	2467	2403	2080	1457
Density, g cm^{-3} at 20 °C	2.698	5.907	7.310	11.85

[b] See footnotes b and c of Table 21.2.

▲ Thermite reaction.

The thermite reaction is highly exothermic and visually spectacular. It is shown in the photograph in the margin.

Gallium metal is of great importance in the electronics industry. It is used to make gallium arsenide (GaAs), a compound that can convert light directly into electricity (photoconduction). This semiconducting material is also used in light-emitting diodes (LEDs) (see Focus On 21: Gallium Arsenide) and in solid-state devices such as transistors.

Indium is a soft silvery metal used to make low-melting alloys. Like GaAs, InAs also finds use in low-temperature transistors and as a photoconductor in optical devices.

Thallium and its compounds are extremely toxic; as a result, they have few industrial uses. One possible use, however, is in high-temperature super conductors. For example, a thallium-based ceramic with the approximate formula $Tl_2Ba_2Ca_2Cu_3O_{8+x}$ exhibits superconductivity at temperatures as high as 125 K.

Oxidation States of Group 13 Metals

▶ As discussed on page 1059 a superconducting material loses its electrical resistance below a certain temperature. Metals typically become superconducting only a few degrees above 0 K.

Aluminum, at the top of the group of four metals in group 13, occurs almost exclusively in the +3 oxidation state in its compounds. Gallium also favors the +3 oxidation state. Indium compounds can be found with +3 and +1 oxidation states, though the +3 is more common. In thallium, this preference is reversed. For example, thallium forms the oxide Tl_2O, the hydroxide TlOH, and the carbonate Tl_2CO_3. These compounds are ionic and in some respects resemble group 1 compounds. Thus, TlOH is both very soluble and a strong base in aqueous solution. The higher stability of the +1 over the +3 oxidation state of thallium is often described as the **inert pair effect**. Thallium has the electron configuration $[\mathrm{Xe}]4f^{14}5d^{10}6s^26p^1$. In forming the Tl^+ ion, a Tl atom loses the $6p$ electron and retains two electrons in its $6s$ subshell. It is this pair of electrons—$6s^2$—that is called the inert pair. The electron configuration $(n-1)s^2(n-1)p^6(n-1)d^{10}ns^2$ is commonly encountered in ions of the post-transition elements. One explanation of the inert pair effect is that the small bond energies and lattice energies associated with the large atoms and ions at the bottom of a group are not sufficiently great to offset the ionization energies of the ns^2 electrons.

Aluminum

Aluminum is the third most abundant element and composes 8.3% by mass of Earth's solid crust. On average, more than 5 million metric tons of aluminum are produced per year in the United States.

Production of Aluminum When an aluminum cap was placed atop the Washington Monument in 1884, aluminum was still a semiprecious metal. At that time it cost \$1 per ounce to produce, equivalent to the daily wage of a skilled laborer working a 10-hour day. As a result, aluminum was used mainly in jewelry and artwork. But just two years later, all this changed. In 1886, Charles Martin Hall in the United States and Paul Héroult in France independently discovered an economically feasible method of producing aluminum from Al_2O_3 by electrolysis.

▶ Stimulated by a remark by one of his professors, Charles Martin Hall invented the electrolytic process for the production of aluminum at the age of 23, eight months after his graduation from Oberlin College. Paul Héroult, a student of Le Châtelier, and also at the age of 23, invented the identical process in the same year.

The manufacture of Al involves several interesting principles. The chief ore, *bauxite*, contains Fe_2O_3 as an impurity that must be removed. The principle used in the separation is that Al_2O_3 is an *amphoteric* oxide and dissolves in NaOH(aq), whereas the iron oxide is a *basic* oxide and does not. When $Al_2O_3(s)$ is added to NaOH(aq), $Al_2O_3(s)$ dissolves because the following reaction converts the solid to soluble $[Al(OH)_4]^-$.

$$Al_2O_3(s) + 2\,OH^-(aq) + 3\,H_2O(l) \longrightarrow 2[Al(OH)_4]^-(aq)$$

When the solution containing $[Al(OH)_4]^-$ is slightly acidified, $Al(OH)_3(s)$ precipitates. Pure Al_2O_3 is obtained by heating the $Al(OH)_3$.

$$[Al(OH)_4]^-(aq) + H_3O^+(aq) \longrightarrow Al(OH)_3(s) + 2H_2O$$
$$2\,Al(OH)_3(s) \xrightarrow{\Delta} Al_2O_3(s) + 3\,H_2O(g)$$

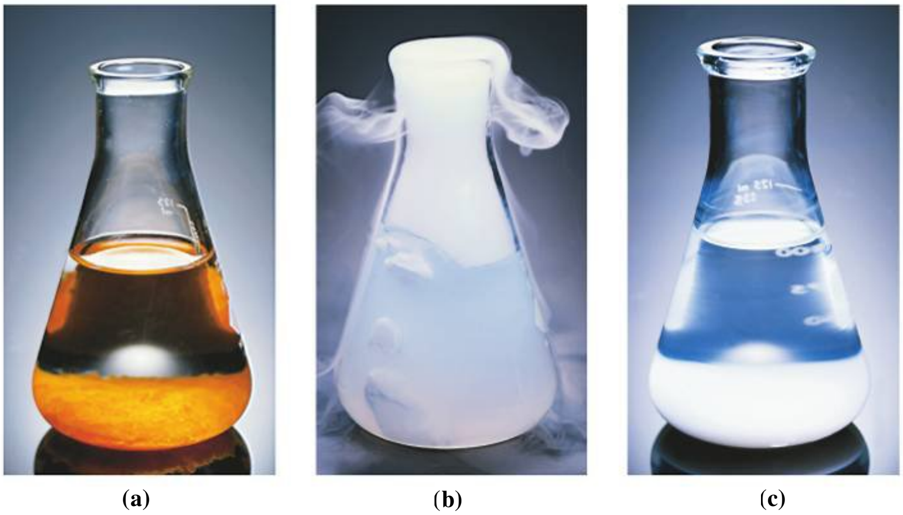
The separation of a mixture of $Fe^{3+}(aq)$ and $Al^{3+}(aq)$, which makes use of these reactions, is illustrated in Figure 21-23.

Al_2O_3 has a very high melting point (2020 °C) and produces a liquid that is a poor electrical conductor. Thus, its electrolysis is not feasible without a better conducting solvent. That was the crux of the discovery by Hall and Héroult. They found, independently, that up to 15% Al_2O_3, by mass, can be dissolved in the molten mineral *cryolite*, Na_3AlF_6, at about 1000 °C. Cryolite consists of Na^+ and AlF_6^- ions. In the molten state, it is a good electrical conductor. In the Hall–Héroult process, aluminum metal is produced by electrolysis of Al_2O_3 in molten cryolite. A typical electrolysis cell, pictured in Figure 21-24, produces aluminum of 99.6%–99.8% purity. The electrode reactions are not known with certainty, but the overall electrolysis reaction is

$$\begin{array}{ll} \textit{Oxidation:} & 3\{C(s) + 2\,O^{2-} \longrightarrow CO_2(g) + 4\,e^-\} \\ \textit{Reduction:} & 4\{Al^{3+} + 3\,e^- \longrightarrow Al(l)\} \\ \hline \textit{Overall:} & 3\,C(s) + 4\,Al^{3+} + 6\,O^{2-} \longrightarrow 4\,Al(l) + 3\,CO_2(g) \end{array} \qquad \textbf{(21.25)}$$

The energy consumed to produce aluminum by electrolysis is very high, about 15 kWh per kg of Al. This is more than three times the amount of energy consumed per kg of Na in the electrolysis of NaCl(aq). Because of the high energy requirements for producing Al(s), aluminum production facilities are generally located near low-cost hydroelectric power sources. The energy required to recycle Al is only about 5% of that to produce the metal from bauxite, and currently about 45% of the Al produced in the United States is obtained from the recycling of scrap aluminum.

Why is so much energy consumed in the electrolytic production of aluminum? Any process that must be carried out at a high temperature requires

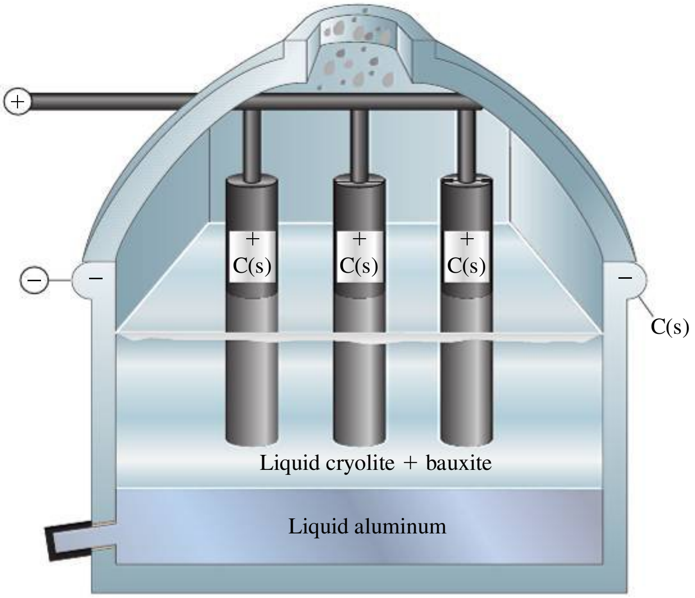


(a) (b) (c)

▲ FIGURE 21-23

Purifying bauxite

(a) When an excess of $OH^-(aq)$ is added to a solution containing $Al^{3+}(aq)$ and $Fe^{3+}(aq)$, the Fe^{3+} precipitates as $Fe(OH)_3(s)$ and the $Al(OH)_3(s)$ first formed redissolves to produce $[Al(OH)_4]^-(aq)$. **(b)** The $Fe(OH)_3(s)$ is filtered off, and the $[Al(OH)_4]^-(aq)$ is made slightly acidic through the action of CO_2, here added as dry ice. **(c)** The precipitated $Al(OH)_3(s)$ collects at the bottom of a clear, colorless solution.

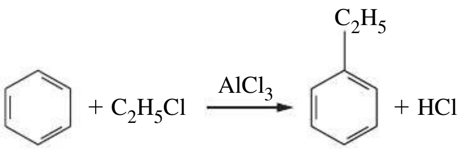


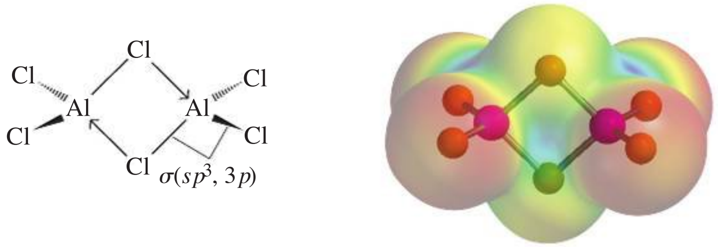
▶ FIGURE 21-24
Electrolysis cell for aluminum production
The cathode is a carbon lining in a steel tank. The anodes are also made of carbon. Liquid aluminum is denser than the electrolyte medium and collects at the bottom of the tank.

large amounts of energy for heating. In the electrolytic production of Al, the electrolysis bath must be kept at about 1000 °C, which is done by means of electric heating. Two other factors, however, are also involved in the large energy consumption. First, to produce one mole of Al, *three* moles of electrons must be transferred: $Al^{3+} + 3\,e^- \longrightarrow Al(l)$. Additionally, the molar mass of Al is relatively low, 27 g mol^{-1}. The electric current equivalent to the passage of one mole of electrons produces only 9 g Al. In contrast, one mole of electrons produces 12 g Mg, 20 g Ca, or 108 g Ag. Yet the same factors that make Al production a significant energy consumer make Al an outstanding energy producer when it is used in a battery. (Recall the aluminum–air battery described on page 893.)

Aluminum Halides Aluminum fluoride, AlF_3, has considerable ionic character. It has a high melting point (1040 °C) and when molten it is a conductor of electric current. In contrast, the other aluminum halides exist as *molecular* species with the formula Al_2X_6 (for which X = Cl, Br, or I). We can think of this molecule as comprising two AlX_3 units. When two identical units combine, the resulting molecule is called a **dimer**. The dimeric structure of Al_2Cl_6 is shown in Figure 21-25. Notice that two Cl atoms are bonded exclusively to each Al atom and two Cl atoms bridge the two metal atoms. Bonding in this molecule can be described by assuming that the Al atoms are sp^3 hybridized. Each bridging Cl atom appears to bond to two Al atoms in two ways. The bond to one Al atom is a conventional covalent bond because each atom contributes one electron to the bond. The bond to a second Al atom is a coordinate covalent bond, where the chlorine atom provides the pair of electrons for the bond, noted by arrows in Figure 21-25.

The aluminum halides, just like the boron halides, are reactive Lewis acids. They readily accept a pair of electrons and form adducts. For example, they form adducts with ethers, as does BF_3. In another example, addition of Cl^- to $AlCl_3$ produces the tetrahedral $[AlCl_4]^-$. The formation of $[AlCl_4]^-$ is important in the use of $AlCl_3$ as an acid–base catalyst in the Friedel–Crafts reaction. The most common reaction of this type involves the addition of an alkyl group, such as the ethyl group, C_2H_5—, to a benzene ring, as shown below.





Bonding scheme

Electrostatic potential map

▲ FIGURE 21-25
Bonding in Al_2Cl_6
Two Cl atoms bridge the $AlCl_3$ units to form Al_2Cl_6. Electrons donated by these Cl atoms to Al atoms are indicated by arrows.

In this reaction, $AlCl_3$ acts as a Lewis acid and assists in generating the positive cation $[C_2H_5]^+$:

$$C_2H_5Cl + AlCl_3 \longrightarrow [C_2H_5]^+ + [AlCl_4]^+$$

The $[C_2H_5]^+$ cation attacks the benzene ring, liberating a proton that reacts with $[AlCl_4]^-$ to regenerate $AlCl_3$ and HCl.

As pointed out on page 947, a very important halide complex of aluminum is cryolite, $NaAlF_6$. Natural deposits of cryolite were discovered in Greenland in 1794 and occur almost nowhere else. For aluminum production, natural cryolite has been largely displaced by cryolite synthesized in a lead-clad vessel by using the following reaction:

$$6\ HF + Al(OH)_3 + 3\ NaOH \longrightarrow Na_3AlF_6 + 6\ H_2O \qquad \textbf{(21.26)}$$

Aluminum Oxide and Hydroxide Aluminum oxide is often referred to as *alumina*; when in crystalline form, it is called *corundum*.

◀ Corundum, when pure, is also known as the gemstone *white sapphire*. Certain other gemstones consist of corundum with small amounts of transition metal ions as impurities: Cr^{3+} in ruby and Fe^{3+} and Ti^{4+} in blue sapphire, for example. Artificial gemstones are made by fusing corundum with carefully controlled amounts of other oxides.

The bonding and crystal structure of alumina account for its physical properties. The small Al^{3+} ions and small O^{2-} ions form a very stable ionic lattice. The crystal has a cubic closest packed structure of O^{2-} ions, with Al^{3+} ions occupying octahedral holes. Alumina is a very hard material and is often used as an abrasive. It is also resistant to heat (mp 2020 °C) and is used in linings for high-temperature furnaces and as a catalyst support in industrial chemical processes. Aluminum oxide is relatively unreactive except at very high temperatures. Its stability at high temperatures classifies it as a *refractory* material.

As mentioned previously, aluminum is protected against reaction with water in the pH range 4.5–8.5 by a thin, impervious coating of Al_2O_3. This coating can be purposely thickened to enhance the corrosion resistance of the metal by a process known as *anodizing*. An aluminum object is used for the anode and a graphite electrode is used for the cathode in an electrolyte bath of $H_2SO_4(aq)$. The half-reaction occurring at the anode during electrolysis is shown below:

$$2\ Al(s) + 3\ H_2O(l) \longrightarrow Al_2O_3(s) + 6\ H^+(aq) + 6\ e^-$$

Al_2O_3 coatings of varying porosity and thickness can be obtained. Also, the oxide can be made to absorb pigments or other additives. Anodized aluminum is used to make everyday items, such as the drinking cups shown in the photograph in the margin, and is used in architectural components of buildings, such as bronze or black window frames.

Aluminum hydroxide is *amphoteric*. It reacts with acids to form $[Al(H_2O)_6]^{3+}$, as shown below:

$$Al(OH)_3(s) + 3\ H_3O^+(aq) \longrightarrow [Al(H_2O)_6]^{3+}(aq) \qquad \textbf{(21.27)}$$

Also, it reacts with bases to form $[Al(OH)_4]^-$:

$$Al(OH)_3(s) + OH^-(aq) \longrightarrow [Al(OH)_4]^-(aq) \qquad \textbf{(21.28)}$$

▲ Drinking cups made of anodized aluminum.

▶ A disadvantage of the use of aluminum sulfate in sizing paper is that its acidic character contributes to deterioration of the paper. In contrast, calcium carbonate maintains an alkaline medium in paper (page 939).

Aluminum Sulfate and Alums Aluminum sulfate, $Al_2(SO_4)_3$, is the most important commercial aluminum compound. It is prepared by the reaction of hot concentrated $H_2SO_4(aq)$ on $Al_2O_3(s)$. The product that crystallizes from solution is $Al_2(SO_4)_3 \cdot 18\,H_2O$. More than 1 million metric tons of aluminum sulfate are produced annually in the United States, about half of which is used in water purification. In this application, the pH of the water is adjusted so that $Al(OH)_3(s)$ precipitates when aluminum sulfate is added. As the $Al(OH)_3(s)$ settles, it removes suspended solids in the water. Another important use is in the sizing of paper. *Sizing* refers to incorporating materials, such as waxes, glues, or synthetic resins, into paper to make the paper more water resistant. $Al(OH)_3$ precipitated from $Al_2(SO_4)_3(aq)$ helps deposit the sizing agent in the paper.

▶ In the industrial world, *alum* usually refers to simple aluminum sulfate; terms such as *potash* (potassium) *alum* and *ammonium alum* designate the double salts.

When an aqueous solution of equimolar amounts of $Al_2(SO_4)_3$ and K_2SO_4 is allowed to crystallize, the crystals obtained are of potassium aluminum sulfate, $KAl(SO_4)_2 \cdot 12\,H_2O$. This is just one of a large class of double salts called alums. **Alums** have the formula $M(I)M(III)(SO_4)_2 \cdot 12\,H_2O$, where M(I) is a unipositive cation (other than Li^+) and M(III) is a tripositive cation—Al^{3+}, Ga^{3+}, In^{3+}, Ti^{3+}, V^{3+}, Cr^{3+}, Mn^{3+}, Fe^{3+}, Co^{3+}, Re^{3+}, or Ir^{3+}. The actual ions present in the alums are $[M(H_2O)_6]^+$, $[M(H_2O)_6]^{3+}$, and $SO_4{}^{2-}$. The most common alums have $M(I) = K^+, Na^+$, or $NH_4{}^+$ and $M(III) = Al^{3+}$. Li^+ does not form alums because the ion is too small to accommodate six water molecules. Sodium aluminum sulfate is the leavening acid in baking powders, and potassium aluminum sulfate is used in dyeing. The fabric to be dyed is dipped into a solution of the alum and heated in steam. Hydrolysis of $[Al(H_2O)_6]^{3+}$ deposits $Al(OH)_3$ into the fibers of the material, and the dye is adsorbed on the $Al(OH)_3$ that deposits.

Diagonal Relationship of Beryllium and Aluminum

The charge densities of Be^{2+} and Al^{3+} are very similar and this similarity has been used to rationalize the following observations:

- The Be^{2+} ion is hydrated in aqueous solutions, forming $[Be(H_2O)_4]^{2+}$. Similarly, Al^{3+} is also hydrated as $[Al(H_2O)_6]^{3+}$. Because the Al^{3+} ion is larger than the Be^{2+} ion, it can accommodate a greater number of water molecules in its primary hydration sphere. In both cases, the cations are sufficiently polarizing that the following reactions occur in aqueous solutions:

  $$[Be(H_2O)_4]^{2+}(aq) + H_2O(l) \rightleftharpoons [Be(H_2O)_3(OH)]^{+}(aq) + H_3O^{+}(aq)$$
  $$[Al(H_2O)_6]^{3+}(aq) + H_2O(l) \rightleftharpoons [Al(H_2O)_5(OH)]^{2+}(aq) + H_3O^{+}(aq)$$

  As a result, aqueous solutions of beryllium and aluminum salts, such as $Be(NO_3)_2$ or $Al(NO_3)_3$, are slightly acidic.
- The hydroxides of beryllium and aluminum are both amphoteric and form tetrahydroxo complexes, $[Be(OH)_4]^{2-}$ or $[Al(OH)_4]^{-}$, in highly basic solutions.
- In air, both metals form a strong oxide coating, which protects the metals from reaction.
- Both metals form carbides (Be_2C and Al_4C_3) containing the C^{4-} ion. The carbides react with water to form methane:

  $$Be_2C(s) + 4\,H_2O(l) \longrightarrow 2\,Be(OH)_2(s) + CH_4(g)$$
  $$Al_4C_3(s) + 12\,H_2O(l) \longrightarrow 4\,Al(OH)_3(s) + 3\,CH_4(g)$$

- Both Be and Al form halides, such as $BeCl_2$ or $AlCl_3$, that can act as Lewis acids and Friedel–Crafts catalysts.

21-9 CONCEPT ASSESSMENT

AlF_3 is almost insoluble in anhydrous HF, but it dissolves if KF is present. Passage of BF_3 through the resulting solution causes AlF_3 to precipitate. How can you explain these observations?

21-5 Group 14: The Carbon Family

The properties of the group 14 elements vary dramatically within the group. Tin and lead, at the bottom of the group, have mainly metallic properties. Germanium is a *metalloid* (or *semi-metal*), and it exhibits semiconductor behavior. Silicon is mostly nonmetallic in its chemical behavior but is sometimes classified as a metalloid. Silicon also exhibits semiconductor behavior. Carbon, the first member of group 14, is a nonmetal. We will first discuss carbon and silicon and then tin and lead; germanium is mentioned only briefly.

The essential differences between carbon and silicon, as outlined in Table 21.7, are perhaps the most striking between any second- and third-period elements within a group in the periodic table. As suggested by the approximate bond energies, strong C—C and C—H bonds account for the central role of carbon–atom chains and rings in establishing the chemical behavior of carbon. A study of these chains and rings and their attached atoms is the focus of organic chemistry (Chapters 26 and 27) and biochemistry (Chapter 28). The Si—Si and Si—H bonds are much weaker than the Si—O bond. The strength of the Si—O bond accounts for the predominance of the silicates and related compounds among silicon compounds.

Carbon

Carbon is so much the central element to the study of organic and biochemistry that the rich and important inorganic chemistry of carbon is sometimes

TABLE 21.7 Comparison of Carbon and Silicon

Carbon	Silicon
Two principal allotropes: graphite and diamond	One stable, diamond-type crystalline structure
Forms two stable *gaseous* oxides, CO and CO_2, and several less stable ones, such as C_3O_2	Forms only one *solid* oxide (SiO_2) that is stable at room temperature; a second oxide (SiO) is stable only in the temperature range of 1180–2480 °C
Insoluble in alkaline media	Reacts in alkaline media, forming $H_2(g)$ and $SiO_4^{4-}(aq)$
Principal oxoanion is CO_3^{2-}, which has a trigonal-planar shape	Principal oxoanion is SiO_4^{2-}, which has a tetrahedral shape
Strong tendency for catenation,[a] with straight and branched chains and rings containing up to hundreds of C atoms	Less tendency for catenation,[a] with silicon atom chains limited to about six Si atoms
Readily forms multiple bonds through use of the orbital sets $sp^2 + p$ and $sp + p^2$	Multiple bond formation much less common than with carbon
Approximate single-bond energies, kJ mol^{-1}: C—C, 347 C—H, 414 C—O, 360	Approximate single-bond energies, kJ mol^{-1}: Si—Si, 226 Si—H, 318 Si—O, 464

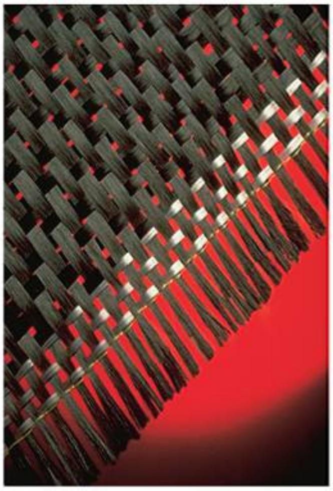
[a] Catenation is the joining together of like atoms into chains.

overlooked. It is the inorganic aspects of the chemistry of carbon that we emphasize in this section.

Production and Uses of Carbon Graphite is a form of carbon that is widely distributed in Earth's crust, some of it in deposits rich enough for commercial exploitation. The bulk of industrial graphite, however, is synthesized from carbon-containing materials. The key requirement is to heat the high-carbon-content material to a temperature of about 3000 °C in an electric furnace. In this process, the carbon atoms fuse into larger and larger ring systems, leading ultimately to the graphite structure shown in Figure 12-33.

Graphite has excellent lubricating properties, even when dry. The planes of carbon atoms in graphite are held together by relatively weak forces and can easily slip past one another. This property is handy in pencil "lead," which is actually a thin rod made from a mixture of graphite and clay that glides easily on paper. Graphite's principal use is based on its ability to conduct electric current; it is used for electrodes in batteries and industrial electrolysis. Graphite's use in foundry molds, furnaces, and other high-temperature environments is based on its ability to withstand high temperatures.

A newly developed use of graphite is in the manufacture of strong, lightweight composites consisting of graphite fibers, shown in the margin, and various plastics. These composites are used in products ranging from tennis rackets to lightweight aircraft. When carbon-based fibers, such as rayon, are carefully heated to a very high temperature, all volatile matter is driven off, leaving a carbon residue with the graphite structure.

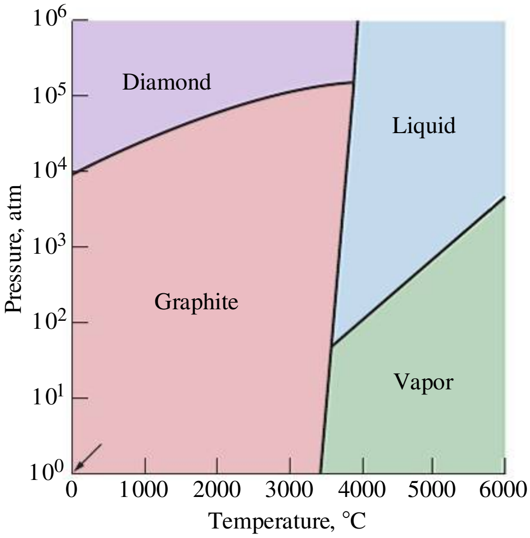


▲ Fabric for use in composite materials woven from carbon fibers.

As indicated in the phase diagram for carbon in Figure 21-26, graphite is the more stable form of carbon, not only at room temperature and normal atmospheric pressure but at temperatures up to 3000 °C and pressures of 10^4 atm and higher. Diamond is the more stable form of carbon at very high pressures. Diamonds can be synthesized from graphite by heating the graphite to temperatures of 1000–2000 °C and subjecting it to pressures of 10^5 atm or more. Usually the graphite is mixed with a metal, such as iron. The metal melts, and the graphite is converted to diamond within the liquid metal. Diamonds can then be picked out of the solidified metal.

According to Figure 21-26, we might expect diamond to revert to graphite at room temperature and pressure. Fortunately for the jewelry industry and for those who treasure diamonds as gems, many phase changes that require a rearrangement in bond type and crystal structure occur extremely slowly. That is very much the case with the diamond–graphite transition.

Most diamonds that are used as gemstones are natural diamonds. For industrial purposes, inferior specimens of natural diamonds or, increasingly,



▶ FIGURE 21-26
Simplified phase diagram for carbon
Notice that pressure is plotted on a logarithmic scale. The arrow marks the point 1 atm, 25 °C.

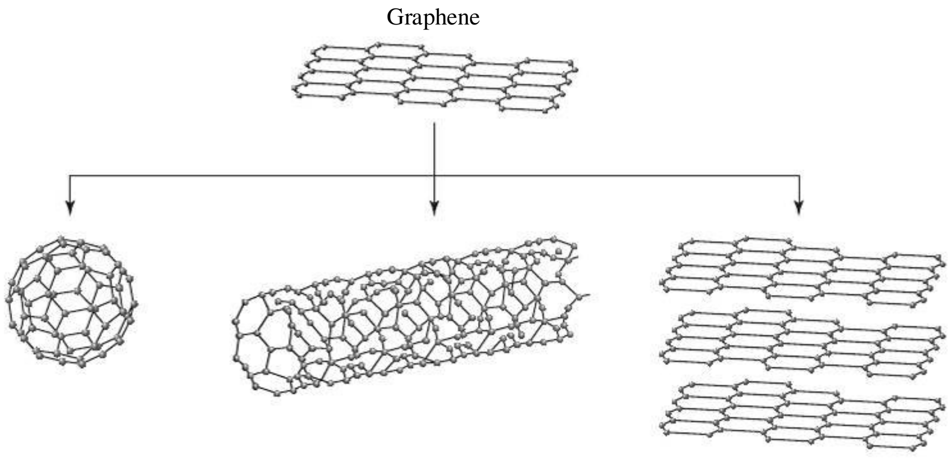
synthetic diamonds, shown in the margin, are used. The industrial use depends on two key properties. Diamonds are used as abrasives because they are extremely hard (10 on the Mohs hardness scale). No harder substance is known. Diamonds also have a high thermal conductivity (they dissipate heat quickly), so they are used in drill bits for cutting steel and other hard materials. The rapid dissipation of heat makes the drilling process faster and increases the lifetime of the bit. A recent development has been the creation of diamond films that can be deposited directly onto metals, which imparts some of the properties of diamond to the metal. For example, when a metal is coated with a thin diamond film, the resulting material has a high thermal conductivity. Such materials have been used in heat sinks for computer chips to help dissipate the heat that computer chips generate.

◀ Because of their expected future importance, diamond films were named "Molecule of the Year" by the journal *Science* in 1990. In 1991, the fullerenes earned that honor.

Carbon can be obtained in several other forms, consisting of mixed crystalline or amorphous structures. Incomplete combustion of natural gas, such as in an improperly adjusted Bunsen burner in the laboratory, produces a smoky flame. The smoke can be deposited as finely divided soot called **carbon black**. Carbon black is used as filler in rubber tires (several kilograms per tire), as a pigment in printing inks, and as the transfer material in carbon paper, typewriter ribbons, laser printers, and photocopying machines. Recently, new allotropes of carbon have been isolated from the decomposition of graphite. These allotropes, known as fullerenes and nanotubes, were presented in Chapter 12 (page 528). Recall that the molecule C_{60} is remarkably stable and has a shape resembling a soccer ball (12 pentagonal faces, 20 hexagonal faces, and 60 vertices). Other fullerenes include C_{70}, C_{74}, and C_{82}. Fullerenes are typically produced by laser decomposition of graphite under a helium atmosphere. Because nitrogen and oxygen interfere with the process of forming fullerenes, soot, which is formed by the combustion of hydrocarbons in air, does not contain fullerenes.

▲ Synthetic diamonds

In Chapter 12, we discussed various forms of carbon: graphite, diamond, fullerenes, and nanotubes. In this chapter we focus on graphene. **Graphene** is a sheet of carbon atoms only one atom thick. The layers of graphite are graphene. A carbon nanotube is a sheet of graphene rolled into a cylinder. A fullerene is obtained when an appropriate number of hexagonal rings in graphene are replaced by pentagonal rings; the presence of the pentagonal rings causes the flat sheet to pucker and form a spherical ball. The relationship between graphene and other forms of carbon is illustrated in Figure 21-27. Graphene has very interesting electronic properties because electrons in these sheets are moving very quickly—at approximately 1/300 of the speed of light. It is expected that graphene will play an important role in the development of electronic devices, possibly replacing silicon.



◀ FIGURE 21-27
The relationship between graphene and the other forms of carbon

It was once thought impossible that a sheet of carbon, only one atom thick, could be made or isolated. However, scientists in the United Kingdom (Andre Geim and Kostya Novosalov at Manchester University) were able to isolate graphene in 2004 by using a technique called micromechanical cleavage. Essentially, the process is just like drawing with a pencil, the "lead" of which contains graphite, and looking among the traces for graphene pieces in the trail left by the pencil. Another way to isolate graphene is to use adhesive tape repeatedly to peel away layers of carbon atoms from a graphite surface in a process called exfoliation. The exfoliation of graphite is illustrated schematically in Figure 21-28. These methods produce flakes that contain 1 to 10 layers of graphene and are up to 100 μm thick. The single-layer flakes have to be found among the thousands of thicker flakes.

Two other noteworthy carbon-containing materials are coke and charcoal. When coal is heated in the absence of air, volatile substances are driven off, leaving a high-carbon residue called *coke*. This same type of destructive distillation of wood produces *charcoal*. Currently, coke is the principal metallurgical reducing agent. It is used in blast furnaces, for instance, to reduce iron oxide to iron metal.

▲FIGURE 21-28
Exfoliation of graphite

Carbon Dioxide The chief oxides of carbon are carbon monoxide, CO, and carbon dioxide, CO_2. There are about 380 ppm of CO_2 in air (0.038% by volume). CO occurs to a much lesser extent. Although they are only minor constituents of air, these two oxides are important in many ways.

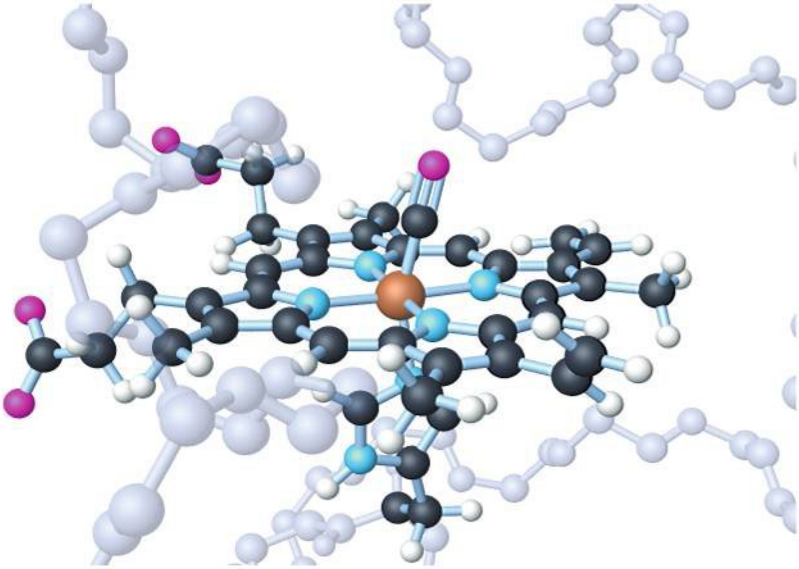
Carbon dioxide is the only oxide of carbon formed when carbon or carbon-containing compounds are burned in an *excess* of air (providing an abundance of O_2). This condition exists when a fuel-lean mixture is burned in an automobile engine. Thus, for the combustion of the gasoline component octane,

$$C_8H_{18}(l) + \frac{25}{2}O_2(g) \longrightarrow 8\,CO_2(g) + 9\,H_2O(l) \qquad \textbf{(21.29)}$$

If the combustion occurs in a *limited* quantity of air, carbon monoxide is also produced. This condition prevails when a fuel-rich mixture is burned in an automobile engine. One possibility for the incomplete combustion of octane is

$$C_8H_{18}(l) + 12\,O_2(g) \longrightarrow 7\,CO_2(g) + CO(g) + 9\,H_2O(l) \qquad \textbf{(21.30)}$$

CO as an air pollutant comes chiefly from the incomplete combustion of fossil fuels in automobile engines. CO is an inhalation poison because CO molecules bond irreversibly to Fe atoms in hemoglobin in blood and displace the O_2 molecules that the hemoglobin normally carries, as illustrated in Figure 21-29.



▶FIGURE 21-29
CO bound to hemoglobin
Carbon monoxide binds to the iron atoms in hemoglobin more strongly than does oxygen. Thus, carbon monoxide's toxicity arises because it prevents hemoglobin from binding with oxygen. The portion of the hemoglobin molecule shown here is called a *heme* group. An iron atom (yellow) is at the center of the group and is surrounded by four nitrogen atoms. In hemoglobin, an O_2 molecule projects above the plane of the iron and nitrogen atoms, but here it has been replaced by a CO molecule (black and red).

TABLE 21.8 Some Industrial Methods of Preparing CO_2

Method	Chemical Reaction
Recovery from exhaust stack gases in the combustion of carbonaceous fuels, such as the combustion of coke	$C(s) + O_2(g) \longrightarrow CO_2(g)$
Recovery in ammonia plants from steam–reforming reactions used to produce hydrogen	$CH_4(g) + 2\,H_2O(g) \longrightarrow CO_2(g) + 4\,H_2(g)$
Decomposition (calcination) of limestone at about 900 °C	$CaCO_3(s) \longrightarrow CaO(s) + CO_2(g)$
Fermentation by-product in the production of ethanol	$\underset{\text{a sugar}}{C_6H_{12}O_6(aq)} \longrightarrow 2\,C_2H_5OH(aq) + 2\,CO_2(g)$

Not only does incomplete combustion of gasoline contribute to air pollution, but also it represents a loss of efficiency. A given quantity of gasoline evolves less heat if $CO(g)$ is formed as a combustion product rather than $CO_2(g)$.

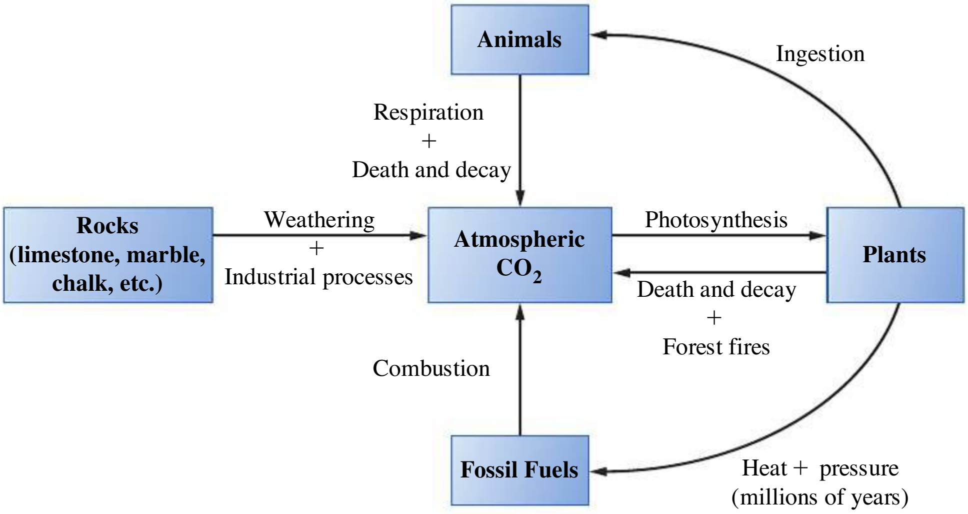
Although carbon dioxide can be obtained directly from the atmosphere as a by-product of the liquefaction of air, this is not an important source. Some of the principal commercial sources of CO_2 are summarized in Table 21.8.

The major use of carbon dioxide (about 50%) is as a refrigerant in the form of dry ice for freezing, preserving, and transporting food. Carbonated beverages account for about 20% of CO_2 consumption. Other important uses are in oil recovery in oil fields and in fire-extinguishing systems. Of course, the major use is not by humans but by algae and plants.

Atmospheric CO_2 is the source of all the carbon-containing compounds (organic compounds) synthesized by green plants. Here we briefly consider the *carbon cycle*—the major exchanges that occur between the atmosphere and the surface of Earth. A portion of the carbon cycle is represented in Figure 21-30. Atmospheric CO_2 is the only source of carbon available to plants for making

21-10 CONCEPT ASSESSMENT

With a minimum of calculation, determine how much less heat is produced per mol of $C_8H_{18}(l)$ burned in reaction (21.30) than in reaction (21.29).



Animals
Ingestion
Respiration + Death and decay
Rocks (limestone, marble, chalk, etc.)
Weathering + Industrial processes
Atmospheric CO₂
Photosynthesis
Plants
Death and decay + Forest fires
Combustion
Fossil Fuels
Heat + pressure (millions of years)

▲ FIGURE 21-30
The carbon cycle

▶ Melvin Calvin won the Nobel Prize in Chemistry in 1961 for his research on the assimilation of carbon dioxide in plants.

organic compounds by the process of *photosynthesis*. The process is extremely complicated, and its details have been known for only a few decades. It involves up to 100 sequential steps for the conversion of 6 mol CO_2 to 1 mol $C_6H_{12}O_6$ (glucose). The overall change is represented by the chemical equation below:

$$6\,CO_2(g) + 6\,H_2O(l) \xrightarrow[\text{sunlight}]{\text{chlorophyll}} C_6H_{12}O_6(s) + 6\,O_2(g) \qquad \Delta H = +2.8 \times 10^3\ \text{kJ}$$

The overall reaction is highly endothermic. The required energy comes from sunlight. Chlorophyll, a green pigment in plants, is crucial to the process. Atmospheric oxygen is a by-product of the reaction.

Here are some of the ideas illustrated in Figure 21-30. When animals consume plants, carbon atoms pass to the animals. Some carbon is returned to the atmosphere as CO_2 when the animals breathe and when they expel gas (methane). Additional CO_2 returns to the atmosphere as plants and animals die and their remains are broken down by bacteria. Some carbon in decaying organic matter is converted to coal, petroleum, and natural gas. This carbon is unavailable for photosynthesis.

Not represented in the drawing is the cycle of CO_2 through the oceans of the world. Phytoplankton (small, floating green organisms) also carry on photosynthesis, converting CO_2 to organic compounds. Phytoplankton are at the bottom of the ocean food chain, directly and indirectly supporting all the animals in the oceans.

Huge quantities of carbon have accumulated in the form of carbonate rocks (mostly $CaCO_3$). These come from the shells of decayed mollusks in ancient seas.

Human activities now play a far more significant role in the carbon cycle than in preindustrial times. The combustion of fossil fuels is replacing stored carbon by carbon dioxide to an even greater extent. We have already seen the possible consequences of this distortion of the carbon cycle: an increased level of atmospheric CO_2 and a future global warming (page 276). Human disruption of the natural carbon cycle has become a widely debated issue.

Carbon Monoxide A modern method of making carbon monoxide is the steam reforming of natural gas, which is based on the following chemical reaction:

$$CH_4(g) + H_2O(g) \longrightarrow CO(g) + 3\,H_2(g) \qquad \textbf{(21.31)}$$

Steam refers to gaseous water. *Reforming* refers to the restructuring of a carbon compound, such as CH_4 to CO. The reforming of natural gas (mostly CH_4) is an important source of $H_2(g)$ for use in the synthesis of NH_3 (page 1008).

There are three main uses of carbon monoxide. One is in synthesizing other compounds. For example, a mixture of CO and H_2 produced by reforming methane or some other hydrocarbon and known as *synthesis gas* can be converted to a new organic chemical product, such as methanol, CH_3OH:

$$CO(g) + 2\,H_2(g) \longrightarrow CH_3OH(l)$$

Another use of CO is as a reducing agent. For instance, CO can be used to reduce iron oxide to iron, as shown below:

$$Fe_2O_3(s) + 3\,CO(g) \longrightarrow 2\,Fe(l) + 3\,CO_2(g)$$

The reaction can be carried out by heating Fe_2O_3 and coke—a form of pure carbon—in a blast furnace. Carbon is first converted to CO and then CO reduces Fe_2O_3 to Fe.

A third use of CO is as a fuel, usually mixed with CH_4, H_2, and other combustible gases. This was discussed in Section 7-9.

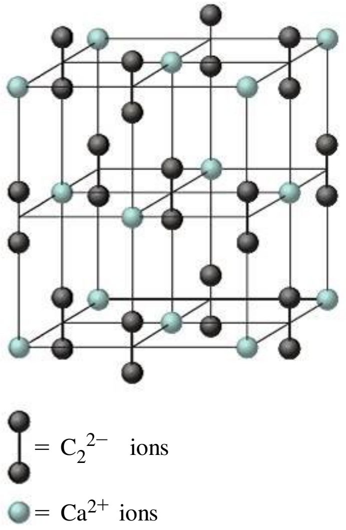
Other Inorganic Carbon Compounds Carbon combines with metals to form *carbides*. In many cases, the carbon atoms occupy the holes or voids, also called interstitial sites, in metal structures, forming *interstitial carbides*. With active metals, the carbides are ionic. *Calcium carbide* forms in the high-temperature reaction of lime and coke:

$$\mathrm{CaO(s)} + 3\,\mathrm{C(s)} \xrightarrow{2000\ ^\circ\mathrm{C}} \mathrm{CaC_2(s)} + \mathrm{CO(g)} \tag{21.32}$$

Calcium carbide is important because acetylene ($HC{\equiv}CH$) can easily be made from it, and acetylene can be used to synthesize many chemical compounds:

$$\mathrm{CaC_2(s)} + 2\,\mathrm{H_2O(l)} \longrightarrow \mathrm{Ca(OH)_2(s)} + \mathrm{C_2H_2(g)} \tag{21.33}$$

Solid CaC_2 can be regarded as a face-centered cubic array of Ca^{2+} ions with the $C_2^{\,2-}$ ions in the octahedral holes, as shown in the figure in the margin.



▲ Structure of calcium carbide

Carbon disulfide, CS_2, can be synthesized by the reaction of methane and sulfur vapor in the presence of a catalyst:

$$\mathrm{CH_4(g)} + 4\,\mathrm{S(g)} \longrightarrow \mathrm{CS_2(l)} + 2\,\mathrm{H_2S(g)} \tag{21.34}$$

Carbon disulfide is a highly flammable, volatile liquid that acts as a solvent for sulfur, phosphorus, bromine, iodine, fats, and oils. Its uses as a solvent are decreasing, however, because CS_2 is poisonous. Other important uses are in the manufacture of rayon and cellophane.

Carbon tetrachloride, CCl_4, can be prepared by the direct chlorination of methane, as shown below:

$$\mathrm{CH_4(g)} + 4\,\mathrm{Cl_2(g)} \longrightarrow \mathrm{CCl_4(l)} + 4\,\mathrm{HCl(g)} \tag{21.35}$$

Although CCl_4 has been extensively used as a solvent, dry-cleaning agent, and fire extinguisher, these uses have been steadily declining because CCl_4 causes liver and kidney damage and is a known carcinogen.

Certain groupings of atoms, several containing C atoms, have some of the characteristics of a halogen atom. They are called *pseudohalogens* and include the following groupings of atoms:

$$\text{—CN (cyanide)} \qquad \text{—OCN (cyanate)} \qquad \text{—SCN (thiocyanate)}$$

The *cyanide* ion, CN^-, is similar to the halide ions, X^-, in that it forms an insoluble silver salt, AgCN, and an acid, HCN. Hydrocyanic acid, HCN, is a liquid that boils at about room temperature. It is a very weak acid, unlike HCl. Despite its extreme toxicity, HCN has important uses in the manufacture of plastics. The combination of two cyanide groups produces *cyanogen*, $(CN)_2$. This gas resembles chlorine gas in undergoing a disproportionation reaction in basic solution:

$$\mathrm{(CN)_2} + 2\,\mathrm{OH^-(aq)} \longrightarrow \mathrm{CN^-(aq)} + \mathrm{OCN^-(aq)} + \mathrm{H_2O(l)} \tag{21.36}$$

Cyanogen is used in organic synthesis, as a fumigant, and as a rocket propellant.

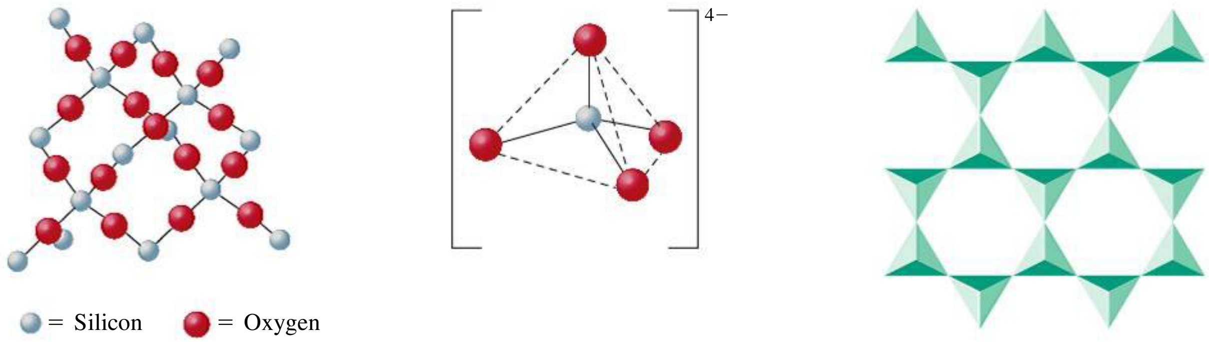
Silicon

Among the elements, silicon is second only to oxygen in its abundance in Earth's crust. Silicon is to the mineral world what carbon is to the living world—the backbone element.

Production and Uses of Silicon Elemental silicon is produced when quartz or sand (SiO_2) is reduced by reaction with coke in an electric arc furnace. The balanced chemical equation for the reaction is given below:

$$\mathrm{SiO_2} + 2\,\mathrm{C} \xrightarrow{\Delta} \mathrm{Si} + 2\,\mathrm{CO(g)} \tag{21.37}$$

Very high purity Si for solar cells can be made by reducing Na_2SiF_6 with metallic Na. The Na_2SiF_6 required for this process is obtained as a by-product



(a) (b) (c)

▲ FIGURE 21-32
Linking of SiO_4 tetrahedra
In **(a)**, two tetrahedra are linked at one corner to form the $Si_2O_7{}^{6-}$ ion. In **(b)**, tetrahedra are linked at two corners to form a long chain. The empirical formula of the chain is $SiO_3{}^{2-}$. In **(c)**, SiO_4 tetrahedra are joined into a double chain.

Oxides of Silicon; Silicates Silica, SiO_2, is the only stable oxide of silicon. Silica is a network covalent solid (not a molecular solid, like CO_2). In silica, each Si atom is bonded to *four* O atoms and each O atom to *two* Si atoms. The structure is that of a network covalent solid, as suggested by Figure 21-31(a). This structure is reminiscent of the diamond structure, and silica has certain properties that resemble those of diamond. For example, quartz, a form of silica, is fairly hard (with a Mohs hardness of 7) but not as hard as diamond (with a Mohs hardness of 10), has a high melting point (about 1700 °C), and is a nonconductor of electricity. Silica is the basic raw material of the glass and ceramics industries.

The central feature of all *silicates* is the $SiO_4{}^{4-}$ tetrahedron depicted in Figure 21-31(b). These tetrahedra may be arranged in a wide variety of ways. Here are just a few examples:

- *Simple SiO_4 tetrahedra.* Typical minerals in which the anions are simple $SiO_4{}^{4-}$ tetrahedra are *thorite* ($ThSiO_4$) and *zircon* ($ZrSiO_4$).
- *Two SiO_4 tetrahedra joined end-to-end.* The silicon atoms in the two tetrahedra share an O atom between them in the anion $Si_2O_7{}^{6-}$, found in the mineral *thortveitite* ($Sc_2Si_2O_7$). See Figure 21-32(a).
- *SiO_4 tetrahedra joined into long chains.* Each Si atom shares an O atom with the Si atom in an adjacent tetrahedron on either side. An example is *spodumene*, the principal source of lithium and lithium compounds. Its empirical formula is $LiAl(SiO_3)_2$. See Figure 21-32(b).
- *SiO_4 tetrahedra joined into a double chain.* Half the Si atoms share three of their four O atoms with Si atoms in adjacent tetrahedra, and half share only two. In *chrysotile asbestos*, double chains are held together by cations (chiefly Mg^{2+}); this mineral has a fibrous appearance. The empirical formula is $Mg_3(Si_2O_5)(OH)_4$. See Figure 21-32(c).
- *SiO_4 tetrahedra are bonded together in two-dimensional sheets.* Each Si atom shares O atoms with the Si atoms in three adjacent tetrahedra. This structure is depicted in Figure 21-31(c). In *muscovite mica*, with the empirical

formula, $KAl_2(AlSi_3O_{10})(OH)_2$, the counterions that bond sheets together in layers are mostly K^+ and Al^{3+}. Bonding within the sheets is stronger than that between the sheets, so muscovite mica flakes easily.

- *SiO_4 tetrahedra are bonded together in three-dimensional structures.* Three-dimensional arrays of tetrahedra result when each Si atom shares all four O atoms with the Si atoms in four adjoining tetrahedra (as shown in Figure 21-31a). This is the most common arrangement, occurring in silica (quartz) and in the majority of silicate minerals.

21-11 CONCEPT ASSESSMENT

The empirical formula of the mineral *beryl* is $Be_3Al_2Si_6O_{18}$. By using the several descriptions of silicate minerals just given as a guide, describe the structure of the silicate anion in beryl.

SiO_2 is a weakly acidic oxide and slowly dissolves in strong bases. It forms a series of silicates, such as Na_2SiO_4 (sodium orthosilicate) and Na_2SiO_3 (sodium metasilicate). These compounds are somewhat soluble in water and, as a result, are sometimes referred to as "water glass."

Silicate anions are bases; when acidified, they produce silicic acids, which are unstable and decompose to silica. The silica obtained, however, is not a crystalline solid or powder. Depending on the acidity of the solution, the silica is obtained as a colloidal dispersion, a gelatinous precipitate, or a solid-like gel in which all the water is entrapped. These hydrated silicates are polymers of silica formed by the elimination of water molecules between neighboring molecules of silicic acid. The process begins with the following reaction:

$$SiO_4{}^{4-}(aq) + 4\,H^+(aq) \longrightarrow Si(OH)_4$$

◀ H_4SiO_4 is called *ortho*silicic acid. When a combination of one H atom and one OH group (equivalent to a molecule of H_2O) are eliminated from the *ortho* acid, the resulting acid, H_2SiO_3, is called *meta*silicic acid.

21-2 ARE YOU WONDERING...

Why silica (SiO_2) does not exist as simple molecules as CO_2 does?

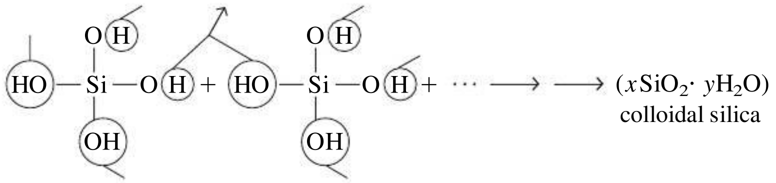
Because both silicon and carbon are in group 14 of the periodic table and have four valence electrons, we might expect them to form oxides with similar properties. In CO_2, the side-to-side overlap of 2*p* orbitals of the C and O atoms is extensive (see page 461). The carbon-to-oxygen double bond in CO_2 proves to be stronger ($799\ kJ\ mol^{-1}$) than two single bonds ($2 \times 360\ kJ\ mol^{-1}$). This results in the familiar Lewis structure of CO_2:

$$:\ddot{O}=C=\ddot{O}:$$

Silicon, being in the third period, would have to use 3*p* orbitals to form double bonds with oxygen. The side-to-side overlap of these orbitals with the 2*p* orbitals of oxygen is quite limited. In terms of energy, a stronger bonding arrangement results if the Si atoms form *four* single bonds with O atoms (bond energy: $4 \times 464\ kJ\ mol^{-1} = 1856\ kJ$ total) rather than *two* double bonds (bond energy: $2 \times 640\ kJ\ mol^{-1} = 1280\ kJ$ total). Because each O atom must simultaneously bond to two Si atoms, the result is a network of $-Si-O-Si-$ bonds (see Figure 21-31a).

On page 935 we contrasted Be and Mg, the second- and third-period members of group 2. Here is another example of how the second-period member of a group (that is, carbon) differs from the higher period members.

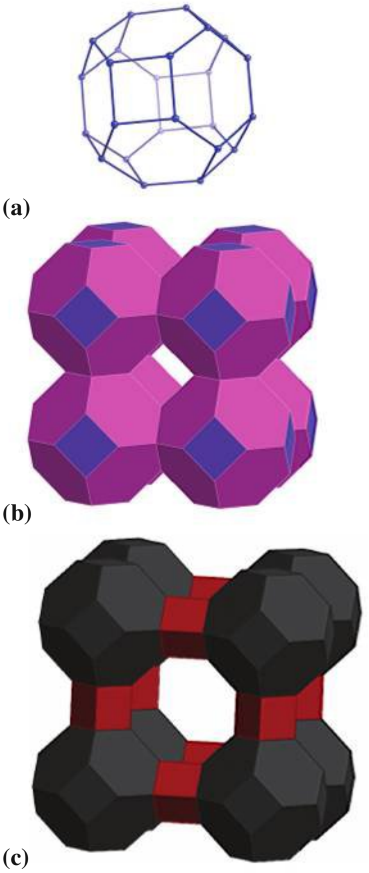
It is followed by the reaction below:



$$\mathrm{HO{-}\overset{\displaystyle OH}{\underset{\displaystyle OH}{Si}}{-}O{-}H + HO{-}\overset{\displaystyle OH}{\underset{\displaystyle OH}{Si}}{-}O{-}H} + \cdots \longrightarrow \longrightarrow (x\mathrm{SiO_2}\cdot y\mathrm{H_2O})$$

colloidal silica

Notice that —H and —OH combine to form water (HOH) and that Si—O—Si bridges are produced.



▲ FIGURE 21-33
Structures of zeolites
(a) The basic structural unit in many zeolites is a β-cage, which consists of six-membered and four-membered rings. **(b)** This is the structure obtained when eight β-cages are joined together by sharing faces of the four-membered rings. This structural unit is found in sodalite, a naturally occurring zeolite. **(c)** This is the structure obtained when the four-membered rings of the β-cages are joined together by bridges. The resulting structure is more open than the structure shown in (b). Such structures are found in zeolite-A, a synthetic zeolite.

Zeolites: An Important Class of Aluminosilicates

A **zeolite** is a three-dimensional network of SiO_4 and AlO_4 tetrahedra. Many of the zeolite structures contain a ring based on $Si_6O_{18}{}^{12-}$. The ring of Si atoms, some of which can be replaced by Al atoms, is represented by a hexagon. The hexagons can be joined together to give the structure in Figure 21-33(a). Bear in mind that the hexagons shown in Figure 21-33 emphasize the positions of the Si and Al atoms. The straight lines do not represent bonds; the atoms at the vertices of the hexagons are, in fact, connected by bent Si—O—Si or Al—O—Al bridges.

The structure shown in Figure 21-33(a) is called a β-cage and it is present in a naturally occurring zeolite known as *sodalite*. In the β-cage, there are four- and six-membered rings of nonoxygen atoms. In sodalite, eight of the β-cages are joined together by sharing the faces of the four-membered rings to give the cubic structure shown in Figure 21-33(b). An alternative is to bridge oxygen at each corner of the four ring faces. This produces the structure shown in Figure 21-33(c), which is found in a synthetic zeolite, $Na_{12}(AlO_2)_{12}(SiO_2)_{12}\cdot 27\ H_2O$, known as zeolite-A. The Na^+ ions in the formula of zeolite-A are required to offset the decrease in positive charge that occurs when Al^{3+} ions replace Si^{4+} ions in the lattice.

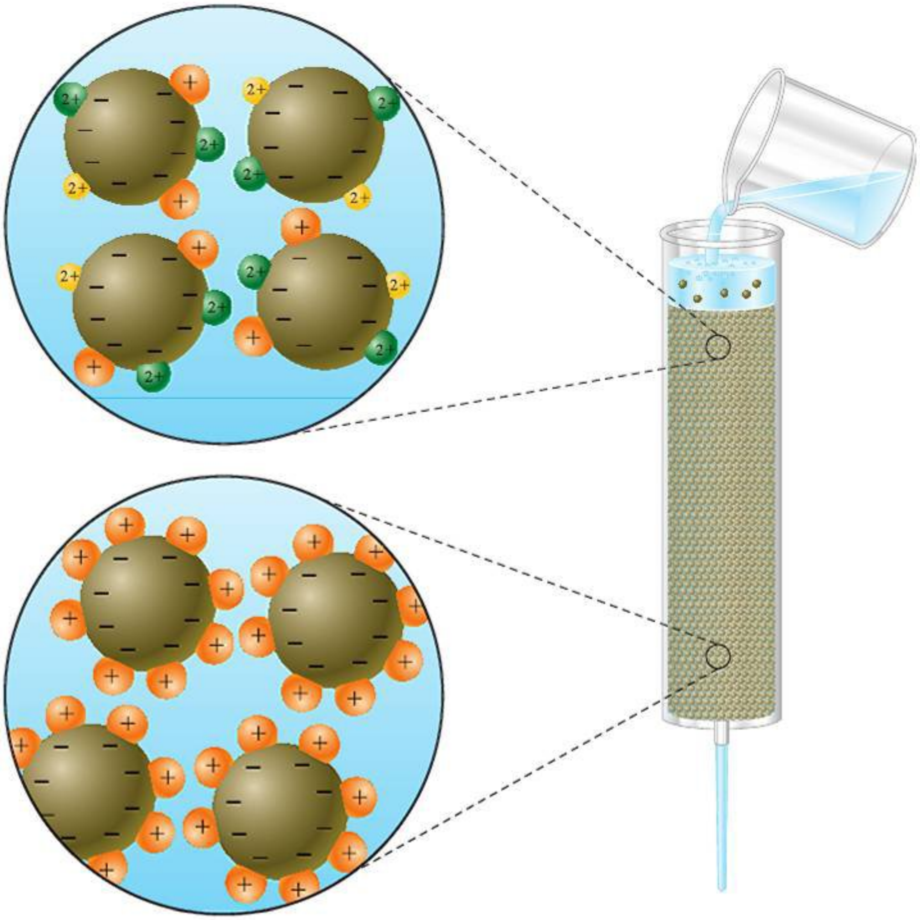
The important consequence of the arrangements described above, and illustrated in Figure 21-33, is the presence of channels and cavities in zeolite structures. These channels and cavities give zeolites their important properties. For example, because small molecules are able to diffuse into cavities and larger molecules are excluded, zeolites have been used as molecular sieves to remove molecules of certain sizes from a mixture. Zeolites, in their dehydrated forms, have also been used for removing water from gases or organic solvents. For example, in the drying of benzene, water molecules diffuse into the zeolite lattice while benzene molecules, which are too large, are excluded. The zeolite can be separated from the benzene and can be regenerated by heating.

Another important application of zeolites is as an ion exchange material in the treatment of hard water, as illustrated in Figure 21-34. Hard water contains significant concentrations of ions, especially Ca^{2+}, Mg^{2+}, or Fe^{3+}, and a zeolite can be used to exchange these ions with Na^+ ions. It is desirable to remove Ca^{2+}, Mg^{2+}, and Fe^{3+} ions from water because these ions react with $CO_3{}^{2-}$ ions or anions of soaps to form insoluble precipitates. For example, Ca^{2+}, Mg^{2+}, and Fe^{3+} ions react with $CO_3{}^{2-}$ ions to form a mixed precipitate of $CaCO_3$, $MgCO_3$, and rust called *boiler scale*. The formation of boiler scale lowers the efficiency of water heaters and builds up in pipes or on the insides of containers used for boiling water. Ca^{2+} and Mg^{2+} ions in hard water combine with anions of soaps—such as the palmitate ion, equation (21.9)—to form insoluble precipitates that accumulate on the surfaces of bathtubs or showers and contribute to the formation of *soap scum* and *bathtub rings*.

The equation below represents the exchange that occurs when, for example, Ca^{2+} ions (in hard water) are exchanged with Na^+ ions (in a zeolite):

$$Na_2[\text{zeolite}](s) + Ca^{2+}(aq) \longrightarrow Ca[\text{zeolite}](s) + 2\ Na^+(aq)$$

▶ The dehydrated form of a zeolite is obtained by heating the zeolite under vacuum. The heating process drives off the waters of hydration from the zeolite structure, leaving behind a structure that has a high affinity for water.



▲ FIGURE 21-34
Ion exchange
The resin shown here is a cation-exchange resin (a zeolite, for example). Multivalent cations (green, Fe^{2+}, yellow, Ca^{2+}) replace Na^+ (orange) at the top of the resin column. By the time the water has reached the bottom of the column, all the multivalent ions have been removed and only Na^+ ions remain as counterions. The exchange can be represented as $2\,NaR + M^{2+} \rightleftharpoons MR_2 + 2\,Na^+$. The reaction occurs in the forward direction during water softening. As expected from Le Châtelier's principle, in the presence of concentrated NaCl(aq), the reverse reaction is favored and the resin is recharged.

Because sodium compounds are generally soluble, the replacement of Ca^{2+} ions by Na^+ ions prevents the formation of insoluble precipitates.

Zeolites are used not only in ion exchange resins but also in detergents to help remove any Ca^{2+} and Mg^{2+} ions that might be present in water used for washing clothes. The removal of these ions helps the detergents foam better and also helps to prevent the formation of insoluble calcium and magnesium compounds.

Modern automobile engines require fuels containing short-chain hydrocarbons with low boiling points, and some require high octane fuels containing branched-chain hydrocarbons. Zeolite catalysts are used to speed up the conversion of long-chain hydrocarbons—found in crude oil—into short-chain or branched-chain hydrocarbons. Consequently, zeolites play an important role in the petroleum industry.

Silicates in Ceramics and Glass Hydrated silicate polymers are important in the ceramics industry. A colloidal dispersion of particles in a liquid is called a *sol*. The sol can be poured into a mold and, following removal of some of the liquid, is converted to a *gel*. The gel is then processed into the final ceramic

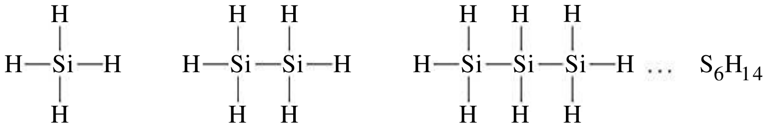
▲ Ceramic components of an automobile engine. (Photo courtesy of Kyocera Industrial Ceramics Corp./Vancouver, WA)

product. This sol-gel process can produce exceptionally lightweight ceramic materials.

Uses of these advanced ceramics fall into two general categories: **(1)** electrical, magnetic, or optical applications (as in the manufacture of integrated circuit components) and **(2)** applications that take advantage of the ceramic's mechanical and structural properties at high temperatures. These latter properties have been explored in developing ceramic components for gas turbines and automotive engines, such as those shown in the photograph in the margin. Quite possibly the automobile engine of the future will be a ceramic engine—lightweight and more fuel-efficient because higher operating temperatures are possible. Some engines already have several ceramic components, such as engine valves and valve seats. There is some truth to the vision of this ceramic future as the new stone age.

If sodium and calcium carbonates are mixed with sand and fused at about 1500 °C, the result is a liquid mixture of sodium and calcium silicates. When cooled, the liquid becomes more viscous and eventually becomes a solid that is transparent to light; this solid is called a **glass**. Crystalline solids have a long-range order, whereas glasses are *amorphous solids* in which order is found over relatively short distances only. Think of the structural units in glass (silicate anions) as being in a jumbled rather than in a regular arrangement. A glass and a crystalline solid also differ in their melting behavior. A glass softens and melts over a broad temperature range, whereas a crystalline solid has a definite, sharp melting point. Different types of glass and methods of making them are described later in this section.

Silanes and Silicones Several silicon–hydrogen compounds are known, but because Si—Si single bonds are not particularly strong, the chain length in these compounds, called *silanes*, is limited to six.

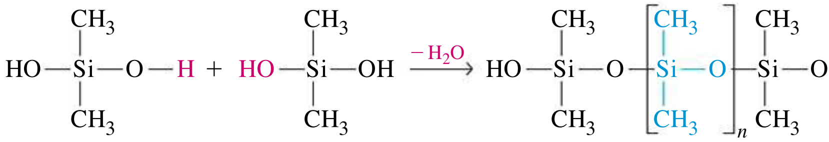


Monosilane Disilane Trisilane Hexasilane

Other atoms or groups of atoms can be substituted for H atoms in silanes to produce compounds called *organosilanes*. Typical is the direct reaction of Si and methyl chloride, CH_3Cl. The equation for the reaction is given below:

$$2\,CH_3Cl + Si \longrightarrow (CH_3)_2SiCl_2$$

The reaction of $(CH_3)_2SiCl_2$, dichlorodimethylsilane, with water produces an interesting compound, *dimethylsilanol*, $(CH_3)_2Si(OH)_2$. Dimethylsilanol undergoes a polymerization reaction in which H_2O molecules are eliminated from among large numbers of silanol molecules. The result of this polymerization is a material consisting of molecules with long silicon-oxygen chains: **silicones**.



A silicone

▲ Some common applications of silicones.

Silicones are important polymers because they are versatile. They are used to make a variety of useful products, such as those shown in the photograph in the margin. Silicones can be obtained either as oils or as rubber-like materials. Silicone oils are not volatile and do not decompose when heated. Also, they can be cooled to low temperatures without solidifying or becoming viscous. Silicone oils are excellent high-temperature lubricants. In contrast, hydrocarbon oils break down at high temperatures, become very viscous, and then solidify at low temperatures. Silicone rubbers retain their elasticity at low temperatures and are chemically resistant and thermally stable. This makes them useful in caulking around windows, for instance.

Silicon Halides Silicon reacts readily with the halogens (X_2) to form the products SiX_4. As we might expect from their molecular structures and molar masses, at room temperature SiF_4 is a gas, $SiCl_4$ and $SiBr_4$ are liquids, and SiI_4 is a solid. Both SiF_4 and $SiCl_4$ are readily hydrolyzed with water, but the former is only partially hydrolyzed. The hydrolysis reactions for SiF_4 and $SiCl_4$ are as follows:

$$2\,SiF_4(g) + 4\,H_2O(l) \rightleftharpoons SiO_2(s) + 2\,H_3O^+(aq) + [SiF_6]^{2-}(aq) + 2\,HF(aq) \quad \textbf{(21.38)}$$

$$SiCl_4(l) + 2\,H_2O(l) \longrightarrow SiO_2(s) + 4\,HCl(aq) \quad \textbf{(21.39)}$$

The ability of the Si atom to expand its valence shell is illustrated by the formation of the ion $[SiF_6]^{2-}$. The corresponding $[SiCl_6]^{2-}$ has not been prepared, probably because the chloride ion is too big for six of them to fit around the Si atom.

$SiCl_4$ is manufactured on a large scale to produce finely divided silica (reaction 21.37), used as a reinforcing filler in silicone rubber, and very pure silicon for transistors used in computer chips.

Glass Making Glass and the art of glassmaking have been known for millennia. Beautiful stained-glass windows can be seen in medieval and modern churches; ancient glass containers for perfume and oil are displayed in many museums. Today, glass is indispensable in almost every facet of life.

Soda–lime glass is the oldest form of glass. The starting material in its manufacture is a mixture of sodium carbonate (*soda* ash), calcium carbonate (which decomposes to form quick*lime* when heated), and silicon dioxide. The mixture can be fused at a relatively low temperature (1300 °C) compared with the melting point of pure silica (1710 °C), and it is easy to form into the shapes needed. The effect of the sodium ions is to break up the crystalline lattice of the SiO_2; the calcium ions render the glass insoluble in water, so it can be used for such items as drinking glasses and windows. At the high temperatures employed, chemical reactions occur that produce a mixture of sodium and calcium silicates as the ultimate glass product.

▲ Stained-glass windows form the 20-meter-high ceiling, called the Glory Window, inside the Chapel of Thanksgiving in Dallas, Texas.

Glass containing even small amounts of Fe_2O_3 has a distinctive green color (bottle glass). Glass can be made colorless by incorporating MnO_2 into the glassmaking process. The MnO_2 oxidizes green $FeSiO_3$ to yellow $Fe_2(SiO_3)_3$ and is itself reduced to Mn_2O_3, which imparts a violet color. The yellow and violet are complementary colors, so the glass appears colorless. Where desired, color can be imparted by means of appropriate additives, such as CoO for cobalt blue glass. To produce an opaque glass, such additives as calcium phosphate are used. In Bohemian crystal, most of the Na^+ is replaced by K^+; a glass with exceptional transparency can be made by incorporating lead oxides.

A problem with soda-lime glass is its high coefficient of thermal expansion—its dimensions change significantly with temperature. The glass cannot withstand thermal shock. This limitation posed a particular problem for the lanterns used in the early days of railroads. In the rain, the hot glass in these lanterns would easily shatter. Adding B_2O_3 to the glass solved the problem. A *borosilicate* glass has a low coefficient of thermal expansion and is thus resistant to thermal shock. This is the glass more commonly known by its trade name, Pyrex. It is widely used in chemical laboratories and for cookware in the home.

Most glass has small bubbles or impurities in it that decrease its ability to transmit light without scattering—a phenomenon observed in the distorted images produced by the thick bottoms of drinking glasses. In modern *fiber-optic* cables, sound waves are converted to electrical impulses, which are transmitted as laser light beams. The light must be transmitted over long distances without distortion or loss of signal. For this purpose, a special glass made of pure silica is required. The key to making this glass is in purifying silica, which can be done by a series of chemical reactions. First, impure quartz or sand is reduced to silicon by using coke as a reducing agent. The silicon is then allowed to react with $Cl_2(g)$ to form $SiCl_4(g)$. The reactions involved in the conversion of SiO_2 to $SiCl_4$ are as follows:

$$SiO_2(s) + 2\,C(s) \longrightarrow Si(s) + 2\,CO(g)$$
$$Si(s) + 2\,Cl_2(g) \longrightarrow SiCl_4(g)$$

Finally, the $SiCl_4$ is burned in a methane–oxygen flame. SiO_2 deposits as a fine ash, and chlorocarbon compounds escape as gaseous products. The SiO_2, with impurity levels reduced to parts per billion, can then be melted and drawn into the fine filaments required in fiber-optic cable. Tens of millions of kilometers of fiber-optic cable are currently produced annually in the United States.

Diagonal Relationship of Boron and Silicon

The following similarities between B and Si are listed here:

- Boron forms a solid acidic oxide, B_2O_3, like that of silicon, SiO_2. In contrast Al_2O_3 is amphoteric and CO_2 is acidic.
- Boric acid, H_3BO_3, is a weak acid similar to silicic acid H_4SiO_4.
- There is a wide range of polymeric borates and silicates, based on shared oxygen atoms.
- Both boron and silicon form gaseous hydrides.

This diagonal relationship is not readily understood and cannot be interpreted in terms of charge density since the bonding in boron compounds and in silicon compounds is exclusively covalent. The elements are, however, both metalloids, have similar electronegativities, and have similar sizes leading to similar chemical behavior.

Properties and Uses of Tin and Lead

The data in Table 21.9 suggest that tin and lead are rather similar to each other. Both are soft and malleable and melt at low temperatures. The ionization

TABLE 21.9 Some Properties of Tin and Lead

	Sn	Pb
Atomic number	50	82
Atomic (metallic) radius, pm	141	175
Ionic (M^{2+}) radius, pm[a]	93	118

Electrical conductivity[b]	14.4	7.68

[a] For coordination number four.
[b] See footnotes c and d of Table 21-2.

energies and standard electrode potentials of the two metals are also about the same. This means that their tendencies to be oxidized to the +2 oxidation state are comparable.

The fact that both tin and lead can exist in two oxidation states, +2 and +4, is an example of the inert pair effect (page 946). In the +2 oxidation state, the inert pair ns^2 is not involved in bond formation, whereas in the +4 oxidation state, the pair does participate. Tin displays a stronger tendency to exist in the +4 oxidation state than does lead. That tendency is consistent with the trend observed in group 13, in which the lower oxidation state is favored farther down a group.

Another difference between tin and lead is that tin exists in two common crystalline forms (α and β), whereas lead has but a single solid form. The α (gray), or nonmetallic, form of tin is stable below 13 °C; the β (white), or metallic, form of tin is stable above 13 °C. Ordinarily, when a sample of β tin is cooled, it must be kept below 13 °C for a long time before the transition to α tin occurs. Once it does begin, however, the transformation takes place rather rapidly and with dramatic results. Because α tin is less dense than the β variety, the tin expands and crumbles to a powder. This transformation leads to the disintegration of objects made of tin. It has been a particular problem in churches in colder climates because some organ pipes are made of tin or tin alloys. The transformation is known in northern Europe as *tin disease*, *tin pest*, or *tin plague*.

The chief tin ore is tin(IV) oxide, SnO_2, known as *cassiterite*. After initial purification, the tin(IV) oxide is reduced with carbon (coke) to produce tin metal, as shown below:

$$SnO_2(s) + C(s) \xrightarrow{\Delta} Sn(l) + CO_2(g) \tag{21.38}$$

Nearly 50% of the tin metal produced is used in tinplate, especially in plating iron for use in cans for storing foods. The next most important use (about 25% of the total produced) is in the manufacture of **solders**—low-melting alloys used to join wires or pieces of metal. Other important alloys of tin are *bronze* (90% Cu, 10% Sn) and *pewter* (85% Sn, 7% Cu, 6% Bi, 2% Sb). Alloys of Sn and Pb are used to make organ pipes.

Lead is found chiefly as lead(II) sulfide, PbS, an ore known as *galena*. Lead(II) sulfide is first converted to lead(II) oxide by heating it strongly in air, a process called **roasting**. The oxide is then reduced with coke to produce the metal. The reactions are as follows:

$$2\,PbS(s) + 3\,O_2(g) \xrightarrow{\Delta} 2\,PbO(s) + 2\,SO_2(g) \qquad \textbf{(21.39)}$$

$$2\,PbO(s) + C(s) \xrightarrow{\Delta} 2\,Pb(l) + CO_2(g) \qquad \textbf{(21.40)}$$

More than half the lead produced is used in lead–acid (storage) batteries. Other uses include the manufacture of solder and other alloys, ammunition, and radiation shields (to protect against X-rays).

Compounds of Group 14 Metals

As mentioned earlier, both tin and lead exhibit the +2 and +4 oxidation states. The charge densities of these ions are shown in Table 21.10. The charge density of Sn^{2+} is such that many of the compounds containing tin in the +2 oxidation state are covalent; however, a few ionic solids containing the Sn^{2+} ion are known. Lead(II) exists in many ionic solids. When the metals are in the +4 oxidation state, they form covalent bonds, not ionic bonds, because these Sn^{4+} and Pb^{4+} have very large charge densities and draw electron density from surrounding anions toward themselves.

TABLE 21.10 Charge Densities of Tin and Lead Ions

Ion	Charge Density, C mm^{-3}
Sn^{2+}	54
Pb^{2+}	32
Sn^{4+}	267
Pb^{4+}	196

Oxides Tin forms two primary oxides: SnO and SnO_2. By heating SnO in air, it can be converted to SnO_2. One use of SnO_2 is as a jewelry abrasive.

Lead forms a number of oxides, and the chemistry of some of these oxides is not completely understood. The best known oxides of lead are yellow PbO, *litharge*; red-brown lead dioxide, PbO_2; and a mixed-valence oxide known as *red lead*, Pb_3O_4. Lead oxides are used in the manufacture of lead–acid (storage) batteries, glass, ceramic glazes, cements (PbO), metal-protecting paints (Pb_3O_4), and matches (PbO_2). Other lead compounds are generally made from the oxides.

▶ Another mixed-valence oxide that we have encountered on several occasions in this text is Fe_3O_4 (see, for example, page 86).

Because lead tends to be in the +2 oxidation state, lead(IV) compounds tend to undergo reduction to compounds of lead(II) and are therefore good oxidizing agents. A case in point is PbO_2. In Chapter 20, we noted its use as the cathode in lead–acid storage cells. The reduction of $PbO_2(s)$ can be represented by the half-equation

$$PbO_2(s) + 4\,H^+(aq) + 2\,e^- \longrightarrow Pb^{2+}(aq) + 2\,H_2O(l) \qquad E^\circ = +1.455\ V$$

$PbO_2(s)$ is a better oxidizing agent than $Cl_2(g)$ and nearly as good as $MnO_4^-(aq)$. For example, $PbO_2(s)$ can oxidize HCl(aq) to $Cl_2(g)$, as shown below:

$$PbO_2(s) + 4\,HCl(aq) \longrightarrow PbCl_2(aq) + 2\,H_2O(l) + Cl_2(g) \qquad E^\circ_{cell} = 0.097\ V$$

Halides Tin (IV) chloride is a covalent compound. It is an oily liquid that reacts with moisture in the air as follows:

$$SnCl_4(l) + 4\,H_2O(l) \longrightarrow Sn(OH)_4(s) + 4\,HCl(g)$$

Lead(IV) chloride is also a covalent compound and a yellow oil that reacts with moisture in the air in a manner similar to $SnCl_4$.

Tin(II) and lead(II) chlorides are quite different. Lead(II) chloride is a white insoluble ionic solid, whereas tin(II) chloride is a covalent solid that is soluble in organic solvents. In the gas phase, $SnCl_2$ is a V-shaped molecule, as expected from VSEPR theory. We might expect $SnCl_2$ to act as a Lewis base, because of the presence of the lone pair. However, it acts as a Lewis acid. For example, $SnCl_2$ reacts with Cl^- to form $SnCl_3^-$.

Both chlorides of tin—$SnCl_2$ and $SnCl_4$—have important uses. Tin(II) chloride, $SnCl_2$, is a good reducing agent and is used in the quantitative analysis of iron ores to reduce iron(III) to iron(II) in aqueous solution. Tin(IV) chloride, $SnCl_4$, is formed by the direct reaction of tin and $Cl_2(g)$; it is the form in which tin is recovered from scrap tinplate. Tin(II) fluoride, SnF_2 (stannous fluoride), was used as an anticavity additive to toothpaste but has largely been replaced by NaF in gel toothpastes.

Other Compounds As we should expect from the solubility guidelines (Table 5.1), one of the few soluble lead compounds is lead(II) nitrate, $Pb(NO_3)_2$. It is formed in the reaction of PbO_2 with nitric acid, as shown below:

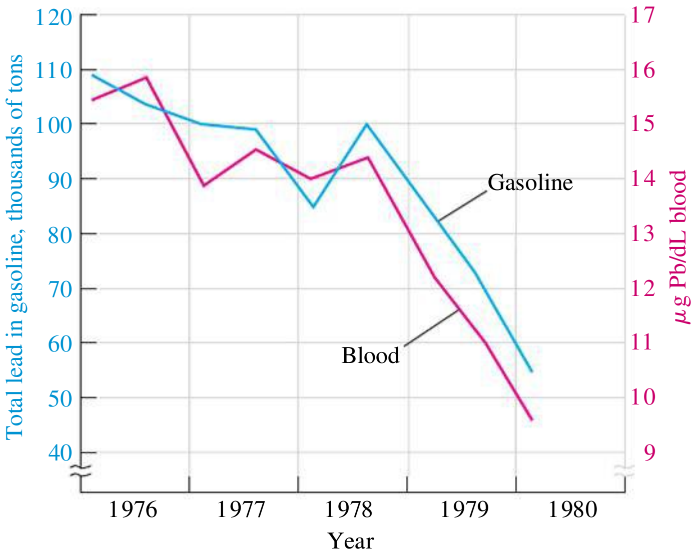
$$2\,PbO_2(s) + 4\,HNO_3(aq) \longrightarrow 2\,Pb(NO_3)_2(aq) + 2\,H_2O(l) + O_2(g)$$

The addition of a soluble chromate salt to $Pb(NO_3)_2(aq)$ produces lead(II) chromate $PbCrO_4$, a yellow pigment known as chrome yellow. Another lead-based pigment used in ceramic glazes and once extensively used in the manufacture of paint is *white lead*, $2\,PbCO_3 \cdot Pb(OH)_2$.

Lead Poisoning

Beginning with the ancient Romans and continuing to fairly recent times, lead has been used in plumbing systems, including those designed to transport drinking water. Exposure to lead has also occurred through cooking and eating utensils and pottery glazes made with lead. In colonial times, lead poisoning was clearly diagnosed as the cause of "dry bellyache" suffered by some North Carolinians who consumed rum made in New England. The distilling equipment used in the manufacture of the rum had components made of lead.

Mild forms of lead poisoning produce nervousness and depression. More severe cases can lead to permanent nerve, brain, and kidney damage. Lead interferes with the biochemical reactions that produce the iron-containing heme group in hemoglobin. As little as 10–15 μg Pb/dL in blood seems to produce physiological effects, especially in small children. The phaseout of leaded gasoline has resulted in a dramatic drop in average lead levels in blood. The drop in blood lead levels is evident in the graph shown in Figure 21-35 and parallels the decline in the use of lead in gasoline. The principal sources of lead contamination now seem to be lead-based painted surfaces found in old buildings and soldered joints in plumbing systems. Lead has been eliminated from modern plumbing solder, which is now a mixture of 95% Sn and 5% Sb. Because lead is toxic, its disposal is closely monitored. Recycling provides about three-quarters of the current lead metal production.



▲ FIGURE 21-35
Lead in gasoline and in blood
The level of lead in the blood of a representative human population showed a dramatic decline that paralleled the decline in the use of lead additives in gasoline in the 1970s. (Data source: Environmental Protection Agency, Office of Policy Analysis, 1984.)

21-12 CONCEPT ASSESSMENT

To prevent the air oxidation of aqueous solutions of Sn^{2+} to Sn^{4+}, metallic tin is sometimes kept in contact with the $Sn^{2+}(aq)$. Suggest how this contact helps prevent the oxidation.

MasteringCHEMISTRY **www.masteringchemistry.com**

Gallium arsenide, GaAs, may be one of the most versatile high-tech materials of our time. For a discussion of some of its properties and uses, go to the Focus On feature for Chapter 21, Gallium Arsenide, on the MasteringChemistry site.

Summary

21-1 Periodic Trends and Charge Density—Trends in atomic or ionic radii, ionization energy, electron affinity, electronegativity, and polarizability (Fig. 21-1), and the **charge density** (equation 21.1) of an ion can be used to rationalize the chemistry of the elements. The greater the charge density, the greater is the tendency for that cation to form bonds with covalent character.

21-2 Group 1: The Alkali Metals—The **alkali metals** (group 1) are the most active of the metals, as indicated by their low ionization energies and large negative electrode potentials. Lithium exhibits some properties similar to magnesium in group 2. Most of the alkali metals are prepared by the electrolysis of their molten salts. Electrolysis of NaCl(aq) produces NaOH(aq), from which many other sodium compounds can be prepared (Fig. 21-5). Na_2CO_3 can be produced from NaCl, NH_3, and $CaCO_3$ by the Solvay process (Fig. 21-7). A **detergent** is a cleansing agent, often sodium salts with long-chain hydrocarbon anions terminating in a sulfate group. A **soap** is also a detergent, but soaps are the sodium salts of long-chain fatty acids terminating in the carboxylate group.

21-3 Group 2: The Alkaline Earth Metals—The **alkaline earth metals** (group 2), like group 1 metals, are also very active. Some group 2 metals are prepared by the electrolysis of a molten salt (Fig. 21-14) and some by chemical reduction. Among the most important of the alkaline earth compounds are the carbonates, especially $CaCO_3$. The oxide of calcium, CaO, called **quicklime**, is formed by the high-temperature decomposition (**calcination**) of limestone. The hydroxide of calcium, $Ca(OH)_2$, called **slaked lime**, is formed in the reaction of quicklime and water. Reversible reactions involving $CO_3{}^{2-}$, $HCO_3{}^{-}$, $CO_2(g)$, and H_2O account for the formation of limestone caves and interior features, such as **stalactites** and **stalagmites** (Fig. 21-15). **Plaster of Paris** is the hemihydrate of calcium sulfate, $CaSO_4 \cdot \frac{1}{2}H_2O$, formed by heating the mineral gypsum, $CaSO_4 \cdot 2\,H_2O$. The similar properties exhibited by the pairs of elements (Li, Mg), (Be, Al), and (B, Si) are known as **diagonal relationships**.

21-4 Group 13: The Boron Family—Group 13 contains one nonmetal, B, and the metals Al, Ga, In, and Tl. Boron compounds are often electron deficient (fewer than an octet of electrons around the B atoms). Three-center, two-electron bonds are used in describing the bonding in diborane (Fig. 21-17). Aluminum occurs almost exclusively in the +3 oxidation state, whereas thallium is mostly in the +1 oxidation state. This is a manifestation of the presence of a pair of *s* electrons in the valence shells of certain post-transition elements. These electrons do not participate in chemical bonding, a consequence referred to as the inert **pair effect**. The principal metal of group 13 is aluminum, whose large-scale use is made possible by an effective method of production (Fig. 21-24). The amphoterism of Al_2O_3 is the basis for separating Al_2O_3 from impurities, mostly Fe_2O_3. Electrolysis is carried out in molten Na_3AlF_6 with Al_2O_3 as a solute. Aluminum is a powerful reducing agent in the **thermite reaction**, in which Fe_2O_3 is reduced to the metal. Aluminum chloride forms a **dimer**, in which two bridging chlorine atoms join together two $AlCl_3$ units (Fig. 21-25). $AlCl_3$ is very reactive. For example, a molecule of $AlCl_3$, a Lewis acid, attaches itself to a Lewis base to form an addition compound called **an adduct**. **Alums** are a class of double salts with the formula $M(I)M(III)(SO_4)_2 \cdot 12\,H_2O$. Gallium has gained importance in the electronics industry because of the desirable semiconductor properties of gallium arsenide (GaAs).

21-5 Group 14: The Carbon Family—Group 14 contains one nonmetal (C), two metalloids (Si and Ge), and the metals Sn, and Pb. Group 14 is notable for the significant differences between the first two members (Table 21.7). Carbon is found in several different physical forms in addition to its allotropes; one of these is **carbon black**. An interesting form of carbon is **graphene**, a sheet of carbon atoms only one atom thick. Carbon monoxide and carbon dioxide are both formed in the combustion of fossil fuels. Carbon monoxide is a poison (Fig. 21-29) and carbon dioxide plays a key role in the carbon cycle (Fig. 21-30). All the elements of group 14 form halides of the type MX_4. All but carbon can employ expanded valence shells to form compounds of the form species, such as the anion $[MX_6]^{2-}$. Progressing down group 14, the halide MX_2 becomes more stable than MX_4 because of the inert pair effect. Silica (SiO_2) and various silicate anions are ubiquitous components of the mineral world. They are also constituents of ceramic materials and **glass**. Organosilanes, compounds in which the hydrogen atoms of silanes are replaced by organic groups, can be polymerized to form **silicones**. **Zeolites** are aluminosilicates that are used as molecular sieves and in treating hard water. Tin and lead in group 14 have some similarities (Table 21.9). They are both soft metals with low melting points. They also have some differences, including the fact that tin acquires the oxidation state +4 rather easily, whereas the +2 oxidation state is favored by lead. One of the most important uses of tin is in low-melting-point alloys known as **solders**. Both elements are obtained by the reduction of their oxides. The metallurgical method of converting a sulfide ore to an oxide, typified by the conversion of PbS to PbO on strong heating, is called **roasting**.

Integrative Example

Without performing detailed calculations, demonstrate that reaction (21.19) correctly describes the dissolving action of rainwater on limestone (for $CaCO_3$, $K_{sp} = 2.8 \times 10^{-9}$).

Analyze

Write the equations that, when combined, yield equation (21.19) for the overall reaction occurring when rainwater acts on limestone. Evaluate the sources and relative importance of the different species involved in the dissolution of the limestone. Describe the overall result.

Solve

The relevant equations to describe the dissolution of calcium carbonate in rainwater are the solubility product expression for $CaCO_3$ and two equations describing the ionization of CO_2 in water (that is, carbonic acid). The three equations are as follows:

$$CaCO_3(s) \rightleftharpoons Ca^{2+}(aq) + CO_3{}^{2-}(aq) \qquad K_{sp} = 2.8 \times 10^{-9}$$

$$CO_2 + 2\,H_2O \rightleftharpoons H_3O^+ + HCO_3{}^- \qquad K_{a_1} = 4.4 \times 10^{-7} \qquad \textbf{(21.17)}$$

$$HCO_3{}^- + H_2O \rightleftharpoons H_3O^+ + CO_3{}^{2-} \qquad K_{a_2} = 4.7 \times 10^{-11} \qquad \textbf{(21.18)}$$

Equation (21.19) is related to these three equations in this way:

$$K_{sp} \text{ expression} + \text{equation}\,(21.17) - \text{equation}\,(21.18)$$

Which leads to

$$CaCO_3(s) + H_2O + CO_2 \rightleftharpoons Ca^{2+}(aq) + 2\,HCO_3{}^-(aq)$$
$$K = (K_{sp} \times K_{a_1})/K_{a_2} = 2.6 \times 10^{-5} \qquad \textbf{(21.19)}$$

Next, consider which is the greater source of $CO_3{}^{2-}$ ions in solution: a saturated aqueous solution of $CaCO_3$ or an aqueous carbonic acid solution. In saturated $CaCO_3(aq)$,

$$[Ca^{2+}] = [CO_3{}^{2-}] \quad K_{sp} = [Ca^{2+}][CO_3{}^{2-}] = [CO_3{}^{2-}]^2 = 2.8 \times 10^{-9}$$

$$[CO_3{}^{2-}] = (2.8 \times 10^{-9})^{\frac{1}{2}} = 5.3 \times 10^{-5}\,M$$

In a carbonic acid solution, H_2CO_3 is a weak *diprotic* acid with $K_{a_2} \ll K_{a_1}$. Thus,

$$[H_3O^+] = [HCO_3{}^-], \text{ and } [CO_3{}^{2-}] = K_{a_2} = 4.7 \times 10^{-11}\,M$$

Note that the carbonate ion concentration in a saturated $CaCO_3$ solution is much greater than the carbonate ion concentration observed in a carbonic acid solution. This means that when the two processes occur simultaneously, carbonate ion from the dissolution of $CaCO_3$ acts as a common ion in the carbonic acid equilibrium. This displaces reaction (21.18) *to the left*, converting $CO_3{}^{2-}$ to $HCO_3{}^-$ while consuming H_3O^+. Removal of H_3O^+ in reaction (21.18) stimulates reaction (21.17) to shift *to the right*, producing more H_3O^+ and, simultaneously, more $HCO_3{}^-$. The overall effect is that H_2O, CO_2, and $CO_3{}^{2-}$ (from $CaCO_3$) are consumed and $HCO_3{}^-$ is produced, just as suggested by equation (21.19).

Assess

We have assessed the qualitative correctness of reaction (21.19). To calculate the quantitative extent of the dissolution of $CaCO_3(s)$ in rainwater is somewhat more difficult. The calculation centers on the combined equilibrium constant expression for reaction (21.19), $K = 2.6 \times 10^{-5}$, and is affected by the partial pressure of atmospheric CO_2 in equilibrium with rainwater. Typical data are given in Chapter 16, Practice Example A, page 738.

PRACTICE EXAMPLE A: Write chemical equations for the reactions that occur when NaCN is dissolved in water and when $Al(NO_3)_3$ is dissolved in water. Then, use data from Appendix D to explain why a precipitate of $Al(OH)_3$ forms when equal volumes of 1.0 M aqueous solutions of NaCN and $Al(NO_3)_3$ are mixed.

PRACTICE EXAMPLE B: The compound $BeCl_2 \cdot 4\,H_2O$ cannot be dehydrated by heating and it dissolves in water to give an acidic solution. Conversely, $CaCl_2 \cdot 6\,H_2O$ can be dehydrated by heating and it dissolves in water to give a solution with neutral pH. Explain these observations and write chemical equations for the reactions that occur, if any, when the salts are heated and when they are dissolved in water.

Exercises

Group 1: The Alkali Metals

1. Use information from the chapter to write chemical equations to represent each of the following:
   (a) reaction of cesium metal with chlorine gas
   (b) formation of sodium peroxide (Na_2O_2)
   (c) thermal decomposition of lithium carbonate
   (d) reduction of sodium sulfate to sodium sulfide
   (e) combustion of potassium to form potassium superoxide
2. Use information from the chapter to write chemical equations to represent each of the following:
   (a) reaction of rubidium metal with water
   (b) thermal decomposition of aqueous $KHCO_3$
   (c) combustion of lithium metal in oxygen gas
   (d) action of concentrated aqueous H_2SO_4 on KCl(s)
   (e) reaction of lithium hydride with water
3. Describe a simple test for determining whether a pure white solid is LiCl or KCl.
4. Describe two methods for determining the identity of an unknown compound that is either Li_2CO_3 or K_2CO_3.
5. Arrange the following compounds in the expected order of increasing solubility in water, and give the basis for your arrangement: Li_2CO_3, Na_2CO_3, $MgCO_3$.
6. The first electrolytic process to produce sodium metal used molten NaOH as the electrolyte. Write probable half-equations and an overall equation for this electrolysis.
7. A 0.872 L NaCl(aq) solution is electrolyzed for 2.50 min with a current of 0.810 A.
   (a) Calculate the pH of the solution after electrolysis.
   (b) Why doesn't the result depend on the initial concentration of the NaCl(aq)?
8. A lithium battery used in a cardiac pacemaker has a voltage of 3.0 V and a capacity of 0.50 A h (ampere hour). Assume that 5.0 μW of power is needed to regulate the heartbeat. [*Hint:* See Appendix B.]
   (a) How long will the implanted battery last?
   (b) How many grams of lithium must be present in the battery for the lifetime calculated in part (a)?
9. An analysis of a Solvay-process plant shows that for every 1.00 kg of NaCl consumed, 1.03 kg of $NaHCO_3$ are obtained. The quantity of NH_3 consumed in the overall process is 1.5 kg.
   (a) What is the percent efficiency of this process for converting NaCl to $NaHCO_3$?
   (b) Why is so little NH_3 required?
10. Consider the reaction $Ca(OH)_2(s) + Na_2SO_4(aq) \rightleftharpoons CaSO_4(s) + 2\,NaOH(aq)$.
    (a) Write a net ionic equation for this reaction.
    (b) Will the reaction essentially go to completion?
    (c) What will be $[SO_4^{2-}]$ and $[OH^-]$ *at equilibrium* if a slurry of $Ca(OH)_2(s)$ is mixed with 1.00 M $Na_2SO_4(aq)$?
11. The Gibbs energies of formation, ΔG_f°, for $Na_2O(s)$ and $Na_2O_2(s)$ are -379.09 kJ mol^{-1} and -449.63 kJ mol^{-1}, respectively, at 298 K. Calculate the equilibrium constant for the reaction below at 298 K. Is $Na_2O_2(s)$ thermodynamically stable with respect to $Na_2O(s)$ and $O_2(g)$ at 298 K?

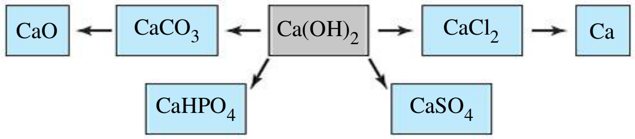
$$Na_2O_2(s) \longrightarrow Na_2O(s) + \frac{1}{2}O_2(g)$$

12. The Gibbs energies of formation, ΔG_f°, for $KO_2(s)$ and $K_2O(s)$ are -240.59 kJ mol^{-1} and -322.09 kJ mol^{-1}, respectively, at 298 K. Calculate the equilibrium constant for the reaction below at 298 K. Is $KO_2(s)$ thermodynamically stable with respect to $K_2O(s)$ and $O_2(g)$ at 298 K?

$$2\,KO_2(s) \longrightarrow K_2O(s) + \frac{3}{2}O_2(g)$$

Group 2: The Alkaline Earth Metals

13. In the manner used to construct Figure 21-5, complete the diagram outlined. Specifically, indicate the reactants (and conditions) you would use to produce the indicated substances from $Ca(OH)_2$.



14. Replace the calcium-containing substances shown in the diagram accompanying Exercise 13 by their magnesium-containing equivalents. Then describe the reactants (and conditions) you would use to produce the indicated substances from $MgSO_4$.
15. In the Dow process (Fig. 21-13), the starting material is Mg^{2+} in seawater and the final product is Mg metal. This process seems to violate the principle of conservation of charge. Does it? Explain.

16. Which has the **(a)** higher melting point, MgO or BaO; **(b)** greater solubility in water, MgF_2 or $MgCl_2$? Explain.

17. Write chemical equations to represent the following:
(a) reduction of BeF_2 to Be metal with Mg as a reducing agent
(b) reaction of barium metal with $Br_2(l)$
(c) reduction of uranium(IV) oxide to uranium metal with calcium as the reducing agent
(d) calcination of dolomite, a mixed calcium magnesium carbonate ($MgCO_3 \cdot CaCO_3$)
(e) complete neutralization of phosphoric acid with quicklime

18. Write chemical equations for the reactions you would expect to occur when
(a) $Mg(HCO_3)_2(s)$ is heated to a high temperature
(b) $BaCl_2(l)$ is electrolyzed
(c) Sr(s) is added to cold dilute HBr(aq)
(d) $Ca(OH)_2(aq)$ is added to $H_2SO_4(aq)$
(e) $CaSO_4 \cdot 2\,H_2O(s)$ is heated

19. *Without performing detailed calculations*, indicate whether equilibrium is displaced either far to the left or far to the right for each of the following reactions. Use data from Appendix D as necessary.
(a) $BaSO_4(s) + CO_3{}^{2-}(aq) \rightleftharpoons BaCO_3(s) + SO_4{}^{2-}(aq)$
(b) $Mg_3(PO_4)_2(s) + 3\,CO_3{}^{2-}(aq) \rightleftharpoons 3\,MgCO_3(s) + 2\,PO_4{}^{3-}(aq)$
(c) $Ca(OH)_2(s) + 2\,F^-(aq) \rightleftharpoons CaF_2(s) + 2\,OH^-(aq)$

20. *Without performing detailed calculations*, indicate why you would expect each of the following reactions to occur to a significant extent as written. Use data from Appendix D as necessary.
(a) $BaCO_3(s) + 2\,CH_3CO_2H(aq) \longrightarrow Ba^{2+}(aq) + 2\,CH_3CO_2{}^-(aq) + H_2O(l) + CO_2(g)$
(b) $Ca(OH)_2(s) + 2\,NH_4{}^+(aq) \longrightarrow Ca^{2+}(aq) + 2\,NH_3(aq) + 2\,H_2O(l)$
(c) $BaF_2(s) + 2\,H_3O^+(aq) \longrightarrow Ba^{2+}(aq) + 2\,HF(aq) + 2\,H_2O(l)$

21. With respect to decomposition to MO(s) and $SO_3(g)$, which of the group 2 sulfates, $MSO_4(s)$, do you expect to be least stable? Explain your answer.

22. With respect to the decomposition to MO(s) and $CO_2(g)$, which of the group 2 carbonates, $MCO_3(s)$, do you expect to be most stable? Explain your answer.

Group 13: The Boron Family

23. The molecule tetraborane has the formula B_4H_{10}.
(a) Show that this is an electron-deficient molecule.
(b) How many bridge bonds must occur in the molecule?
(c) Show that butane, C_4H_{10}, is not electron deficient.

24. Write Lewis structures for the following species, both of which involve coordinate covalent bonding:
(a) tetrafluoroborate ion, $BF_4{}^-$, used in metal cleaning and in electroplating baths
(b) boron trifluoride ethylamine, used in curing epoxy resins (ethylamine is $C_2H_5NH_2$)

25. Write chemical equations to represent the following:
(a) the preparation of boron from BBr_3
(b) the formation of BF_3 from B_2O_3
(c) the combustion of boron in hot $N_2O(g)$

26. Assign oxidation states to all the atoms in a perborate ion based on the structure on page 942.

27. Write chemical equations to represent the
(a) reaction of Al(s) with HCl(aq);
(b) reaction of Al(s) with NaOH(aq);
(c) oxidation of Al(s) to $Al^{3+}(aq)$ by an aqueous solution of sulfuric acid; the reduction product is $SO_2(g)$.

28. Write plausible equations for the
(a) reaction of Al(s) with $Br_2(l)$;
(b) production of Cr from $Cr_2O_3(s)$ by the thermite reaction, with Al as the reducing agent;
(c) separation of Fe_2O_3 impurity from bauxite ore.

29. In some foam-type fire extinguishers, the reactants are $Al_2(SO_4)_3(aq)$ and $NaHCO_3(aq)$. When the extinguisher is activated, these reactants mix, producing $Al(OH)_3(s)$ and $CO_2(g)$. The $Al(OH)_3–CO_2$ foam extinguishes the fire. Write a net ionic equation to represent this reaction.

30. Some baking powders contain the solids $NaHCO_3$ and $NaAl(SO_4)_2$. When water is added to this mixture of compounds, $CO_2(g)$ and $Al(OH)_3(s)$ are two of the products. Write plausible net ionic equations for the formation of these two products.

31. The maximum resistance to corrosion of aluminum is between pH 4.5 and 8.5. Explain how this observation is consistent with other facts about the behavior of aluminum presented in this text.

32. Describe a series of *simple* chemical reactions that you could use to determine whether a particular metal sample is “aluminum 2S” (99.2% Al) or “magnalium” (70% Al, 30% Mg). You are permitted to destroy the metal sample in the testing.

33. In the purification of bauxite ore, a preliminary step in the production of aluminum, $[Al(OH)_4]^-(aq)$ can be converted to $Al(OH)_3(s)$ by passing $CO_2(g)$ through the solution. Write an equation for the reaction that occurs. Could HCl(aq) be used instead of $CO_2(g)$? Explain.

34. In 1825, Hans Oersted produced aluminum chloride by passing chlorine over a heated mixture of carbon and aluminum oxide. In 1827, Friedrich Wöhler obtained aluminum by heating aluminum chloride with potassium. Write plausible equations for these reactions.

35. A description for preparing potassium aluminum alum calls for dissolving aluminum foil in KOH(aq). The solution obtained is treated with $H_2SO_4(aq)$, and the alum is crystallized from the resulting solution. Write plausible equations for these reactions.

36. Handbooks and lists of chemicals do not contain entries under the formulas $Al(HCO_3)_3$ and $Al_2(CO_3)_2$. Explain why these compounds do not exist.

37. Digallane, Ga_2H_6, is a volatile compound and decomposes above −10 °C to gallium metal and hydrogen gas. Suggest a plausible structure for the digallane molecule and describe the bonding.

38. Draw a plausible structure for the GaH_2Cl_2 molecule and describe the bonding. [*Hint:* Each Cl atom is simultaneously bonded to two gallium atoms.]

Group 14: The Carbon Family

39. Comment on the accuracy of a jeweler's advertising that "diamonds last forever." In what sense is the statement true, and in what ways is it false?

40. A temporary fix for a "sticky" lock is to scrape a pencil point across the notches on the key and to work the key in and out of the lock a few times. What is the basis of this fix?

41. Write a chemical equation to represent
(a) the reduction of silica to elemental silicon by aluminum;
(b) the preparation of potassium metasilicate by the high-temperature fusion of silica and potassium carbonate;
(c) the reaction of Al_4C_3 with water to produce methane.

42. Write a chemical equation to represent
(a) the reaction of potassium cyanide solution with silver nitrate solution;
(b) the combustion of Si_3H_8 in an excess of oxygen;
(c) the reaction of dinitrogen with calcium carbide to give calcium cyanamide (CaNCN).

43. Describe what is meant by the terms *silane* and *silanol*. What is their role in the preparation of silicones?

44. Describe and explain the similarities and differences between the reaction of a silicate with an acid and that of a carbonate with an acid.

45. Methane and sulfur vapor react to form carbon disulfide and hydrogen sulfide. Carbon disulfide reacts with $Cl_2(g)$ to form carbon tetrachloride and S_2Cl_2. Further reaction of carbon disulfide and S_2Cl_2 produces additional carbon tetrachloride and sulfur. Write a series of equations for the reactions described here.

46. In a manner similar to that outlined on page 962,
(a) write equations to represent the reaction of $(CH_3)_3SiCl$ with water, followed by the elimination of H_2O from the resulting silanol molecules.
(b) Does a silicone polymer form from part (a)?
(c) What would be the corresponding product obtained from CH_3SiCl_3?

47. Show that the empirical formula given for muscovite mica is consistent with the expected oxidation states of the elements present.

48. Show that the empirical formula given for crysotile asbestos is consistent with the expected oxidation states of the elements present.

49. Write plausible chemical equations for the **(a)** dissolving of lead(II) oxide in nitric acid; **(b)** heating of $SnCO_3(s)$; **(c)** reduction of lead(II) oxide by carbon; **(d)** reduction of $Fe^{3+}(aq)$ to $Fe^{2+}(aq)$ by $Sn^{2+}(aq)$; **(e)** formation of lead(II) sulfate during high-temperature roasting of lead(II) sulfide.

50. Write plausible chemical equations for preparing each compound from the indicated starting material: **(a)** $SnCl_2$ from SnO; **(b)** $SnCl_4$ from Sn; **(c)** $PbCrO_4$ from PbO_2. What reagents (acids, bases, salts) and equipment commonly available in the laboratory are needed for each reaction?

51. Lead(IV) oxide, PbO_2, is a good oxidizing agent. Use appropriate data from Appendix D to determine whether $PbO_2(s)$ in a solution with $[H_3O^+] = 1$ M is a sufficiently good oxidizing agent to carry the following oxidations to the point at which the concentration of the species being oxidized decreases to one-thousandth of its initial value.
(a) Fe^{2+}(1 M) to Fe^{3+}
(b) $SO_4{}^{2-}$(1 M) to $S_2O_8{}^{2-}$
(c) $Mn^{2+}(1 \times 10^{-4}$ M) to $MnO_4{}^-$

52. Tin(II) ion, Sn^{2+}, is a good reducing agent. Use data from Appendix D to determine whether Sn^{2+} is a sufficiently good reducing agent to reduce **(a)** I_2 to I^-; **(b)** Fe^{2+} to Fe(s); **(c)** Cu^{2+} to Cu(s); **(d)** $Fe^{3+}(aq)$ to $Fe^{2+}(aq)$ Assume that all reactants and products are in their standard states.

53. Would you expect the reaction of Pb(s) and $Cl_2(g)$ to yield $PbCl_2$ or $PbCl_4$?

54. Would you expect the reaction of Ge(s) and $F_2(g)$ to yield GeF_2, with germanium in the +2 oxidation state, or GeF_4, with germanium in the +4 oxidation state?

Integrative and Advanced Exercises

55. A chemical that should exist as a crystalline solid is seen to be a mixture of a solid and liquid in a container on a storeroom shelf. Give a plausible reason for that observation. Should the chemical be discarded or is it still useful for some purposes?

56. The following series of observations is made: (1) a small piece of dry ice $[CO_2(s)]$ is added to 0.005 M $Ca(OH)_2(aq)$. (2) Initially, a white precipitate forms. (3) After a short time the precipitate dissolves.
(a) Write chemical equations to explain these observations.
(b) If the 0.005 M $Ca(OH)_2(aq)$ is replaced by 0.005 M $CaCl_2(aq)$, would a precipitate form? Explain.
(c) If the 0.005 M $Ca(OH)_2(aq)$ is replaced by 0.010 M $Ca(OH)_2(aq)$, a precipitate forms but does not re-dissolve. Explain why.

57. The melting point of NaCl(s) is 801 °C, much higher than that of NaOH (322 °C). More energy is consumed to melt and maintain molten NaCl than NaOH. Yet the preferred commercial process for the production of sodium is electrolysis of NaCl(l) rather than NaOH(l). Give a reason or reasons for this discrepancy.

58. Although the triiodide ion, $I_3{}^-$, is known to exist in aqueous solutions, the ion is stable in only certain ionic solids. For example, CsI_3 is stable with respect to decomposition to CsI and I_2, but LiI_3 is not stable with respect to LiI and I_2. Draw a Lewis structure for the $I_3{}^-$ ion and suggest a reason why CsI_3 is stable with respect to decomposition to the iodide but LiI_3 is not.

59. At 298 K, the ΔG_f° values for $Li_2O(s)$ and $Li_2O_2(s)$ suggest that $Li_2O_2(s)$ is thermodynamically more stable than $Li_2O(s)$. At 1000 K, however, the situation is reversed. The Gibbs energies of formation, ΔG_f°, for $Li_2O(s)$ and $Li_2O_2(s)$ are -466.40 kJ mol^{-1} and -419.02 kJ mol^{-1}, respectively, at 1000 K. Calculate the equilibrium constant for the reaction below at

1000 K and the equilibrium partial pressure of $O_2(g)$ above a sample of $Li_2O_2(s)$ at 1000 K.

$$Li_2O_2(s) \longrightarrow Li_2O(s) + \frac{1}{2}O_2(g)$$

60. The chemical equation for the hydration of an alkali metal ion is $M^+(g) \rightarrow M^+(aq)$. The Gibbs energy change and the enthalpy change for the process are denoted by $\Delta G^\circ_{hydr.}$ and $\Delta H^\circ_{hydr.}$, respectively. $\Delta G^\circ_{hydr.}$ and $\Delta H^\circ_{hydr.}$ values are given below for the alkali metal ions.

M^+	Li^+	Na^+	K^+	Rb^+	Cs^+
$\Delta H^\circ_{hydr.}$	-522	-407	-324	-299	-274 kJ mol^{-1}
$\Delta G^\circ_{hydr.}$	-481	-375	-304	-281	-258 kJ mol^{-1}

Use the data above to calculate $\Delta S^\circ_{hydr.}$ values for the hydration process. Explain the trend in the $\Delta S^\circ_{hydr.}$ values.

61. Lithium superoxide, $LiO_2(s)$, has never been isolated. Use ideas from Chapter 12, together with data from this chapter and Appendix D, to estimate ΔH°_f for $LiO_2(s)$ and assess whether $LiO_2(s)$ is thermodynamically stable with respect to $Li_2O(s)$ and $O_2(g)$.

(a) Use the Kapustinskii equation, along with appropriate data below, to estimate the lattice energy, *U*, for $LiO_2(s)$. (See exercise 126 in Chapter 12.) The ionic radii for Li^+ and O_2^- are 73 pm and 144 pm, respectively.

(b) Use your result from part (a) in the Born–Fajans–Haber cycle to estimate ΔH°_f for $LiO_2(s)$. [*Hint:* For the process $O_2(g) + e^- \rightarrow O_2^-(g)$, $\Delta H^\circ = -43$ kJ mol^{-1}. See Table 21.2 and Appendix D for the other data that are required.]

(c) Use your result from part (b) to calculate the enthalpy change for the decomposition of $LiO_2(s)$ to $Li_2O(s)$ and $O_2(g)$. For $Li_2O(s)$, $\Delta H^\circ_f = -598.73$ kJ mol^{-1}.

(d) Use your result from part (c) to decide whether $LiO_2(s)$ is thermodynamically stable with respect to $Li_2O(s)$ and $O_2(g)$. Assume that entropy effects can be neglected.

62. When a 0.200 g sample of Mg is heated in air, 0.315 g of product is obtained. Assume that all the Mg appears in the product.

(a) If the product were pure MgO, what mass should have been obtained?

(b) Show that the 0.315 g product could be a mixture of MgO and Mg_3N_2.

(c) What is the mass percent of MgO in the $MgO-Mg_3N_2$ mixed product?

63. Comment on the feasibility of using a reaction similar to (21.4) to produce **(a)** lithium metal from LiCl; **(b)** cesium metal from CsCl, with Na(l) as the reducing agent in each case. [*Hint:* Consider data from Table 21.2.]

64. Concerning the thermite reaction,

(a) use data from Appendix D to calculate ΔH° at 298 K for the reaction.

$$2\ Al(s) + Fe_2O_3(s) \longrightarrow 2\ Fe(s) + Al_2O_3(s)$$

(b) Write an equation for the reaction when $MnO_2(s)$ is substituted for $Fe_2O_3(s)$, and calculate ΔH° for this reaction.

(c) Show that if MgO were substituted for Fe_2O_3, the reaction would be *endothermic*.

65. Use data from Appendix D (Table D-2) to calculate a value of E° for the reduction of $Li^+(aq)$ to Li(s), and compare your result with the value listed in Table 21.2.

66. The electrolysis of 0.250 L of 0.220 M $MgCl_2$ is conducted until 104 mL of gas (a mixture of H_2 and water vapor) is collected at 23 °C and 748 mmHg. Will $Mg(OH)_2(s)$ precipitate if electrolysis is carried to this point? (Use 21 mmHg as the vapor pressure of the solution.)

67. A particular water sample contains 56.9 ppm SO_4^{2-} and 176 ppm HCO_3^-, with Ca^{2+} as the only cation.

(a) How many parts per million of Ca^{2+} does the water contain?

(b) How many grams of CaO are consumed in removing HCO_3^-, from 602 kg of the water?

(c) Show that the Ca^{2+} remaining in the water after the treatment described in part (b) can be removed by adding Na_2CO_3.

(d) How many grams of Na_2CO_3 are required for the precipitation referred to in part (c)?

68. An aluminum production cell of the type pictured in Figure 21-24 operates at a current of 1.00×10^5 A and a voltage of 4.5 V. The cell is 38% efficient in using electrical energy to produce chemical change. (The rest of the electrical energy is dissipated as thermal energy in the cell.)

(a) What mass of Al can be produced by this cell in 8.00 h?

(b) If the electrical energy required to power this cell is produced by burning coal (85% C; heat of combustion of C = 32.8 kJ/g) in a power plant with 35% efficiency, what mass of coal must be burned to produce the mass of Al determined in part (a)?

69. Use data from Appendix D (Table D-2) to estimate the minimum voltage required to electrolyze Al_2O_3 in the Hall-Héroult process, reaction (21.25). Use $\Delta G^\circ_f[Al_2O_3(l)] = -1520$ kJ mol^{-1}. Show that the oxidation of the graphite anode to $CO_2(g)$ permits the electrolysis to occur at a lower voltage than if the electrolysis reaction were $Al_2O_3(l) \longrightarrow 2\ Al(l) + \frac{3}{2}O_2(g)$.

70. At 20 °C, a saturated aqueous solution of $Pb(NO_3)_2$ maintains a relative humidity of 97%. What must be the composition of this solution, expressed as g $Pb(NO_3)_2/100.0$ g H_2O?

71. Use information from this chapter and elsewhere in this text to explain why the compounds $PbBr_4$ and PbI_4 do *not* exist.

72. The reaction of borax, calcium fluoride, and concentrated sulfuric acid yields sodium hydrogen sulfate, calcium sulfate, water, and boron trifluoride as products. Write a balanced equation for this reaction.

73. The dissolution of $MgCO_3(s)$ in $NH_4^+(aq)$ can be represented as

$$MgCO_3(s) + NH_4^+(aq) \rightleftharpoons Mg^{2+}(aq) + HCO_3^-(aq) + NH_3(aq)$$

Calculate the molar solubility of $MgCO_3$ in each of the following solutions: **(a)** 1.00 M $NH_4Cl(aq)$; **(b)** a buffer that is 1.00 M NH_3 and 1.00 M NH_4Cl; **(c)** a buffer that is 0.100 M NH_3 and 1.00 M NH_4Cl.

74. Show that, in principle, $Na_2CO_3(aq)$ can be converted almost completely to NaOH(aq) by the reaction

$$Ca(OH)_2(s) + Na_2CO_3(aq) \longrightarrow CaCO_3(s) + 2\,NaOH(aq)$$

75. Assume that the packing of spherical atoms in crystalline metals is the same for Li, Na, and K, and explain why Na has a higher density than *both* Li and K. [*Hint:* Use data from Table 21.2.]

76. Would you expect the lattice energy of MgS(s) to be less than, greater than, or about the same as that of MgO(s)? Use appropriate data from various locations in this text to obtain the values of the two lattice energies. Use a value of 456 kJ for the process $S^-(g) + e^- \longrightarrow S^{2-}(g)$.

77. There has been some interest in the alkali metal fullerides, $M_nC_{60}(s)$, because at low temperatures, some of these compounds become superconducting. The alkali metal fullerides are ionic crystals comprising M^+ ions and ${C_{60}}^{n-}$ ions. The value of n can be deduced from the crystal structure. If M_nC_{60} consists of a cubic closest packed array of fulleride ions, with M^+ ions occupying all the octahedral and tetrahedral holes in the fulleride lattice, then what is the value of n and what is the empirical formula of the fulleride?

Feature Problems

78. In Chapter 20, we examined the relationship of electrode potentials to thermodynamic data. In fact, electrode potentials can be calculated from tabulated thermodynamic data (many of which, in turn, were established from electrochemical measurements). To demonstrate this fact and to pursue further the discussion in Are You Wondering 21-1, combine the three steps for the oxidation of Li(s) with a corresponding set of three steps for the reduction of H^+ (1 M) to $H_2(g)$. Obtain $\Delta H°$ for the overall reaction.

(a) Neglect entropy changes that occur (that is, assume that $\Delta G° \approx \Delta H°$), and estimate the value of $E°_{Li^+/Li}$.

(b) Combine the calculated $\Delta H°$ value with a value of $\Delta S°$ to obtain another estimate of $E°_{Li^+/Li}$. [*Hint:* Hydration energies for $Li^+(g)$ and $H^+(g)$ to form 1 M solutions are –522 and –1094 kJ/mol, respectively. Also, use data from various locations in this text.]

79. Mono Lake in eastern California is a rather unusual salt lake. The lake has no outlets; water leaves only by evaporation. The rate of evaporation is great enough that the lake level would be lowered by three meters per year if not for fresh water entering through underwater springs and streams originating in the nearby Sierra Nevada mountains. The principal salts in the lake are the chlorides, bicarbonates, and sulfates of sodium. An approximate "recipe" for simulating the lake water is to dissolve 18 tablespoons of sodium bicarbonate, 10 tablespoons of sodium chloride, and 8 teaspoons of Epsom salt (magnesium sulfate heptahydrate) in 4.5 liters of water (although the lake water actually contains only trace amounts of magnesium ion). Assume that 1 tablespoon of any of the salts weighs about 10 g. (1 tablespoon = 3 teaspoons.)

(a) Expressed as grams of salt per liter, what is the approximate salinity of Mono Lake? How does this salinity compare with seawater, which is approximately 0.438 M NaCl and 0.0512 M $MgCl_2$?

(b) Estimate an approximate pH for Mono Lake water. How does your estimate compare with the observed pH of about 9.8? Actually, the recipe for the lake water also calls for a pinch of borax. How would its presence affect the pH? [Borax is a sodium salt, $Na_2B_4O_7 \cdot 10\,H_2O$, related to the weak monoprotic boric acid ($pK_a = 9.25$).]

(c) Mono Lake has some unusual limestone formations called *tufa*. They form at the site of underwater springs and grow only underwater, although some project above water, having formed at a time when the lake level was higher. Explain how the tufa form. [*Hint*: What chemical reaction(s) is(are) involved?]

Self-Assessment Exercises

80. In your own words, define the following terms: **(a)** dimer; **(b)** adduct; **(c)** calcination; **(d)** amphoteric oxide; **(e)** three-center two-electron bond.

81. Briefly describe each of the following ideas, methods, or phenomena: **(a)** diagonal relationship; **(b)** preparation of deionized water by ion exchange; **(c)** thermite reaction; **(d)** inert pair effect.

82. Explain the important distinction between each pair of terms: **(a)** peroxide and superoxide; **(b)** quicklime and slaked lime; **(c)** soap and detergent; **(d)** silicate and silicone; **(e)** sol and gel.

83. Of the following oxides, the one with the highest melting point is **(a)** Li_2O; **(b)** BaO; **(c)** MgO; **(d)** SiO_2.

84. The best oxidizing agent of the following oxides is **(a)** Li_2O; **(b)** MgO; **(c)** Al_2O_3; **(d)** CO_2; **(e)** SnO_2; **(f)** PbO_2.

85. Predict the products of the following reactions:

(a) $BCl_3(g) + NH_3(g)$

(b) $K(s) + O_2(g)$

(c) $Li(s) + O_2(g)$
(d) $BaO_2(s) + H_2O(l)$

86. A chemist knows that aluminum is more reactive toward oxygen than is iron, but many people believe the opposite. What evidence was provided in this chapter that demonstrates that aluminum is a much stronger reducing agent (and is much more reactive) than iron? If aluminum is so reactive, then why is it that aluminum can be used for making products—pots, pans, aluminum foil, siding for houses—that last so long?

87. Listed are several pairs of substances. For some pairs, one or both members of the pair react individually with water to produce a gas. For others, neither member of the pair reacts with water. The pair for which *each* member reacts with water and yields the *same* gaseous product is **(a)** Al(s) and Ba(s); **(b)** Ca(s) and $CaH_2(s)$; **(c)** Na(s) and $Na_2O_2(s)$; **(d)** K(s) and $KO_2(s)$; **(e)** $NaHCO_3(s)$ and HCl(aq).

88. Complete and balance the following. Write the simplest equation possible. If no reaction occurs, so state.

(a) $Li_2CO_3(s) \xrightarrow{\Delta}$
(b) $CaCO_3(s) + HCl(aq) \longrightarrow$
(c) $Al(s) + NaOH(aq) \longrightarrow$
(d) $BaO(s) + H_2O(l) \longrightarrow$
(e) $Na_2O_2(s) + CO_2(g) \longrightarrow$

89. Assuming that water, common reagents (acids, bases, salts), and simple laboratory equipment are available, give a practical method to prepare **(a)** $MgCl_2$ from $MgCO_3(s)$; **(b)** $NaAl(OH)_4$ from Na(s) and Al(s); and **(c)** Na_2SO_4 from NaCl(s).

90. Write the simplest chemical equation to represent the reaction of **(a)** $K_2CO_3(aq)$ and $Ba(OH)_2(aq)$; **(b)** $Mg(HCO_3)_2(aq)$ on heating; **(c)** tin(II) oxide when heated with carbon; **(d)** $CaF_2(s)$ and H_2SO_4(concd aq); **(e)** $NaHCO_3(s)$ and HCl(aq); **(f)** $PbO_2(s)$ and HBr(aq); and **(g)** the reduction of SiF_4 to pure Si, by using Na as the reducing agent.

91. Write an equation to represent the reaction of gypsum, $CaSO_4 \cdot 2\,H_2O$, with ammonium carbonate to produce ammonium sulfate (a fertilizer), calcium carbonate, and water.

92. Write chemical equations to represent the most probable outcome in each of the following. If no reaction is likely to occur, so state.

(a) $B(OH)_3 \xrightarrow{\Delta}$
(b) $Al_2O_3(s) \xrightarrow{\Delta}$
(c) $CaSO_4 \cdot 2\,H_2O(s) \xrightarrow{\Delta}$

93. A chemical dictionary gives the following descriptions of the production of some compounds. Write plausible chemical equations based on these descriptions.

(a) lead(II) carbonate: adding a solution of sodium bicarbonate to a solution of lead nitrate
(b) lithium carbonate: reaction of lithium oxide with ammonium carbonate solution
(c) hydrogen peroxide: by the action of dilute sulfuric acid on barium peroxide
(d) lead(IV) oxide: action of an alkaline solution of calcium hypochlorite on lead(II) oxide

94. Name the chemical compound(s) you would expect to be the *primary* constituent(s) of **(a)** stalactites; **(b)** gypsum; **(c)** "barium milkshake"; **(d)** blue sapphires.

95. How many cubic meters of $CO_2(g)$ at 102 kPa and 288 K are produced in the calcination of 5.00×10^3 kg of the mineral dolomite, $CaMg(CO_3)_2$?

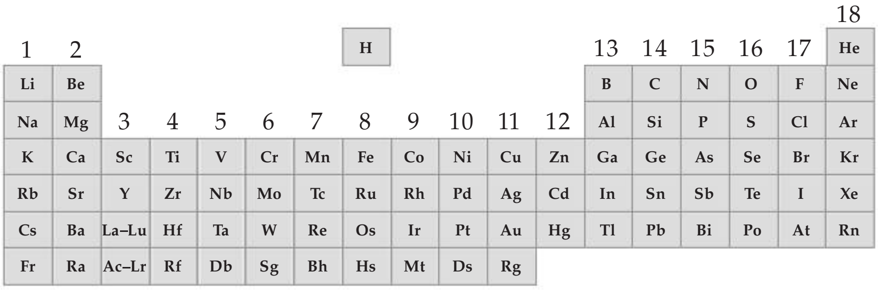
Bromine, a nonmetal, is a reactant in the synthesis of flame retardants for use in plastics.

In this chapter we continue our discussion of the *p*-block elements. We will progress from right to left through the periodic table and begin with a survey of the noble gases (group 18), the atoms of which have filled valence shells. The filled valence shells of the group 18 atoms makes these gases special—or noble—in the sense that they are particularly unreactive, though not totally so, as we will soon see. We next examine the halogens (group 17) and then proceed to groups 16 and 15. In each successive group, proceeding from right to left, the number of electrons in the *p*-subshell of an atom decreases by one and as a consequence, the tendency to form more than one covalent bond increases. Finally, in this chapter we will consider hydrogen. Hydrogen has unique chemistry and is not easily placed in any group of the periodic table. To emphasize the uniqueness of hydrogen, some chemists prefer to use a version of the periodic table, such as that shown at the top of page 977, in which hydrogen is separated from the rest of the table.



1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18

▲ **An alternative version of the periodic table**
This version differs slightly from the one given on the inside front cover in that hydrogen is separated from the rest of the elements. Also, it does not explicitly show the lanthanides (La–Lr) or the actinides (Ac–Lr). Some chemists prefer to put H on its own because of the uniqueness of hydrogen and the difficulty in placing it in a specific group.

Among the fundamental concepts emphasized in this chapter are atomic, physical, and thermodynamic properties; bonding and structure; acid–base chemistry; and oxidation states, redox reactions, and electrochemistry.

22-1 Periodic Trends in Bonding

To uncover trends in bonding it is instructive to consider a series of binary compounds with a common element, such as fluorine or oxygen. First, we will consider the fluorides of the second- and third-row elements, with the general formula AF_n.

As we progress from left to right through the periodic table, the metallic character of the elements decreases (see Figure 9-12) and the bonding in the fluorides, AF_n, changes from ionic bonding to covalent bonding. In Table 22.1 we show the formulas, bonding types, and phases at room temperature of the binary fluorides of the second- and third-period elements. In the fluorides, we observe a transition from ionic bonding to covalent bonding as we move left to right across a period. Notice that BeF_2 and AlF_3 are network covalent solids. In a network covalent solid, each atom is bonded to one or more atoms by covalent bonds to form a giant molecule. Most of the fluorides are molecular compounds, with covalent bonds holding together the atoms of the molecule and with intermolecular forces, such as dipole-dipole or London dispersion forces, contributing to the attraction among individual molecules. In Table 22.1, such compounds are called *molecular* covalent compounds to distinguish them from the *network* covalent compounds.

The diagonal relationship between beryllium and aluminum, discussed previously in Chapter 21, is evident in Table 22.1. Both beryllium (in group 2) and aluminum (in group 13) form network covalent solids with fluorine.

TABLE 22.1 Binary Fluorides, AF_n, of the Second- and Third-Row Elements[a]

Group	1	2	13	14	15	16	17
Formula	LiF(s)	BeF_2(s)	BF_3(g)	CF_4(g)	NF_3(g)	OF_2(g)	F_2(g)
Bonding	Ionic	Network Covalent	Molecular Covalent	Molecular Covalent	Molecular Covalent	Molecular Covalent	Molecular Covalent
Formula	NaF(s)	MgF_2(s)	AlF_3(s)	SiF_4(g)	PF_5(g)	SF_6(g)	ClF_5(g)
Bonding	Ionic	Ionic	Network Covalent	Molecular Covalent	Molecular Covalent	Molecular Covalent	Molecular Covalent

[a] For each element, the substance shown is the one that has the greatest number of fluorine atoms per atom of A. The phase indicated is the phase at 25 °C.

The phase of the compound at room temperature is a reflection of the type of bonding in the compound. Ionic solids melt at very high temperatures because the melting process requires the breaking of strong ionic bonds in the crystal lattice. Similarly, network covalent solids have very high melting temperatures because covalent bonds have to be broken in the melting process. In the molecular covalent substances, only weak intermolecular forces contribute to the attraction between the molecules; thus, these species are gases at room temperature.

For the fluorides of the second-row elements, the formulas are relatively easy to predict and explain. The number of fluorine atoms per formula unit is equal to the number of valence electrons an atom must gain or lose to attain a noble gas configuration. For the fluorides of groups 14 to 16, the number of fluorine atoms per formula unit is equal to the number of valence electrons required to fill the valence shell of carbon, nitrogen, or oxygen. For example, a carbon atom with configuration $[\mathrm{He}]2s^2 2p^2$ requires four electrons to complete its valence shell, and because each fluorine atom has only one unpaired valence electron, carbon and fluorine combine in the ratio 1 : 4 to give CF_4. For the fluorides of groups 1, 2, and 13, however, the number of fluorine atoms per formula unit is equal to the number of valence electrons a lithium, beryllium, or boron atom would have to lose to attain a $2s^2$ configuration. For example, lithium must lose only one electron to attain a $2s^2$ configuration, and because a fluorine atom needs only one electron to complete its valence shell, lithium and fluorine combine 1 : 1 to give LiF. The formulas of BeF_2 and BF_3 are related to the number of valence electrons a Be or B atom must lose to attain a noble gas (He) configuration, even though neither Be nor B actually loses any of its valence electrons—both Be and B form covalent bonds with fluorine.

For the fluorides of the third-row elements, the number of fluorine atoms per formula unit is more difficult to predict. For the fluorides shown in Table 22.1, the oxidation state of the element bonded to fluorine increases in steps of 1 as we move left to right across the third period, except in going from sulfur to chlorine. Chlorine has an oxidation state of +7 in some of its compounds, as is the case in $HClO_4$ and Cl_2O_7, but it does not form the heptafluoride (ClF_7) with Cl in the +7 oxidation state. Presumably, this occurs because the chlorine atom is not large enough to interact simultaneously with seven fluorine atoms. This argument is supported by the observation that iodine, also in group 17 but a much larger atom, forms the heptafluoride IF_7.

Similar trends in bonding are observed for the oxides of the second- and third-row elements, as can be seen in Table 22.2. Also shown in Table 22.2 are the acid–base properties of the oxides. Half of these oxides are acidic, only three are basic (Li_2O, Na_2O, and MgO), and two are amphoteric (BeO and Al_2O_3).

[a] Some elements form more than one compound with oxygen. The substance shown is the one having the element in its most highly oxidized form. The phase indicated is the phase at 25 °C.

[b] OF_2 is included in the table even though OF_2 is not an oxide. It is a fluoride with oxygen having an oxidation state of +2.

[c] In the liquid phase, SO_3 consists of a trimer of SO_3 molecules, as shown in Figure 22-14.

The diagonal relationships between Be and Al and between B and Si are evident. Both Be and Al form amphoteric oxides and both B and Si form network covalent oxides that are acidic. A transition occurs from basic oxides to acidic oxides as we proceed from metallic to nonmetallic elements, or, stated another way, as we proceed from the least electronegative elements to the most electronegative elements. For example, sodium oxide reacts with water to give sodium hydroxide, while sulfur trioxide reacts with water to give sulfuric acid, as shown below:

$$\mathrm{Na_2O(s)} + \mathrm{H_2O(l)} \longrightarrow 2\,\mathrm{NaOH(aq)}$$
$$\mathrm{SO_3(l)} + \mathrm{H_2O(l)} \longrightarrow \mathrm{H_2SO_4(l)}$$

With the exception of OF_2, the oxides of the elements in groups 14 to 17 react with water to give oxoacids, as shown above for SO_3. OF_2 reacts with water, but the reaction gives a binary acid (HF) and not the oxoacid (HOF). That the acid–base behavior of OF_2 is different from the oxides of other *p*-block elements comes as no surprise; OF_2 is not an oxide. It is a fluoride with oxygen having an oxidation state of +2.

The oxides of Be and Al, as we saw in Chapter 21, are amphoteric because these oxides react with both acids and bases. Beryllium oxide, BeO, reacts as follows:

$$\mathrm{BeO(s)} + 2\,\mathrm{H_3O^+(aq)} + \mathrm{H_2O(l)} \longrightarrow [\mathrm{Be(OH_2)_4}]^{2+}\mathrm{(aq)}$$
$$\mathrm{BeO(s)} + 2\,\mathrm{OH^-(aq)} + \mathrm{H_2O(l)} \longrightarrow [\mathrm{Be(OH)_4}]^{2-}\mathrm{(aq)}$$

We should not forget the point made in Chapter 21: *as we move down a group, the metallic character of an element increases*. This has an important consequence for the oxides of the group 14 elements. The oxides of C and Si are acidic, the oxide of Sn is amphoteric, and the oxide of Pb is basic. The amphoterism of SnO is evident in the reactions of SnO with HCl(aq) and NaOH(aq), which are given below:

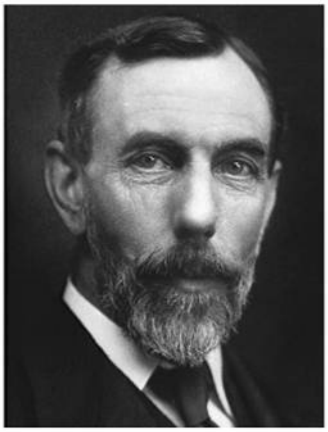
$$\mathrm{SnO(s)} + 2\,\mathrm{HCl(aq)} \longrightarrow \mathrm{SnCl_2(aq)} + \mathrm{H_2O(l)}$$
$$\mathrm{SnO(s)} + \mathrm{NaOH(aq)} + \mathrm{H_2O(l)} \longrightarrow \mathrm{Na^+(aq)} + [\mathrm{Sn(OH)_3}]^-\mathrm{(aq)}$$

As we discuss the chemistry of the elements of groups 15 through 18, we will see these trends repeated many times. Explanations of these trends are based on differences in electronegativities and differences in the sizes of the atoms involved.

22-2 Group 18: The Noble Gases

In 1785, Henry Cavendish, the discoverer of hydrogen, passed electric discharges through air to form oxides of nitrogen. (A similar process occurs during lightning storms.) He then dissolved these oxides in water to form nitric acid. Even by using excess oxygen, Cavendish was unable to get all the air to react. He suggested that air contained an unreactive gas making up "not more than 1/120 of the whole." John Rayleigh and William Ramsay isolated this gas one century later (1894) and named it argon. The name is derived from the Greek *argos*, "lazy one," meaning "inert." Its *inability* to form chemical compounds with any of the other elements—its chemical inertness—was found to be argon's most notable feature. Because argon resembled no other known element, Ramsay placed it in a separate group of the periodic table and reasoned that there should be other members of this group.

Ramsay then began a systematic search for other inert gases. In 1895, he extracted helium from a uranium mineral. A few years later, by very carefully distilling liquid argon, he was able to extract three additional inert gases: neon, krypton, and xenon. The final member of the group of inert gases, a radioactive element called radon, was discovered in 1900. In 1962, compounds of Xe were first prepared, and so the inert gases proved to be not completely



▲ **William Ramsay (1852–1916)** This distinguished Scottish chemist received the 1904 Nobel Prize in Chemistry for his work on the noble gases.

inert after all. Since that time, this group of gases has been called the **noble gases**. They are found in group 18 of the periodic table shown on the inside front cover.

CLUB

▲ Gaseous atoms in the region of an electric discharge emit light. The light emitted by neon atoms is red-orange in color. Neon lights of other colors use other noble gases or mixtures of gases.

Occurrence

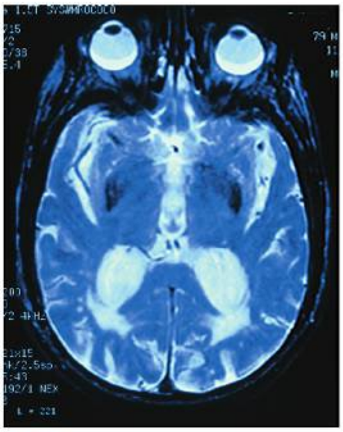
Air contains 0.000524% He, 0.001818% Ne, and 0.934% Ar, by volume. The proportion of Kr is about 1 ppm by volume, and that of Xe, 0.05 ppm. The atmosphere is the only source of all these gases except helium. The main source of helium is certain natural gas wells in the western United States that produce natural gas containing up to 8% He by volume. It is cost-effective to extract helium from natural gas even down to levels of about 0.3%. Underground helium accumulates as a result of α-particle emission by radioactive elements in Earth's crust. Whereas the abundance of He on Earth is very limited, it is second only to hydrogen in the universe as a whole.

Most of the noble gases have escaped from the atmosphere since Earth was formed, but Ar is an exception. The concentration of Ar remains quite high because it is constantly being formed by the radioactive decay of potassium-40, a reasonably abundant, naturally occurring radioactive isotope. Helium is also constantly produced through α-particle emissions by radioactive decay processes, but because the molar mass of He is 10 times less than that of Ar, it escapes from the atmosphere into outer space at a higher rate.

Properties and Uses

The lighter noble gases are commercially important, in part because they are chemically inert. The efficiency and life of electric lightbulbs are increased when they are filled with an argon–nitrogen mixture. Electric discharge through neon-filled glass or plastic tubes produces a distinctive red light (neon light). Krypton and xenon are used in lasers and in flashlamps in photography. Helium has several unique physical properties. Best known of these is that it exists as a liquid at temperatures approaching 0 K. All other substances freeze to solids at temperatures well above 0 K. (The melting point of solid H_2, for example, is 14 K.) Because of their inertness, both He and Ar are used to protect materials from nitrogen and oxygen in the air; consequently, He and Ar are used for this purpose in certain types of welding, in metallurgical processes, and in the preparation of ultrapure Si and Ge and other semiconductor materials. Helium mixed with oxygen is used as a breathing mixture for deep-sea diving and in certain medical applications. Large quantities of liquid helium are used to maintain low temperatures (cryogenics). Some metals essentially lose their electrical resistivity at liquid He temperatures and become *superconductors*. Powerful magnets can be made by immersing the coils of electromagnets in liquid helium. Such magnets are used in particle accelerators and in nuclear fusion research. More familiar uses of large electromagnets cooled by liquid helium are nuclear magnetic resonance (NMR) instruments in research laboratories and magnetic resonance imaging (MRI) devices in hospitals. Helium is also used to fill lighter-than-air airships (blimps). Some of these applications are highlighted in the margin.

▶ As we learned in Chapter 13 (page 572), using helium–oxygen mixtures instead of air for deep-sea diving prevents the condition known as the *bends* because helium is more rapidly and smoothly expelled from the blood than is nitrogen.



▲ An MRI image of a head.

Xenon Compounds

In this section, we focus exclusively on compounds of xenon because most of the known noble gas compounds contain xenon. A few compounds of krypton, such as KrF_2, have been synthesized and well characterized. Radon is expected to form compounds even more readily than xenon, because of its lower ionization energy, but the chemistry of radon is complicated by its radioactivity.

For a long time, the noble gases were thought to be chemically inert. This apparent inertness helped provide a theoretical framework for the Lewis theory of bonding. Subsequently it was found that compounds of xenon can be made fairly easily, and these compounds have added significantly to our knowledge of chemical bonding.

In the 1930s, Linus Pauling did theoretical calculations that suggested xenon should form oxide and fluoride compounds, but attempts to make them failed at that time. In 1962, Neil Bartlett and Derek H. Lohmann discovered that O_2 and PtF_6 would combine in a 1 : 1 mole ratio to form the compound O_2PtF_6. Properties of this compound suggest it to be ionic: $[O_2]^+[PtF_6]^-$. The energy required to extract an electron from O_2 is 1177 $kJ\ mol^{-1}$, almost identical to the first ionization energy of Xe, 1170 $kJ\ mol^{-1}$. The size of the Xe atom is also roughly the same as that of the dioxygen molecule. Thus, it was reasoned that the compound $XePtF_6$ might also exist. Bartlett and Lohmann were able to prepare a yellow crystalline solid with that composition.*

Soon thereafter, chemists around the world synthesized several additional noble gas compounds. In general, the conditions necessary to form noble gas compounds are as Pauling predicted. The formation of a noble gas compound requires:

- a readily ionizable (therefore, high atomic number) noble gas atom
- highly electronegative atoms (such as F or O) to bond to it

Xenon compounds have been synthesized that have Xe in four possible oxidation states, as summarized below:

	+ 2	**+ 4**	**+ 6**	**+ 8**
Examples:	XeF_2	XeF_4, $XeOF_2$	XeF_6, XeO_3	XeO_4, H_4XeO_6

Because it is difficult to oxidize Xe to these positive oxidation states, we would expect Xe compounds to be easily reduced, making them very strong oxidizing agents. For example, in aqueous acidic solution, XeF_2 is an excellent oxidizing agent, as indicated by the large $E°$ value for the following half-reaction:

$$XeF_2(aq) + 2\,H^+(aq) + 2\,e^- \longrightarrow Xe(g) + 2\,HF(aq) \qquad E° = +2.64\ V$$

The significance of this large $E°$ value is that XeF_2 is not very stable in aqueous solution. In aqueous solution, XeF_2 oxidizes the water, producing $O_2(g)$, as shown below:

$$\begin{array}{lrcl}
\textit{Reduction:} & 2\{XeF_2(aq) + 2\,H^+(aq) + 2\,e^- & \longrightarrow & Xe(g) + 2\,HF(aq)\} \\
\textit{Oxidation:} & 2\,H_2O(l) & \longrightarrow & 4\,H^+(aq) + O_2(g) + 4\,e^- \\
\hline
\textit{Overall:} & 2\,XeF_2(aq) + 2\,H_2O(l) & \longrightarrow & 2\,Xe(g) + 4\,HF(aq) + O_2(g)
\end{array}$$

$$\begin{aligned}
E°_{cell} &= E°(\text{reduction}) - E°(\text{oxidation}) \\
&= E°_{XeF_2/Xe} - E°_{O_2/H_2O} \\
&= 2.64\ V - (1.229\ V) = 1.41\ V
\end{aligned}$$

Xenon reacts directly only with F_2. Three different xenon fluorides can be produced by heating xenon and fluorine in nickel reaction vessels, but the product obtained depends on the experimental conditions, as summarized below:

$$\begin{aligned}
Xe(g) + F_2(g) &\xrightarrow[400\ °C,\ 1\ atm]{Xe\,:\,F_2\ =\ 2\,:\,1} XeF_2(s) \\
Xe(g) + 2\,F_2(g) &\xrightarrow[400\ °C,\ 6\ atm]{Xe\,:\,F_2\ =\ 1\,:\,5} XeF_4(s) \\
Xe(g) + 3\,F_2(g) &\xrightarrow[300\ °C,\ 50\ atm]{Xe\,:\,F_2\ =\ 1\,:\,20} XeF_6(s)
\end{aligned}$$

All three of these xenon fluorides are colorless, volatile solids. Notice that, for each synthesis, the $Xe : F_2$ mole ratio is significantly different from the

◀ In 2000, chemists at the University of Helsinki reported* they had made HArF molecules that were stable at very low temperatures (below 27 K). The report has generated much discussion—and debate—among chemists about the existence of argon compounds and the possibilities for synthesizing argon compounds that are stable at higher temperatures.

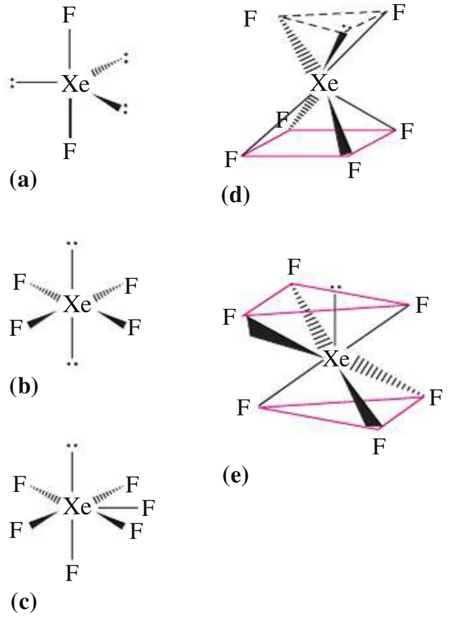
*L. Khriachtchev, M. Pettersson, N. Runenburg, J. Lundell, and M. Rasanen, *Nature*, **406**, 874 (2000).

▲ Because of the explosive nature of hydrogen, helium is now used in airships.

▲ Crystals of xenon tetrafluoride under magnification.

---

*It has since been established that this solid is more complicated than first thought. It has the formula $Xe(PtF_6)_n$, where n is between 1 and 2.



▶ FIGURE 22-1
Electron group geometries for XeF_2, XeF_4, and XeF_6
(a) XeF_2; **(b)** XeF_4; **(c)** XeF_6 pentagonal bipyramid; **(d)** XeF_6 capped trigonal prism; **(e)** XeF_6 capped octahedron.

stoichiometry of the reaction. For example, the synthesis of XeF_2 requires an excess of Xe, and the synthesis of XeF_6 requires large excess of F_2. A major difficulty in synthesizing the xenon fluorides is that all three products tend to form simultaneously. The most difficult to prepare in pure form, starting from Xe and F_2, is XeF_4. Xenon tetrafluoride can be prepared in high purity by the reaction below, which uses $O_2F_2(g)$ instead of $F_2(g)$:

$$Xe(g) + 2\,O_2F_2(g) \longrightarrow XeF_4(g) + 2\,O_2(g)$$

The shapes of the XeF_2, XeF_4, and XeF_6 molecules are shown in Figure 22-1. The XeF_2 and XeF_4 molecules have shapes that are easily understood in terms of VSEPR theory, but the shape of the XeF_6 molecule is a little more difficult to interpret. In the XeF_6 molecule, the xenon atom is surrounded by seven electron pairs, and three possible arrangements of these pairs are shown in Figure 22-1. These are pentagonal bipyramid, capped trigonal prism, and capped octahedron. These structures are expected to have nearly the same energy and the preferred arrangement depends strongly on the exact conditions. In the gas phase, the XeF_6 molecule has a capped octahedral structure (Figure 22-1e). In this structure, the six fluorine atoms form a distorted octahedron, and the lone pair on xenon is directed toward the center of one of the triangular faces. In the solid phase, XeF_6 exists as XeF_5^+, which is square pyramidal, and F^-, with the F^- ions forming bridges between XeF_5^+ ions.

To conform to the shapes indicated by VSEPR theory (or experiment, when the structure is known), bonding theory based on hybridization of orbitals requires the hybrid orbitals sp^3d for XeF_2, sp^3d^2 for XeF_4, and sp^3d^3 for XeF_6. However, in light of the observed bond lengths and bond energies in these fluorides and the high energy (estimated to be 1000 kJ mol^{-1}) required to promote an electron from a $5p$ to a $5d$ orbital, there is doubt as to whether d orbitals are involved in the bond formation. A molecular orbital description can be constructed that does not involve the participation of the xenon $5d$ orbitals, but in its simplest form this description cannot explain the nonoctahedral shape of XF_6. The situation described here reinforces the caveat that approximate theories of chemical bonding must be viewed critically.

▶ Actually, the XeF_6 molecule does possess a small dipole moment (about 0.03 debye). Compare this value with that for H_2O (1.84 debye) and HCl (1.03 debye).

Some properties of XeF_2, XeF_4, and XeF_6 are listed in Table 22.3. Because of their molecular structures, the XeF_2, XeF_4, and XeF_6 molecules are all nonpolar, and thus we expect that in each of these fluorides, the molecules interact with each other primarily through London dispersion forces. However, the melting points of these fluorides decrease as the molecular size increases,

TABLE 22.3 Some Properties[a] of XeF_2, XeF_4, and XeF_6

	XeF_2	XeF_4	XeF_6

[a] The ΔH°_f and ΔG°_f values are for 25 °C. The bond energies and bond lengths are average values.

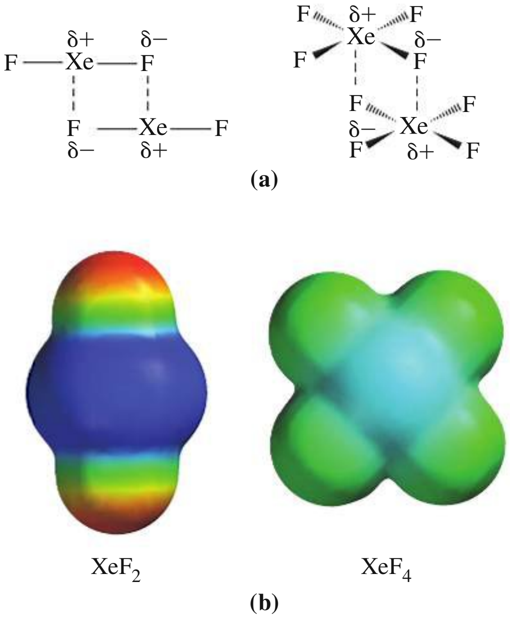
contrary to what we would expect if only London dispersion forces contributed to the attraction among molecules. The trend in melting points indicates that, in the xenon fluorides, there are additional interactions to consider. It has been suggested that, while the XeF_2 and XeF_4 molecules are nonpolar, the polar Xe—F bonds interact with each other in the manner suggested in Figure 22-2. The electrostatic potential maps shown in Figure 22-2 indicate that the Xe—F bonds in XeF_2 are more polar than they are in XeF_4; thus, the interactions of the bond dipoles are more important in $XeF_2(s)$ than in $XeF_4(s)$. The interactions of bond dipoles help to explain not only why the xenon fluorides have high melting points but also why the melting point of $XeF_2(s)$ is higher than that of $XeF_4(s)$.

Xenon forms other compounds, in which xenon is bonded to chlorine, oxygen, or nitrogen. Some of the simpler compounds include $XeCl_2$, XeO_3, XeO_4, $XeOF_2$, XeO_2F_2, and $XeOF_4$. However, many of these compounds must be prepared by using an indirect route. For example, XeO_3 can be made from XeF_6 by using the following reaction:

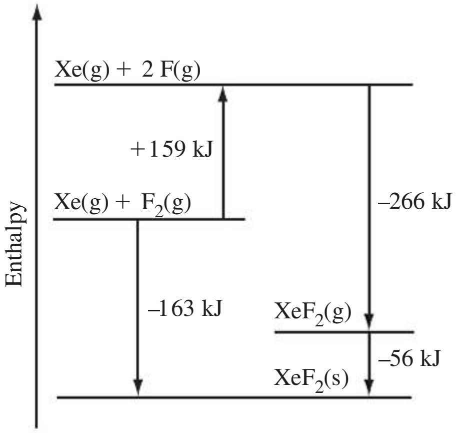
$$2\,XeF_6(s) + 3\,SiO_2(s) \longrightarrow 2\,XeO_3(s) + 3\,SiF_4(g)$$

Why is it that Xe(g) reacts directly with only $F_2(g)$? We can formulate an answer to this question by focusing on the following synthesis:

$$Xe(g) + F_2(g) \longrightarrow XeF_2(s)$$



◀ FIGURE 22-2
Interactions and electrostatic potential maps of XeF_2 and XeF_4
(a) Possible interactions between bond dipoles in XeF_2 and XeF_4 lead to relatively high melting points. **(b)** The electrostatic potential maps of XeF_2 and XeF_4 show that the Xe—F bond dipole is smaller in XeF_4 than it is in XeF_2.



▶ FIGURE 22-3
Enthalpy diagram for the formation of $XeF_2(s)$

▶ The low bond energy of the F—F bond is probably the result of repulsions involving the lone-pair electrons on the two F atoms. The repulsions are rather strong because the atomic radius of fluorine is small, and thus the six lone pairs are in close proximity. The weakness of the F—F bond contributes to the reactivity of F_2.

The enthalpy diagram shown in Figure 22-3 shows that the reaction of Xe(g) and $F_2(g)$ is exothermic (and energetically favorable) because the reaction involves the breaking of relatively weak F—F bonds (159 kJ mol^{-1}) and the formation of twice as many Xe—F bonds, each of which is almost as strong as an F—F bond. (For the synthesis of all the xenon fluorides, starting from Xe(g) and $F_2(g)$, the number of Xe—F bonds formed is always two times the number of F—F bonds broken.) None of the other noble gases react directly with fluorine because, for the other noble gases, the bond energy of the bond formed with F is not large enough to offset the energy requirements of breaking the F—F bond. For example, the bond energy of the Kr—F bond, in KrF_2, is only about 50 kJ mol^{-1}.

A similar analysis can also be used to help us to understand why xenon does not react directly with Cl_2 or O_2 to form chlorides or oxides. Such an analysis (see exercise 109) reveals that the Xe—Cl or Xe—O bond energy is much too small to offset the energy requirements for breaking the Cl—Cl or O═O bonds. (The bond energies of Cl_2 and O_2 are 243 kJ mol^{-1} and 498 kJ mol^{-1}, respectively.)

All the xenon fluorides react with water to form various products. For example, in aqueous solution, xenon hexafluoride is first hydrolyzed to xenon oxide tetrafluoride, $XeOF_4$, which is further hydrolyzed to xenon trioxide. The reactions are as follows:

$$XeF_6(s) + H_2O(l) \longrightarrow XeOF_4(aq) + 2\,HF(aq)$$
$$XeOF_4(l) + 2\,H_2O(l) \longrightarrow XeO_3(aq) + 4\,HF(aq)$$

The xenon fluorides are good fluorinating agents. Xenon difluoride is sometimes used in organic chemistry to add fluorine atoms to carbon compounds. An advantage of using XeF_2 for this purpose is that the by-product, Xe(g), is easily separated from the desired product. For example, XeF_2 can be used to add F atoms to either side of a carbon–carbon double bond, as shown below:

$$XeF_2(s) + CH_2{=}CH_2(g) \longrightarrow CH_2FCH_2F(g) + Xe(g)$$

The xenon fluorides are also strong oxidizing agents and can be used to oxidize fluorides of other elements. In the reaction below, XeF_4 is used to oxidize SF_4 to SF_6. In the reaction below, the oxidation state of sulfur changes from +4 to +6.

$$XeF_4(s) + 2\,SF_4(g) \longrightarrow 2\,SF_6(g) + Xe(g)$$

22-1 CONCEPT ASSESSMENT

Which is likely to be the more stable, XeF_2 or $XeCl_2$? Explain.

22-3 Group 17: The Halogens

The word *halogen* was introduced in 1811 to describe the ability of chlorine to form ionic compounds with metals. The name is based on the Greek words *halos* and *gen* meaning "salt former." The name was later extended to include fluorine, bromine, and iodine as well. Mendeleev placed the halogens in Group VII of his periodic table (page 362), which is now group 17 in the IUPAC table (page 51). Current interest in the halogens extends far beyond their ability to form metallic salts.

Properties

The **halogens** exist as diatomic molecules, symbolized by X_2, where X is a generic symbol for a halogen atom. That these elements occur as nonpolar diatomic molecules accounts for their relatively low melting and boiling points (Table 22.4). As expected, melting and boiling points increase as we move down the group from the smallest and lightest member of the group, fluorine, to the largest and heaviest, iodine. Conversely, chemical reactivity toward other elements and compounds increases in the *opposite* order, with fluorine being the most reactive and iodine the least reactive.

All the halogen atoms have large electron affinities (see Table 22.4 and Figure 9-11), and show a strong tendency to gain electrons. Consequently, the halogens are rather good oxidizing agents.

We have mentioned previously, and we will see again, that the elements of period 2 have distinctly different chemistry from the rest of the group because of their small sizes and inability to expand their valence shells. However, for the halogens, the differences between the second-row element (fluorine) and the members of the group are much less dramatic. Still, fluorine differs from the other halogens in a few ways. For example, a fluorine atom almost always forms just one covalent bond, whereas chlorine, bromine, and iodine atoms typically form more than one bond and as many as seven in some of their compounds. Although all the halogens are quite reactive and are found in nature only as compounds, fluorine is considerably more reactive than the other members of the group. It reacts directly with almost all the elements, except for oxygen, nitrogen, and the lighter noble gases, and forms compounds with even the most unreactive metals. It reacts with almost all materials, especially organic compounds, to produce fluorides. The reactivity of fluorine can be attributed to the weakness of the fluorine–fluorine bond in F_2, which arises, as mentioned earlier, because of the small size of the fluorine atom and the repulsion between the lone pairs on the fluorine atoms.

◀ In the perhalic acids, HXO_4, where X = Cl, Br, or I, the halogen atom forms seven bonds, four of which are sigma bonds and three of which are pi bonds. The Lewis structure for perchloric acid is shown below.

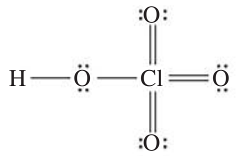


TABLE 22.4 Group 17 Elements: The Halogens

	Fluorine (F)	Chlorine (Cl)	Bromine (Br)	Iodine (I)
Physical form at room temperature	Pale yellow gas	Yellow-green gas	Dark red liquid	Violet-black solid
Melting point, °C	−220	−101	−7.2	114
Boiling point, °C	−188	−35	58.8	184
Electron configuration	$[He]2s^22p^5$	$[Ne]3s^23p^5$	$[Ar]3d^{10}4s^24p^5$	$[Kr]4d^{10}5s^25p^5$
Covalent radius, pm	71	99	114	133
Ionic (X^-) radius, pm	133	181	196	220
First ionization energy, kJ mol^{-1}	1681	1251	1140	1008
Electron affinity, kJ mol^{-1}	−328.0	−349.0	−324.6	−295.2
Electronegativity	4.0	3.0	2.8	2.5
Standard electrode potential, V ($X_2 + 2\,e^- \longrightarrow 2\,X^-$)	2.866	1.358	1.065	0.535

Fluorine differs from the other halogens in that it shows a much greater tendency to form ionic bonds with metals. Perhaps this is most evident when we look at the binary compounds formed by the halogens and the group 13 metals. The trifluorides of Al, Ga, and In are all ionic compounds, with very high lattice energies and very high melting points (>1000 °C) whereas the trichlorides are volatile compounds with much lower melting points (<600 °C). For $AlCl_3$, $GaCl_3$, and $InCl_3$, the bonding is largely covalent because chloride ions are much larger, and much more polarizable, than fluoride ions. Also, in the solid state, the chlorides of the group 13 metals contain dimers, M_2Cl_6, whereas the fluorides of the group 13 metals are all ionic lattices containing M^{3+} and F^- ions.

Another important difference between fluorine and the other halogens is that fluorine shows the ability to stabilize other elements in very high oxidation states. For example, fluorine reacts with sulfur to give SF_6, with sulfur in the +6 oxidation state, whereas chlorine reacts directly with molten sulfur to give S_2Cl_2, with sulfur in the +1 oxidation state.

KEEP IN MIND

that the halogens are extremely toxic.

Much of the reaction chemistry of the halogens involves oxidation–reduction reactions in aqueous solutions. For these reactions, standard electrode potentials are helpful for understanding the reactivity of the halogens. Among the properties of the halogens listed in Table 22.4 are potentials for the following half-reaction:

$$X_2 + 2\,e^- \longrightarrow 2\,X^-(aq)$$

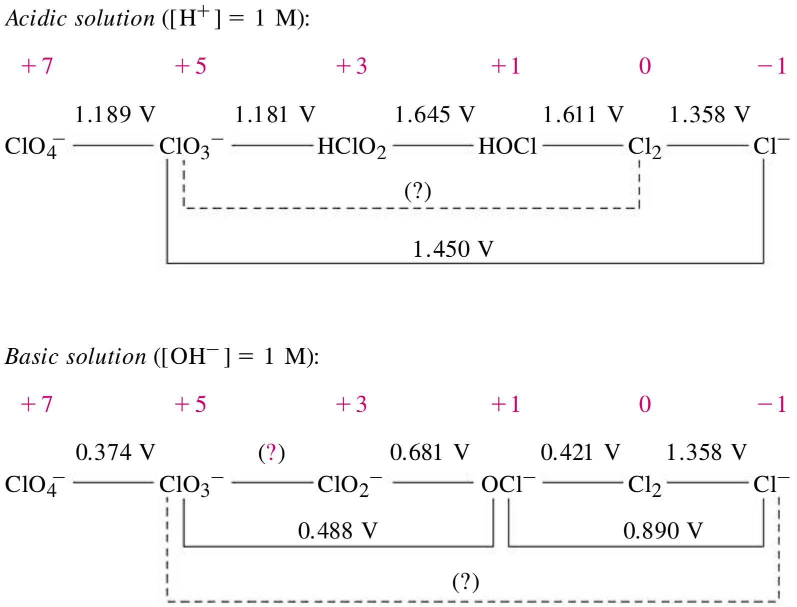
By this measure, fluorine is clearly the most reactive element of the group ($E° = 2.866$ V). Of all the elements, it shows the greatest tendency to gain electrons and is therefore the most easily reduced. Given this fact, it is not surprising that fluorine occurs naturally only in combination with other elements, and only as the fluoride ion, F^-. Although both chlorine and bromine can exist in a variety of positive oxidation states, they are found in their naturally occurring compounds only as chloride and bromide ions. There are, however, naturally occurring compounds in which iodine is in a positive oxidation state (such as the iodate ion, IO_3^-, in $NaIO_3$). In the case of iodine, the tendency for I_2 to be reduced to I^- is not particularly great ($E° = 0.535$ V).

Electrode Potential Diagrams

When we summarize the reduction tendencies of main-group metals and their ions, generally one or, at most, a few $E°$ values tell the story, and these values are easily incorporated into tables, such as that in Appendix D. However, the oxidation–reduction chemistry of some of the nonmetals is much richer and involves a larger number of relevant $E°$ values. In these cases, *electrode potential diagrams* are particularly useful for summarizing $E°$ data. Partial diagrams for chlorine are shown in Figure 22-4. In these diagrams, a number written above a line segment is the $E°$ value for reduction of the species on the left (higher oxidation state) to the one on the right (lower oxidation state). For a reduction involving species not joined by a line segment, we generally can calculate the appropriate value of $E°$ by the method illustrated in Example 22-1.

Production and Uses

Although the existence of fluorine had been known since early in the nineteenth century, no one was able to devise a chemical reaction to extract the free element from its compounds. Finally, in 1886, H. Moissan succeeded in preparing $F_2(g)$ by an electrolysis reaction. Moissan's method, which is still the only important commercial method for fluorine extraction, involves the



◀ FIGURE 22-4
Standard electrode potential diagrams for chlorine
The numbers in color are the oxidation states of the Cl atom. $E°$ values are written above the line segments for the reduction of the species on the left to the species on the right. All reactants and products are at unit activity. Because of the basic properties of the ClO_2^- and OCl^- ions, the weak acids $HClO_2$ and HOCl form in acidic solution.

EXAMPLE 22-1 Using an Electrode Potential Diagram to Determine $E°$ for a Half-Reaction

Determine $E°$ for the reduction of ClO_3^- to ClO_2^- in a basic solution, which is marked (?) in Figure 22-4.

Analyze

One way we can approach this problem is to identify a route that (1) converts ClO_3^- to ClO_2^- and (2) involves $E°$ values that are known. One such route involves converting ClO_3^- to OCl^-, for which $E° = 0.488$ V, and then converting OCl^- to ClO_2^-, for which $E° = -0.681$ V. (The $E°$ value for converting ClO_2^- to OCl^- is given as 0.681 V in Figure 22-4. For the reverse process, the $E°$ value has the opposite sign.) First, we should write balanced equations for $ClO_3^- \longrightarrow ClO^-$ and $ClO^- \longrightarrow ClO_2^-$, and then focus on how we combine the equations and corresponding $E°$ values to obtain the equation and $E°$ value for the desired conversion, $ClO^- \longrightarrow ClO_2^-$. Because the desired process is a reduction process (and not an oxidation–reduction process), we cannot simply add or subtract the $E°$ values to obtain $E°$ for the desired process (see page 875). We must first convert the given $E°$ values to $\Delta G°$ values, then combine those $\Delta G°$ values to obtain a $\Delta G°$ value for the desired process, and finally convert this $\Delta G°$ value back to a value of $E°$.

Solve

Figure 22-4 identifies only the oxidized and reduced forms of the chlorine species. By using the method described on page 174, we obtain the following balanced equations for the conversions of ClO_3^- to ClO^- and ClO^- to ClO_2^-:

$$\begin{array}{lll} ClO_3^-(aq) + 2\,H_2O(l) + 4\,e^- \longrightarrow OCl^-(aq) + 4\,OH^-(aq) & E° = 0.488\text{ V} & \Delta G° = -4F \times 0.488\text{ V} \\ OCl^-(aq) + 2\,OH^-(aq) \longrightarrow ClO_2^-(aq) + H_2O(l) + 2\,e^- & E° = -0.681\text{ V} & \Delta G° = -2F \times (-0.681\text{ V}) \end{array}$$

The overall equation for the desired process is the sum of the two equations above, and the corresponding $\Delta G°$ value is the sum of the $\Delta G°$ values.

$$ClO_3^-(aq) + H_2O(l) + 2\,e^- \longrightarrow ClO_2^-(aq) + 2\,OH^-(aq) \qquad \Delta G° = -F\,(4 \times 0.488 - 2 \times 0.681)\text{ V}$$

The $\Delta G°$ value for the process above is related to the $E°$ value by the expression $\Delta G° = -2FE°$, and so, the $E°$ value is calculated as follows.

$$E° = \frac{F[(2 \times 0.681) - (4 \times 0.488)]\text{ V}}{-2F} = 0.295\text{ V}$$

Assess

When adding half-equations to give another half-equation, we must add the $\Delta G°$ values, not the $E°$ values.

PRACTICE EXAMPLE A: Determine the missing $E°$ value for the dashed line that joins ClO_3^- and Cl^- in basic solutions in Figure 22-4.

PRACTICE EXAMPLE B: Determine the missing $E°$ value for the dashed line that joins ClO_3^- and Cl_2 in acidic solutions in Figure 22-4.

▶ The hydrogen difluoride ion in KHF_2 features a strong hydrogen bond, with a H^+ midway between two F^- ions: $[F—H—F]^-$.

electrolysis of HF dissolved in molten KHF_2. The chemical equation for the reaction is given below:

$$2\,HF \xrightarrow[KF \cdot 2\,HF(l)]{\text{electrolysis}} H_2(g) + F_2(g) \qquad \textbf{(22.1)}$$

The corresponding half-reactions are as follows:

$$\textit{Anode:} \qquad 2\,F^- \longrightarrow F_2(g) + 2\,\mathbf{e}^-$$
$$\textit{Cathode:} \qquad 2\,H^+ + 2\,\mathbf{e}^- \longrightarrow H_2(g)$$

Moissan also developed the electric furnace and was honored for both these achievements with the Nobel Prize in chemistry in 1906. Nevertheless, the challenge of producing fluorine by means of a chemical reaction remained. In 1986, one century after Moissan isolated fluorine, the chemical synthesis of fluorine was announced (see Exercise 14).

Although chlorine can be prepared by several chemical reactions, electrolysis of NaCl(aq) is the usual industrial method, as we have mentioned previously (see page 902). The electrolysis reaction is

$$2\,Cl^-(aq) + 2\,H_2O(l) \xrightarrow{\text{electrolysis}} 2\,OH^-(aq) + H_2(g) + Cl_2(g) \qquad \textbf{(22.2)}$$

▲ **Salt formation in the Dead Sea**
The high concentrations of salts in the Dead Sea make it a good source of bromine and a number of other chemicals.

Bromine can be extracted from seawater, where it occurs in concentrations of about 70 ppm as Br^-, or from inland brine sources. Seawater from the Dead Sea, highlighted in the margin, is a good source of bromine. The seawater or brine solution is adjusted to pH 3.5 and treated with $Cl_2(g)$, which oxidizes Br^- to Br_2 in the following displacement reaction:

$$Cl_2(g) + 2\,Br^-(aq) \longrightarrow Br_2(l) + 2\,Cl^-(aq) \qquad E^\circ_{cell} = 0.293\ V \qquad \textbf{(22.3)}$$

The liberated Br_2 is swept from seawater with a current of air or from brine with steam. A dilute bromine vapor forms and can be concentrated by various methods. The reaction above also forms the basis of a test for the presence of Br^-, as described in the margin.

▲ **A test for Br^-(aq)**
Reaction (22.3) is used as a qualitative test in the laboratory. The liberated Br_2 is extracted from the top aqueous layer into the bottom layer, here the organic solvent chloroform, $CHCl_3$.

Certain marine plants, such as seaweed, absorb and concentrate I^- selectively in the presence of Cl^- and Br^-. Iodine is obtained in small quantities from such plants. In the United States, I_2 is obtained from inland brines by a process similar to that for the production of Br_2. Another abundant natural source of iodine is $NaIO_3$, found in large deposits in Chile. Because the oxidation state of iodine must be reduced from +5 in IO_3^- to 0 in I_2, the conversion of IO_3^- to I_2 requires the use of a reducing agent. Aqueous sodium hydrogen sulfite (sodium bisulfite) is used as the reducing agent in the first part of a two-step procedure, followed by the reaction of I^- with additional IO_3^- to produce I_2. The net ionic equations for the reactions are given below:

$$IO_3^-(aq) + 3\,HSO_3^-(aq) \longrightarrow I^-(aq) + 3\,SO_4^{2-}(aq) + 3\,H^+(aq) \qquad \textbf{(22.4)}$$

$$5\,I^-(aq) + IO_3^-(aq) + 6\,H^+(aq) \longrightarrow 3\,I_2(s) + 3\,H_2O(l) \qquad \textbf{(22.5)}$$

The halogen elements form a variety of useful compounds, and the elements themselves are largely used to produce these compounds. All the halogens are used to make halogenated organic compounds. For example, elemental fluorine is used to produce compounds such as polytetrafluoroethylene, a plastic more commonly known as Teflon. In the past, fluorine was used to make chlorofluorocarbons (CFCs), which were used as refrigerants, but international treaties have banned the production of CFCs in most countries because they damage the stratospheric ozone layer (see Focus On 22, www.masteringchemistry.com). Now fluorine is used to make hydrochlorofluorocarbons (HCFCs), which are more environmentally benign alternatives to CFCs. Fluorinated organic compounds tend to be chemically inert, and it is this inertness that makes them useful as components in harsh chemical environments. Fluorine is a key element in a variety of useful inorganic compounds. Some of these compounds and their uses are listed in Table 22.5.

TABLE 22.5 Important Inorganic Compounds of Fluorine

Compound	Uses
Na_3AlF_6	Manufacture of aluminum
BF_3	Catalyst
CaF_2	Optical components, manufacture of HF, metallurgical flux
ClF_3	Fluorinating agent, reprocessing nuclear fuels
HF	Manufacture of F_2, AlF_3, Na_3AlF_6, and fluorocarbons
LiF	Ceramics manufacture, welding, and soldering
NaF	Fluoridating water, dental prophylaxis, insecticide
SF_6	Insulating gas for high-voltage electrical equipment
SnF_2	Manufacture of toothpaste
UF_6	Manufacture of uranium fuel for nuclear reactors

With an annual production of more than 13 million metric tons, elemental chlorine ranks about eighth in quantity among manufactured chemicals in the United States. It has three main commercial uses: (1) production of chlorinated organic compounds (about 70%), chiefly ethylene dichloride, CH_2ClCH_2Cl, and vinyl chloride, $CH_2{=}CHCl$ (the monomer of polyvinyl chloride, PVC); (2) as a bleach in the paper and textile industries and for the treatment of swimming pools, municipal water, and sewage (about 20%); and (3) production of dozens of chlorine-containing inorganic chemicals (about 10%).

◀ The major industrial source of HCl is the chlorination of organic compounds. For example, HCl is obtained as a by-product in the chlorination of methane, as shown below:

$$CH_4 + Cl_2 \longrightarrow CH_3Cl + HCl$$

Bromine is used to make brominated organic compounds. Some of these are used as fire retardants and pesticides. Others are used extensively as dyes and pharmaceuticals. An important inorganic bromine compound is AgBr, the primary light-sensitive agent used in photographic film.

Iodine is of much less commercial importance than chlorine. Iodine and its compounds, however, do have applications as catalysts, antiseptics, and germicides and in the preparation of pharmaceuticals and photographic emulsions (as AgI).

Hydrogen Halides

We have encountered the hydrogen halides from time to time throughout this text. In aqueous solution, they are called the *hydrohalic acids*. Except for HF, hydrohalic acids are strong acids in water. An explanation for why HF is a weak acid was given on page 728.

One well-known property of HF is its ability to etch (and ultimately to dissolve) glass, an application that is highlighted in the margin. The reaction is similar to one between HF and silica, SiO_2.

$$SiO_2(s) + 4\,HF(aq) \longrightarrow 2\,H_2O(l) + SiF_4(g) \qquad \textbf{(22.6)}$$

▲ Glass etched with hydrofluoric acid.

Because HF reacts with glass, it must be stored in special containers coated with a lining of Teflon or polyethylene.

Hydrogen fluoride is commonly produced by a method discussed in Section 21-2. When a halide salt (such as fluorite, CaF_2) is heated with a *nonvolatile* acid, such as concentrated $H_2SO_4(aq)$, a sulfate salt and the volatile hydrogen halide are produced.

$$CaF_2(s) + H_2SO_4(\text{concd aq}) \xrightarrow{\Delta} CaSO_4(s) + 2\,HF(g) \qquad \textbf{(22.7)}$$

This method also works for preparing HCl(g) but not for HBr(g) or HI(g). Concentrated $H_2SO_4(aq)$ is a sufficiently strong oxidizing agent to oxidize Br^- to Br_2 and I^- to I_2. For example, the reaction of NaBr(s) and concentrated $H_2SO_4(aq)$ yields $Br_2(g)$ and not HBr(g).

$$2\,NaBr(s) + 2\,H_2SO_4(\text{concd aq}) \xrightarrow{\Delta} Na_2SO_4(s) + 2\,H_2O(l) + Br_2(g) + SO_2(g) \qquad \textbf{(22.8)}$$

TABLE 22.6 Free Energy of Formation of Hydrogen Halides at 298 K

	ΔG_f°, kJ mol^{-1}
HF(g)	−273.2
HCl(g)	−95.30
HBr(g)	−53.45
HI(g)	+1.70

We can get around this difficulty by using a *nonoxidizing* nonvolatile acid, such as phosphoric acid, H_3PO_4. Also, all the hydrogen halides can be formed by the direct combination of the elements, as shown below:

$$H_2(g) + X_2(g) \longrightarrow 2\,HX(g) \tag{22.9}$$

The reaction of $H_2(g)$ and $F_2(g)$ is very fast, however, occurring with explosive violence under some conditions. With $H_2(g)$ and $Cl_2(g)$, the reaction also proceeds rapidly (explosively) in the presence of light (photochemically initiated), although some HCl is made this way commercially. With Br_2 and I_2, the reaction occurs more slowly and a catalyst is required.

The data in Table 22.6 show that the standard free energies of formation of HF(g), HCl(g), and HBr(g) are large and negative, suggesting that for them reaction (22.9) goes to completion. For HI(g), ΔG_f° is small and positive. This suggests that even at room temperature HI(g) should dissociate to some extent into its elements. Because the dissociation of HI(g) has a high activation energy, however, the dissociation occurs only very slowly in the absence of a catalyst. As a result, HI(g) is stable at room temperature.

EXAMPLE 22-2 Determining K_p for a Dissociation Reaction from Gibbs Energies of Formation

What is the value of K_p for the dissociation of HI(g) into its elements at 298 K?

Analyze

Dissociation of HI(g) into its elements is the reverse of the formation reaction, and ΔG° for the dissociation reaction is the negative of ΔG_f° listed in Table 22.6. The value of K for the dissociation reaction can be calculated by using the expression $\Delta G^\circ = -RT \ln K$.

Solve

The dissociation reaction and the value of ΔG° are as follows:

$$HI(g) \longrightarrow \frac{1}{2}H_2(g) + \frac{1}{2}I_2(s) \qquad \Delta G^\circ = -1.70\text{ kJ} \tag{22.10}$$

Now we can use the relationship $\Delta G^\circ = -RT \ln K$.

$$\ln K_p = \frac{-\Delta G^\circ}{RT} = \frac{-(-1.70 \times 10^3\text{ J mol}^{-1})}{8.3145\text{ J mol}^{-1}\text{ K}^{-1} \times 298\text{ K}} = 0.686$$

$$K_p = e^{0.686} = 1.99$$

Assess

The value of K is reasonable at just slightly larger than 1 because ΔG° for the dissociation reaction is just slightly less than zero. When $\Delta G^\circ = 0$, the value of K is equal to 1. When ΔG° is a small negative number, the forward reaction is slightly favored and K is just slightly larger than one.

PRACTICE EXAMPLE A: What is the value of K_p for the dissociation of HF(g) into its elements at 298 K? Use data from Table 22.6.

PRACTICE EXAMPLE B: Use data from Table 22.6 to determine K_p and the percent dissociation of HCl(g) into its elements at 298 K.

Oxoacids and Oxoanions

Fluorine, the most electronegative element, adopts the −1 oxidation state in its compounds. The other halogens, when bonded to a more electronegative element such as oxygen, can have any one of several positive oxidation states: +1, +3, +5, or +7. This variability of oxidation states, which was illustrated through electrode potential diagrams for chlorine (Fig. 22-4), is emphasized again by the oxoacids listed in Table 22.7. The structures of some of these

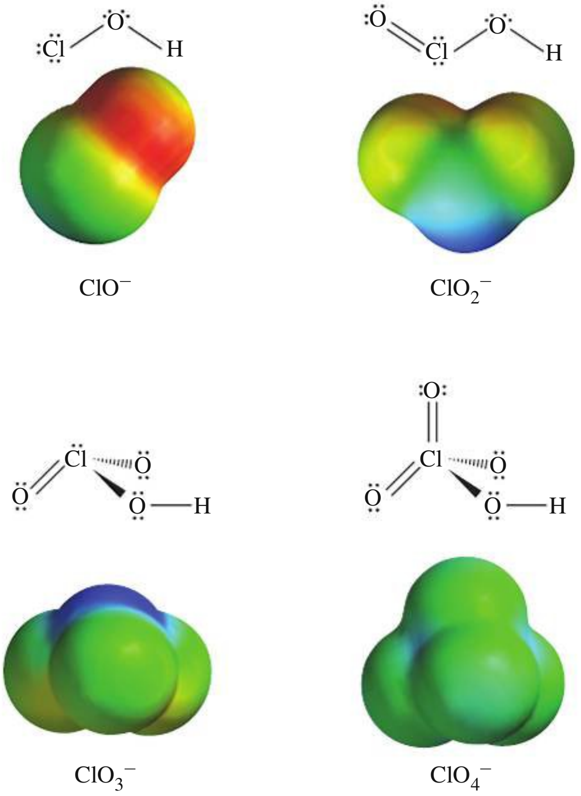
TABLE 22.7 Oxoacids of the Halogens[a]

Oxidation State of Halogen	Chlorine	Bromine	Iodine
+1	$HOCl$	$HOBr$	HOI
+3	$HClO_2$	—	—
+5	$HClO_3$	$HBrO_3$	HIO_3
+7	$HClO_4$	$HBrO_4$	HIO_4; H_5IO_6

[a] In all these acids, H atoms are bonded to O atoms—as shown for HOCl, HOBr, and HOI—not to the central halogen atom. More accurate representations of the other acids would be HOClO (instead of $HClO_2$), $HOClO_2$ (instead of $HClO_3$), and so on.

oxoacids are shown in Figure 22-5. Chlorine forms a complete set of oxoacids in all these oxidation states, but bromine and iodine do not. Only a few of the oxoacids can be isolated in pure form ($HClO_4$, HIO_3, HIO_4, H_5IO_6); the rest are stable only in aqueous solution.

The shapes of the oxoacids (and the corresponding oxoanions) are based on a tetrahedral arrangement of the electron pairs around the chlorine atom. The structures of the acids and the electrostatic potential maps for the anions are displayed in Figure 22-5. Two things are noteworthy in Figure 22-5. First, in the structures for $HClO_3$ and $HClO_4$, the bonds shown with dashes are double bonds. The chlorine-oxygen double bonds, with a bond length of about 141 pm, are much shorter than a Cl—O single bond, which has a bond length of about 164 pm. Second, the electrostatic potential maps indicate that, as the number of oxygen atoms increases, the negative charge on the anion gets progressively delocalized. In OCl^-, the oxygen atom is shown in red, which indicates that the negative charge is highly localized on the oxygen atom. In the other anions, the oxygens are shown in yellow or green, which indicates that they are much less negative. (See Figure 10-5 for a description of the color scheme used in the electrostatic potential maps.) Generally speaking, the more



ClO^-

ClO_2^-

ClO_3^-

ClO_4^-

◀ FIGURE 22-5 **Shapes of the oxoacids of chlorine and the electrostatic potential maps of the corresponding anions** In the structures shown for $HClO_3$ and $HClO_4$, the dotted double lines represent double bonds that point behind the plane of the page, away from the viewer.

delocalized the charge, the more stable the anion is in aqueous solution and the weaker it is as a Brønsted–Lowry base. Because the charge of the anion is delocalized to the greatest extent in ClO_4^-, we conclude that ClO_4^- is the weakest base, and $HClO_4$, its conjugate acid, is the strongest acid.

▶ Never mix bleach with ammonia. The formation of toxic chlorine gas can result.

An easily prepared oxidizing agent for laboratory use is an aqueous solution of chlorine ("chlorine water"). The solution is not just one of Cl_2, however, because $Cl_2(aq)$ disproportionates into HOCl(aq) and HCl(aq).

$$\begin{array}{lrl} \textit{Reduction:} & Cl_2(g) + 2\,e^- & \longrightarrow 2\,Cl^-(aq) \\ \textit{Oxidation:} & Cl_2(g) + 2\,H_2O(l) & \longrightarrow 2\,HOCl(aq) + 2\,H^+(aq) + 2\,e^- \\ \hline \textit{Overall:} & Cl_2(g) + H_2O(l) & \longrightarrow HOCl(aq) + H^+(aq) + Cl^-(aq) \end{array} \qquad \textbf{(22.11)}$$

$$E^\circ = E^\circ_{Cl_2/Cl^-} - E^\circ_{HOCl/Cl_2} = 1.358\text{ V} - 1.611\text{ V} = -0.253\text{ V}$$
$$\Delta G^\circ = -nFE^\circ = 48.8\text{ kJ}$$

KEEP IN MIND

that E_{Cl_2/Cl^-} is independent of pH, but both E_{HOCl/Cl_2} and E_{OCl^-/Cl_2} are pH dependent. They become smaller as the pH increases, increasing E_{cell} and making ΔG less positive and eventually negative. In terms of Le Châtelier's principle, the smaller $[H^+]$ (greater $[OH^-]$), the more the disproportionation reaction is favored.

Although the disproportionation of Cl_2 in water is nonspontaneous when all reactants and products are in their standard states, the reaction does occur to a limited extent in solutions that are not strongly acidic, as the E° and ΔG° values indicate.

In contrast, the disproportionation is spontaneous for standard-state conditions in basic solution, because ΔG° for the reaction is negative, as demonstrated below:

$$\begin{array}{lrl} \textit{Reduction:} & Cl_2(g) + 2\,e^- & \longrightarrow 2\,Cl^-(aq) \\ \textit{Oxidation:} & Cl_2(g) + 4\,OH^-(aq) & \longrightarrow 2\,OCl^-(aq) + 2\,H_2O(l) + 2\,e^- \\ \hline \textit{Overall:} & Cl_2(g) + 2\,OH^-(aq) & \longrightarrow OCl^-(aq) + Cl^-(aq) + H_2O(l) \end{array} \qquad \textbf{(22.12)}$$

$$E^\circ = E^\circ_{Cl_2/Cl^-} - E^\circ_{OCl/Cl_2} = 1.358\text{ V} - 0.421\text{ V} = 0.937\text{ V}$$
$$\Delta G^\circ = -nFE^\circ = -181\text{ kJ}$$

▲ **Bleaching with hypochlorite ion**
Both strips of cloth are heavily stained with tomato sauce. Pure water (left) has little ability to remove the stain. NaOCl (right) rapidly bleaches (oxidizes) the colored components of the sauce to colorless products.

HOCl(aq) is an effective germicide used, for example, in water purification and the treatment of swimming pools. Aqueous solutions of *hypochlorite* salts, notably NaOCl(aq), are used as common household bleaches. The bleaching action of NaOCl(aq) is highlighted in the margin. Reaction (22.12) is used to make solid household bleaches, such as Ca(OCl)Cl, which is a mixed salt containing both OCl^- and Cl^- ions. An aqueous solution of Ca(OCl)Cl is obtained from the reaction of $Ca(OH)_2(aq)$ and Cl_2:

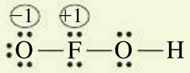
$$Ca(OH)_2(aq) + Cl_2(g) \longrightarrow Ca(OCl)Cl(aq) + H_2O(l)$$

Solid Ca(OCl)Cl is obtained when the water evaporates.

22-1 ARE YOU WONDERING...

If there are oxoacids of fluorine?

The hypothetical oxoacid of fluorine, $HFO_2(HOFO)$, would have a *positive* formal charge on the central F atom.



$$\overset{\ominus}{:\ddot{\underset{..}{O}}}-\overset{\oplus}{\ddot{\underset{..}{F}}}-\ddot{\underset{..}{O}}-H$$

This is not something that we would expect of fluorine, the most electronegative of all the elements. Hypothetical oxoacids with more O atoms would have the F atom with even higher positive formal charges. Fluorine does form HOF, an oxoacid with no formal charges $H-\ddot{\underset{..}{O}}-\ddot{\underset{..}{F}}:$, but HOF exists only in the solid and liquid states. In water, HOF decomposes to HF, H_2O_2, and O_2.

Chlorine dioxide, ClO_2, is an important bleach for paper and fibers. Its reduction with peroxide ion in aqueous solution produces *chlorite* salts:

$$2\,ClO_2(g) + O_2^{2-}(aq) \longrightarrow 2\,ClO_2^-(aq) + O_2(g) \qquad \textbf{(22.13)}$$

Sodium chlorite is used as a bleaching agent for textiles.

Chlorate salts, which contain the ClO_3^- ion, form when $Cl_2(g)$ disproportionates in hot alkaline solutions, as shown below. (Hypochlorites form in cold alkaline solutions; recall reaction 22.12.)

$$3\,Cl_2(g) + 6\,OH^-(aq) \longrightarrow 5\,Cl^-(aq) + ClO_3^-(aq) + 3\,H_2O(l) \qquad \textbf{(22.14)}$$

Chlorates are good oxidizing agents. Also, solid chlorates produce oxygen gas when they decompose, which makes them useful in matches and fireworks. A simple laboratory method of producing $O_2(g)$ involves heating $KClO_3(s)$ in the presence of $MnO_2(s)$, a catalyst.

$$2\,KClO_3(s) \xrightarrow[MnO_2]{\Delta} 2\,KCl(s) + 3\,O_2(g) \qquad \textbf{(22.15)}$$

A similar reaction is used as a source of emergency oxygen in aircraft and submarines.

Perchlorate salts are prepared mainly by electrolyzing chlorate solutions. Oxidation of ClO_3^- occurs at a Pt anode through the half-reaction

$$ClO_3^-(aq) + H_2O(l) \longrightarrow ClO_4^-(aq) + 2\,H^+(aq) + 2\,e^- \qquad E^\circ = -1.189\ V \qquad \textbf{(22.16)}$$

Compared with the other oxoacid salts, perchlorates are relatively stable. For example, they do not disproportionate, because no oxidation state higher than +7 is available to chlorine. At elevated temperatures or in the presence of a readily oxidizable compound, however, perchlorate salts may react explosively, so caution is advised when using them. Mixtures of ammonium perchlorate and powdered aluminum are used as the propellant in some solid-fuel rockets, such as those used on the space shuttle. Ammonium perchlorate is especially dangerous to handle, because an explosive reaction may occur when the oxidizing agent ClO_4^- acts on the reducing agent NH_4^+.

◀ A particularly destructive explosion of ammonium perchlorate occurred at a rocket fuel plant in Henderson, Nevada, in 1988.

Interhalogen Compounds

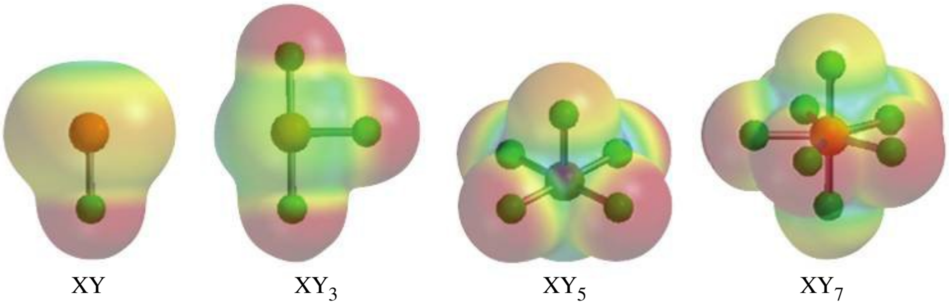
Interhalogen compounds contain two different halogens. The general formulas for interhalogens are XY, XY_3, XY_5, or XY_7, where X and Y represent two different halogens. Some of the more common ones are listed in Table 22.8. The molecular structures of the interhalogen compounds feature the large, less electronegative halogen as the central atom and the smaller halogen atoms as terminal atoms. Molecular shapes of the interhalogen compounds agree quite well with VSEPR theory predictions. Structures for $IF_x\,(x = 1, 3, 5, 7)$ are shown in Figure 22-6, including one type that we have not seen previously. In IF_7, *seven* electron pairs are distributed around the central I atom in the form of a pentagonal-bipyramid.

Most interhalogen compounds are very reactive. For example, ClF_3 and BrF_3 react explosively with water, organic materials, and some inorganic materials.

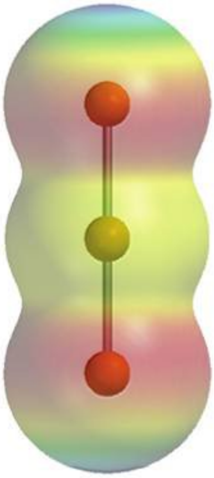
TABLE 22.8 Some Interhalogen Compounds

XY	XY_3	XY_5	XY_7
$ClF(g)$[a]	$ClF_3(g)$	$ClF_5(g)$	
$BrF(g)$	$BrF_3(l)$	$BrF_5(l)$	
$BrCl(g)$	$IF_3(s)$	$IF_5(l)$	$IF_7(g)$
$ICl(s)$	$ICl_3(s)$		
$IBr(s)$			

[a] The states of matter are given for 25 °C and 1 atm, except IF_3 which decomposes above −28 °C.



▲ FIGURE 22-6
Structures and electrostatic potential maps of the interhalogen compounds of iodine and fluorine



▲ FIGURE 22-7
Structure of the I_3^- ion
Notice that in the electrostatic potential map for I_3^-, the three lone pairs around the central iodine atom lead to a neutral charge distribution at this atom, not the negative charge suggested by formal charge arguments.

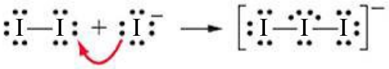
These two fluorides are used to make fluorinated compounds. For example, ClF_3 can be used to convert U(s) to $UF_6(g)$, so that the isotopes of uranium can be separated from each other by gaseous diffusion (see page 224).

$$U(s) + 3\,ClF_3(g) \longrightarrow UF_6(l) + 3\,ClF(g)$$

ICl is used as an iodination reagent in organic chemistry.

Polyhalide Ions

The triiodide ion, I_3^-, is one of a group of species called **polyhalide ions** that are produced by the reaction of a halide ion with a halogen molecule. In the reaction below, the I^- ion acts as a *Lewis base* (an electron-pair donor) and the I_2 molecule as a *Lewis acid* (an electron-pair acceptor).



(22.17)

The structure of the I_3^- ion is shown in Figure 22-7. The familiar iodine solutions used as antiseptics typically contain triiodide ion, and triiodide ion solutions are widely used in analytical chemistry.

22-2 CONCEPT ASSESSMENT

Do you expect the ions ICl_2^+ and ICl_2^- to have the same shape? Explain.

22-4 Group 16: The Oxygen Family

Of the group 16 elements, oxygen and sulfur are clearly nonmetallic in their behavior, but the heavier elements have some metallic properties.

Properties

On the basis of electron configurations alone, we expect oxygen and sulfur to be similar. Both elements form ionic compounds with active metals, and both form similar covalent compounds, such as H_2S and H_2O, CS_2 and CO_2, SCl_2 and Cl_2O.

Even so, there are important differences between oxygen and sulfur compounds. For example, H_2O has a very high boiling point (100 °C) for a compound of such low molecular mass (18 u), whereas the boiling point of H_2S (molecular mass, 34 u) is much lower (−61 °C). This difference in behavior can be explained in terms of the extensive hydrogen bonding that occurs in H_2O but not in H_2S (see page 503). Table 22.9 is a comparison of some properties

TABLE 22.9 Comparisons of Oxygen and Sulfur

Oxygen	Sulfur
$O_2(g)$ at 298 K and 1 atm	$S_8(s)$ at 298 K and 1 atm
Two allotropes: $O_2(g)$ and $O_3(g)$	Two solid crystalline forms and many different molecular species in liquid and gaseous states
Principal oxidation states: $-2, -1, 0\ \left(-\frac{1}{2} \text{ in } O_2{}^-\right)$	Possible oxidation states: all values from -2 to $+6$
$O_2(g)$ and $O_3(g)$ are very good oxidizing agents	$S_8(s)$ is a poor oxidizing agent
Forms, with metals, oxides that are mostly ionic in character	Forms ionic sulfides with the most active metals, but many metal sulfides have partial covalent character
O^{2-} completely hydrolyzes in water, producing OH^-	S^{2-} strongly hydrolyzes in water to HS^- (and OH^-)
O is not often the central atom in a structure and can never have more than four atoms bonded to it; more commonly it has two (as in H_2O) or occasionally three (as in H_3O^+)	S is the central atom in many structures; can easily accommodate up to six electron pairs around itself (e.g., SO_3, $SO_4{}^{2-}$, SF_6)
Can form only two-atom and three-atom chains, as in H_2O_2 and O_3; compounds with $O{-}O$ bonds decompose readily	Can form molecules with up to six S atoms per chain in compounds such as H_2S_n, Na_2S_n, $H_2S_nO_6$
Forms the oxide CO_2, which reacts with NaOH(aq) to produce $Na_2CO_3(aq)$	Forms the sulfide CS_2, which reacts with NaOH(aq), producing $Na_2CS_3(aq)$ and $Na_2CO_3(aq)$
Forms, with hydrogen, the compound H_2O, which is a liquid at 298 K and 1 atm; is extensively hydrogen bonded; has a large dipole moment; is an excellent solvent for ionic solids; forms hydrates and aqua complexes; is oxidized with difficulty	Forms, with hydrogen, the compound H_2S, which is a (poisonous) gas at 298 K and 1 atm; is not hydrogen bonded; has a small dipole moment; is a poor solvent; forms no complexes; is easily oxidized

of sulfur and oxygen. In general, the differences can be attributed to the following characteristics of the oxygen atom: (1) small size, (2) high electronegativity, and (3) its inability to employ an expanded valence shell in Lewis structures.

As indicated in Table 22.9, the principal oxidation states of oxygen are -2, -1, and 0. Sulfur, conversely, can exhibit all oxidation states from -2 to $+6$, including several "mixed" oxidation states, such as $+2.5$ in the tetrathionate ion, $S_4O_6{}^{2-}$.

Occurrence, Production, and Uses

Oxygen Oxygen is the most abundant element in Earth's crust, making up 45.5% by mass. It is also the most abundant element in seawater, accounting for nearly 90% of the mass. In the atmosphere, it is second only to nitrogen in abundance, accounting for 23.15% by mass and 21.04% by volume. Although it is obtained to a limited extent by the decomposition of oxygen-containing compounds and the electrolysis of water, the principal commercial source of oxygen is the fractional distillation of liquid air, which also produces nitrogen, argon, and other noble gases. This process involves only physical changes and is described in Figure 22-8.

Annually, oxygen is one of the principal chemicals manufactured in the United States. The uses of oxygen gas are summarized in Table 22.10. With its commercial availability, O_2 is not commonly prepared in the laboratory. In a submarine, in spacecraft, and in an emergency breathing apparatus, however, it is necessary to generate small quantities of oxygen from solids. The reaction of potassium *superoxide* with CO_2 works well for this purpose because, as the reaction below shows, KO_2 removes CO_2 while O_2 is being formed:

$$4\,KO_2(s) + 2\,CO_2(g) \longrightarrow 2\,K_2CO_3(s) + 3\,O_2(g)$$

▶ FIGURE 22-8

The fractional distillation of liquid air—a simplified representation

Clean air is fed into a compressor and cooled by refrigeration. The cold air then expands through a nozzle and is cooled still further—enough to cause it to liquefy. The liquid air is filtered to remove solid CO_2 and hydrocarbons and then distilled. Liquid air enters the top of the column where nitrogen, the most volatile component (lowest boiling point), passes off as a gas. In the middle of the column, gaseous argon is removed. Liquid oxygen, the least volatile component, collects at the bottom. The normal boiling points of nitrogen, argon, and oxygen are 77.4, 87.5, and 90.2 K, respectively.

22-3 CONCEPT ASSESSMENT

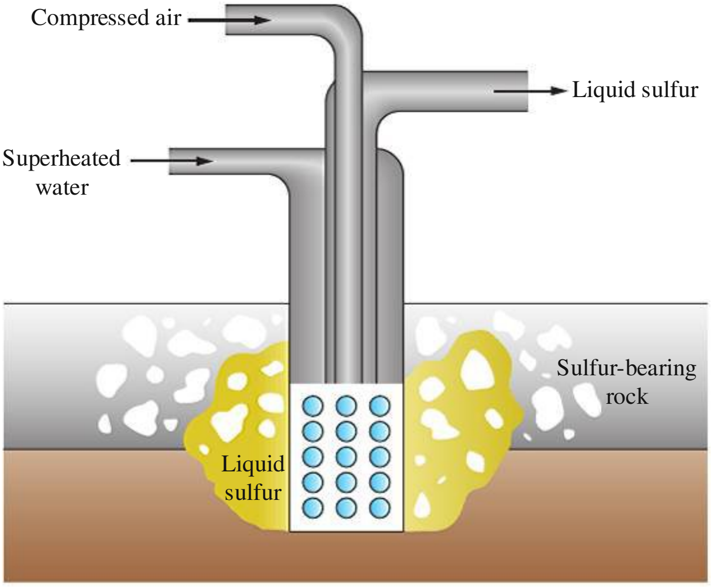
Which of the following dilute aqueous solutions can be used to obtain oxygen and hydrogen gases simultaneously through electrolysis using platinum electrodes: $H_2SO_4(aq)$, $CuSO_4(aq)$, $NaOH(aq)$, $KNO_3(aq)$, $NaI(aq)$? Explain.

▲ These vast formations of solid sulfur were formed by the solidification of liquid sulfur obtained by the Frasch process.

Sulfur Sulfur is the sixteenth most abundant element in Earth's crust, accounting for 0.0384% by mass. Sulfur occurs as elemental sulfur, as mineral sulfides and sulfates, as $H_2S(g)$ in natural gas, and as organosulfur compounds in oil and coal. Extensive deposits of elemental sulfur are found in Texas and Louisiana, some of them in offshore sites. This sulfur is mined using the **Frasch process,** which is illustrated in Figure 22-9. Superheated water (at about 160 °C and 16 atm) is forced down the outermost of three concentric pipes into an underground bed of sulfur-containing rock. The sulfur melts and forms a liquid pool. Compressed air (at 20–25 atm) is pumped down the innermost pipe and forces the liquid sulfur–water mixture up the remaining pipe. The evaporation of water from the mixture yields formations of solid sulfur, such as those shown in the margin.

Although the Frasch process was once the principal source of elemental sulfur, that is no longer the case. This change has been brought about by the need to control sulfur emissions from industrial operations. Today, most elemental sulfur is obtained from H_2S, which is a common impurity in oil and natural gas. After being removed from the fuel, H_2S is reduced to elemental sulfur in a two-step process. A stream of H_2S gas is split into two parts. One part (about one-third of the stream) is burned to convert H_2S to SO_2. The streams are rejoined in a catalytic converter at 200–300 °C, where the following reaction occurs:

$$2\,H_2S(g) + SO_2(g) \longrightarrow 3\,S(g) + 2\,H_2O(g) \tag{22.18}$$



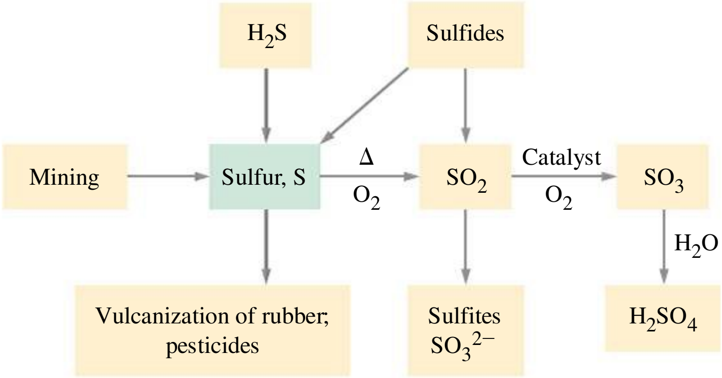
◀ FIGURE 22-9
The Frasch process
Sulfur is melted by using superheated water, and liquid sulfur is forced to the surface.

About 90% of all the sulfur produced is burned to form $SO_2(g)$, and in turn, most $SO_2(g)$ is converted to sulfuric acid, H_2SO_4. The conversion of S to H_2SO_4 is only one of several possibilities identified in Figure 22-10. Elemental sulfur does have a few uses of its own, however. One of these is in vulcanizing rubber (page 1251); another is as a fungicide used for dusting grapevines.

Selenium and Tellurium Selenium and tellurium have properties similar to those of sulfur, but they are more metallic. For example, sulfur is an electrical insulator, whereas selenium and tellurium are semiconductors. Selenium and tellurium are obtained mostly as by-products of metallurgical processes, such as in the anode mud deposited in the electrolytic refining of copper (page 901). Although there is not much use for tellurium compounds, selenium is used in the manufacture of rectifiers (devices that convert alternating to direct electric current). Both Se and Te are employed in the preparation of alloys, and their compounds are used as additives to control the color of glass.

Selenium also displays the property of *photoconductivity*: The electrical conductivity of selenium increases in the presence of light. This property is used, for example, in photocells in cameras. In some modem photocopying machines, the light-sensitive element is a thin film of Se deposited on aluminum. The light and dark areas of the image being copied are converted into a distribution of charge on the light-sensitive element. A dry black powder (toner) coats the charged portions of the light-sensitive element, and this image is transferred to a sheet of paper. Next, the dry powder is fused to the paper. In the final step, the electrostatic charge on the light-sensitive element is neutralized to prepare it for the next cycle.

▲ A selenium-coated light-sensitive element from a photocopier.



◀ FIGURE 22-10
Sources and uses of sulfur and its oxides

Polonium Polonium is a very rare, radioactive metal, and the only element that crystallizes in a simple cubic lattice. Because it is extremely low in abundance, it has not found much practical use. Polonium was the first new radioactive element isolated from uranium ore by Marie and Pierre Curie in 1898. Madame Curie named it after her native Poland.

Allotropy of Oxygen: Ozone

As we first learned in Chapter 3, allotropy refers to the existence of an element in two or more different molecular forms, and we were introduced to the allotrope of ordinary dioxygen, O_2; it is ozone, O_3. Normally, the quantity of O_3 in the atmosphere is quite limited at low altitudes, about 0.04 part per million (ppm). However, its level increases (perhaps severalfold), in smog situations as described on page 635. Ozone levels exceeding 0.12 ppm are considered unhealthful.

The reaction below produces $O_3(g)$ from $O_2(g)$. The reaction is highly endothermic and occurs only rarely in the lower atmosphere.

$$3\,O_2(g) \longrightarrow 2\,O_3(g) \qquad \Delta H^\circ = +285\text{ kJ}$$

This reaction does occur in high-energy environments, such as electrical storms. The pungent odor you may at times smell around heavy-duty electrical equipment or xerographic office copiers is probably O_3. The chief method of producing ozone in the laboratory, in fact, is to pass an electric discharge (high-energy electrons) through $O_2(g)$. Because ozone is unstable and decomposes back to $O_2(g)$, it is always generated at the point of use.

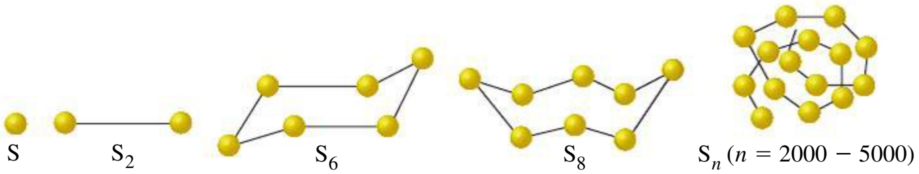
Ozone is an excellent oxidizing agent. Its oxidizing ability is surpassed by few other substances (two are F_2 and OF_2). The following standard reduction potentials show that, in acid solution, $O_3(g)$ is a much stronger oxidizing agent than $O_2(g)$, but not as strong as $F_2(g)$ or $OF_2(g)$.

Half-Equation	E°
$F_2(g) + 2\,e^- \longrightarrow 2\,F^-(aq)$	+2.87 V
$OF_2(g) + 2\,H^+(aq) + 4\,e^- \longrightarrow H_2O(l) + 2\,F^-(aq)$	+2.0 V
$O_3(g) + 2\,H^+(aq) + 2\,e^- \longrightarrow O_2(g) + H_2O(l)$	+2.07 V
$O_2(g) + 4\,H^+(aq) + 4\,e^- \longrightarrow 2\,H_2O(l)$	+1.23 V

Christian F. Schönbein, the discoverer of ozone, was a German-born chemist working at the University of Basel in Switzerland. In 1866, he noted that when ozone is passed through a concentrated aqueous KOH solution, a red color forms. Subsequently, it was established that an ozonide, containing $O_3{}^-$ ions, is formed by the following reaction:

$$2\,KOH(aq) + 5\,O_3(g) \longrightarrow 2\,KO_3(aq) + 5\,O_2(g) + H_2O(l)$$

The ozonide subsequently reacts with water to give KOH(aq) and $O_2(g)$. By using other methods of preparation, it has been possible to prepare other alkali metal ozonides. However, the stability of these ozonides decreases as the size of the metal cation decreases because, as discussed in Chapter 21, a large polarizable anion, such as $O_3{}^-$, is not particularly stable in the presence of small, highly polarizing cations.



▶ FIGURE 22-11
Some molecular forms of sulfur

The most important use of ozone is as a substitute for chlorine in purifying drinking water. Its advantages are that it does not impart a taste to the water and it does not form the potentially carcinogenic chlorination products that chlorine can. Its main disadvantage is that O_3 decomposes quickly and disappears from water fairly soon after it is treated. Over time, water that has been treated with ozone is not as well protected against bacterial contamination as is water treated with chlorine.

An important environmental problem centered on atmospheric ozone is discussed in Focus On 22-1, available on the MasteringChemistry website at www.masteringchemistry.com.

22-4 CONCEPT ASSESSMENT

Would you expect the shape of the ozonide ion to be the same as that of ozone? Explain.

Allotropy and Polymorphism of Sulfur

Sulfur has more allotropes than most elements. The most common structural unit in the solid state is the S_8 ring, although an additional half-dozen cyclic structures are known with up to 20 S atoms per ring. In sulfur vapor, S, S_2, S_4, S_6, and S_8 can all exist under the appropriate conditions. Long-chain molecules of sulfur atoms are found in liquid sulfur. *Rhombic sulfur* (S_α), the stable solid at room temperature, is made up of cyclic S_8 molecules. At 95.5 °C, it converts to *monoclinic sulfur* (S_β), which is also made up of S_8 molecules but has a different crystal structure than S_α. At 119 °C, S_β melts, yielding *liquid sulfur* (S_λ), a straw-colored liquid comprising mostly S_8 molecules but with other cyclic molecules containing from 6 to 20 atoms. At 160 °C, the cyclic molecules open up and recombine into long spiral-chain molecules, producing another form of *liquid sulfur* (S_μ), a dark, viscous liquid. The chain length and viscosity reach a maximum at about 180 °C. At higher temperatures, the chains break up and the viscosity decreases. At 445 °C, the liquid boils, producing *sulfur vapor*. At the boiling point, S_8 molecules predominate in the vapor but they break down into smaller molecules at higher temperatures. *Plastic sulfur* forms if liquid S_μ is poured into cold water. Plastic sulfur consists of long, spiral-chain molecules and has rubberlike properties. On standing, it reverts to rhombic sulfur, a brittle solid.

The following sequence summarizes the phase transitions that occur in sulfur as the temperature increases:

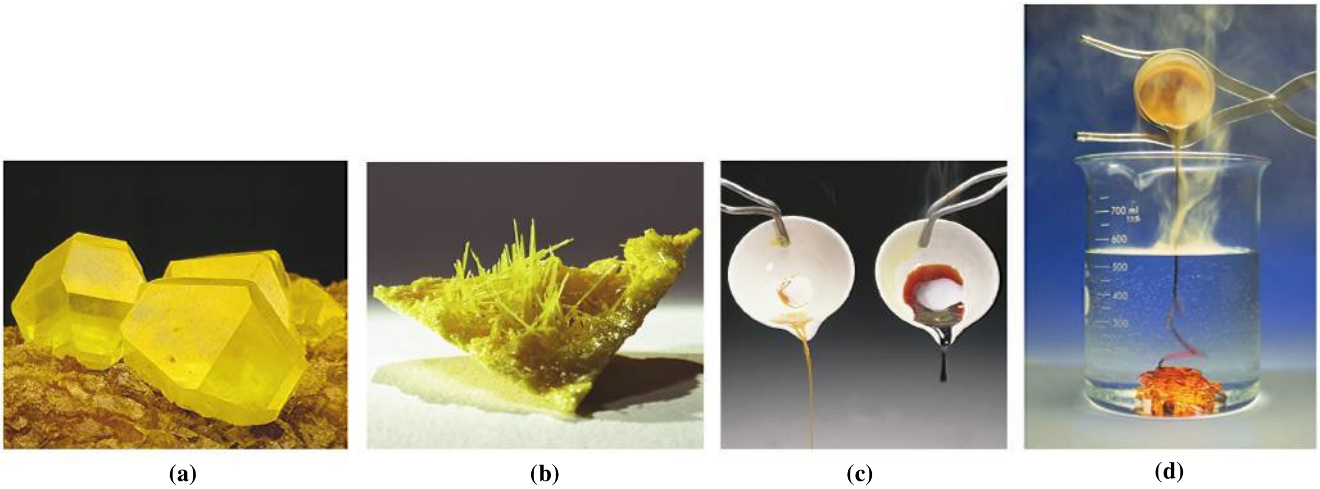
$$S_\alpha \xrightarrow{95.5\,°C} S_\beta \xrightarrow{119} S_\lambda \xrightarrow{160} S_\mu \xrightarrow{445} S_8(g) \longrightarrow S_6 \longrightarrow S_4 \xrightarrow{1000} S_2 \xrightarrow{2000} S$$

Some of these forms of sulfur are shown in Figure 22-12.

Because some of these transitions, especially those in the solid state, are sluggish, additional phenomena are occasionally seen. For example, if rhombic sulfur is heated rapidly, it may melt at 113 °C and fail to convert to monoclinic sulfur. However, monoclinic sulfur may then freeze from this liquid, only to melt again at 119 °C.

Oxygen Compounds

Oxygen is so central to the study of chemistry that we constantly refer to its physical and chemical properties in developing a framework of chemical principles. For instance, our discussion of stoichiometry began with combustion reactions—reactions of substances with $O_2(g)$ to form products such as $CO_2(g)$, $H_2O(l)$, and $SO_2(g)$. Combustion reactions also figured prominently in the presentation of thermochemistry. Many of the molecules and polyatomic anions described in the chapters on chemical bonding were oxygen-containing species. Water was a primary subject in the discussion of liquids, solids, and



▲ FIGURE 22-12
Several macroscopic forms of sulfur

intermolecular forces as well as in the study of acid–base and other solution equilibria. The dual roles of hydrogen peroxide as an oxidizing agent and a reducing agent were described in Section 5-6; and the kinetics of the decomposition of H_2O_2 was examined in detail in Chapter 14. The acidic, basic, and amphoteric properties of element oxides were outlined in Chapter 9.

A systematic study of oxygen compounds is generally done in conjunction with the study of the other elements. Thus, the oxides of boron were considered in the discussion of boron chemistry in Chapter 21; the oxides of carbon were also considered there. The survey of the chemistry of the alkali and alkaline earth metals in Chapter 21 provided an opportunity to describe normal oxides, peroxides, and superoxides; and the important oxides of sulfur, nitrogen, and phosphorus are discussed in this chapter.

Sulfur Compounds

As in the corresponding discussion for the halogens (Section 22-3), oxidation–reduction chemistry is a primary concern here. To assist in this discussion, we provide electrode potential diagrams for some important sulfur-containing species in Figure 22-13.

Electrode potential diagrams for sulfur

Sulfur Dioxide and Sulfur Trioxide More than a dozen oxides of sulfur have been reported, but only sulfur dioxide, SO_2, and sulfur trioxide, SO_3, are commonly encountered. Typical structures are shown in Figure 22-14. The main commercial methods of producing $SO_2(g)$ are the direct combustion of sulfur, reaction (22.19), and the roasting of metal sulfides, reaction (22.20):

$$S(s) + O_2(g) \xrightarrow{\Delta} SO_2(g) \tag{22.19}$$

$$2\,ZnS(s) + 3\,O_2(g) \xrightarrow{\Delta} 2\,ZnO(s) + 2\,SO_2(g) \tag{22.20}$$

The main use of SO_2 is in the synthesis of SO_3 to make sulfuric acid, H_2SO_4. In the *contact process*, $SO_2(g)$ is formed by reaction (22.19) or (22.20). Then sulfur trioxide is produced by oxidizing $SO_2(g)$ in an exothermic, reversible reaction:

$$2\,SO_2(g) + O_2(g) \rightleftharpoons 2\,SO_3(g) \tag{22.21}$$

Reaction (22.21) is the key step in the process, but it occurs very slowly unless catalyzed. The principal catalyst is V_2O_5 mixed with alkali metal sulfates. The catalysis involves adsorption of the $SO_2(g)$ and $O_2(g)$ on the catalyst, followed by reaction at active sites and desorption of SO_3.

SO_3

$(SO_3)_3$

S_6O

S_8O

▲ FIGURE 22-14
Structures of some sulfur oxides
To conform to the observed structures of SO_2, S_2O, and SO_3, the hybridization scheme proposed for the central S atom is sp^2 · S_2O has a similar structure to SO_2 but with a S atom substituted for one O atom. The SO_3 exists in equilibrium with the trimer $(SO_3)_3$, in which the O—S—O angle is approximately tetrahedral and the hybridization of the S should be sp^3. The oxides S_6O and S_8O illustrate sulfur's ability to form ring compounds.

Sulfuric Acid SO_3 reacts with water to form H_2SO_4, but the direct reaction of $SO_3(g)$ and water produces a fine mist of $H_2SO_4(aq)$ droplets with unreacted $SO_3(g)$ trapped inside the droplets. This misting would result in a great loss of product and a tremendous pollution problem. To avoid these outcomes, $SO_3(g)$ is instead bubbled through 98% H_2SO_4 in towers packed with a ceramic material. The $SO_3(g)$ readily dissolves in the sulfuric acid and reacts with the small amount of water present to increase the concentration of the sulfuric acid. The result is a form of sulfuric acid sometimes called *oleum* but more commonly called *fuming sulfuric acid*. In a sense, the product is greater than 100% H_2SO_4. Sufficient water is added to the circulating acid in the tower to maintain the required concentration. Later, sulfuric acid of the strength desired is produced by dilution with water. If we use the formula $H_2S_2O_7$ (disulfuric acid) as an example of a particular oleum, the reactions are

$$SO_3(g) + H_2SO_4(l) \longrightarrow H_2S_2O_7(l) \tag{22.22}$$

$$H_2S_2O_7(l) + H_2O(l) \longrightarrow 2\,H_2SO_4(l) \tag{22.23}$$

$$H_2SO_4(l) \xrightarrow{H_2O} H_2SO_4(aq) \tag{22.24}$$

Dilute sulfuric acid, $H_2SO_4(aq)$, enters into all the common reactions of a strong acid, such as neutralizing bases. It reacts with metals to produce $H_2(g)$ and dissolves carbonates to liberate $CO_2(g)$.

Concentrated sulfuric acid has some distinctive properties. It has a very strong affinity for water, strong enough that it will even remove H and O atoms (in the proportion H_2O) from some compounds. In the reaction of concentrated sulfuric acid with a carbohydrate like sucrose, all the H and O atoms are removed and a residue of pure carbon is left, as shown in the photo. The chemical equation for the reaction that occurs is given below:

$$C_{12}H_{22}O_{11}(s) \xrightarrow{H_2SO_4(concd)} 12\,C(s) + 11\,H_2O(l) \tag{22.25}$$

Concentrated sulfuric acid is a moderately good oxidizing agent and is able, for example, to react with copper.

$$Cu(s) + 2\,H_2SO_4(concd) \longrightarrow Cu^{2+}(aq) + SO_4{}^{2-}(aq) + 2\,H_2O(l) + SO_2(g) \tag{22.26}$$

For a very long time, sulfuric acid has ranked among the top manufactured chemicals, with annual production in the United States of about 45 million metric tons. Sulfuric acid continues to have many uses, but the bulk of H_2SO_4 is used in the manufacture of fertilizers. Other uses are found in various metallurgical processes, oil refining, and the manufacture of the white pigment

(a) (b)

▶ **(a)** Concentrated sulfuric acid is added to cane sugar. **(b)** Carbon is produced in the reaction.

titanium dioxide. Also familiar is its use as the electrolyte in storage batteries for automobiles and emergency power supplies. We might say that sulfuric acid was the workhorse of the "old economy" but that it has a lesser role in the "new economy."

When $SO_2(g)$ reacts with water, it produces $H_2SO_3(aq)$, but this acid, *sulfurous acid*, has never been isolated in pure form. Salts of sulfurous acid, *sulfites*, are good reducing agents and are easily oxidized by $O_2(g)$. In aqueous solution, sulfite ions, SO_3^{2-}, are oxidized by O_2 to SO_4^{2-} ions, as shown below:

$$O_2(g) + 2\,SO_3^{2-}(aq) \longrightarrow 2\,SO_4^{2-}(aq) \qquad \textbf{(22.27)}$$

Interestingly, sulfite ion can also act as an oxidizing agent, as in this reaction with H_2S.

$$2\,H_2S(g) + 2\,H^+(aq) + SO_3^{2-}(aq) \longrightarrow 3\,H_2O(l) + 3\,S(s) \qquad \textbf{(22.28)}$$

Both H_2SO_3 and H_2SO_4 are diprotic acids. They ionize in two steps and produce two types of salts, one in each ionization step. The term **acid salt is** sometimes used for salts such as $NaHSO_3$ and $NaHSO_4$ because their anions undergo a further *acid* ionization. H_2SO_3 is a weak acid in both ionization steps, whereas H_2SO_4 is strong in the first step and somewhat weak in the second. If a solution of H_2SO_4 is sufficiently dilute, however (less than about 0.001 M), we can treat the acid as if both ionization steps go to completion.

▶ Actually, $NaHSO_3$ cannot be isolated as a solid. When we attempt to crystallize this salt from an aqueous solution containing HSO_3^-, the reaction $2\,HSO_3^- \longrightarrow S_2O_5^{2-} + H_2O$ occurs. The product obtained is sodium *metabisulfite*, $Na_2S_2O_5$.

Sulfates and Sulfites Sulfate and sulfite salts have a number of important uses. Calcium sulfate dihydrate (gypsum) is used to make the hemihydrate (plaster of Paris) for the building industry (page 939). Aluminum sulfate is used in water treatment and in sizing paper (page 950). Copper(II) sulfate is employed as a fungicide and an algicide and in electroplating. The chief application of sulfites is in the pulp and paper industry. Sulfites solubilize *lignin*, a polymeric substance that coats the cellulose fibers in wood. This treatment frees the fibers for processing into wood pulp and then paper. Sulfites are also used as reducing agents in photography and as scavengers of $O_2(aq)$ in treating boiler water (reaction 22.27). Compounds of sulfur(IV) have long been used as food preservatives and antioxidants. For example, exposure to $SO_2(g)$ prevents the discoloration of dried fruits, and soluble sulfites act as antimicrobial agents in winemaking.

Thiosulfates In addition to sulfite and sulfate ions, another important sulfur–oxygen ion is thiosulfate ion, $S_2O_3^{2-}$. The prefix *thio* signifies that a S atom replaces an O atom in a compound. Thus, the thiosulfate ion can be viewed as a sulfate ion, SO_4^{2-}, in which a S atom replaces one of the O atoms. The formal oxidation state of S in $S_2O_3^{2-}$ is +2, but as Figure 22-15 indicates, the two S atoms are not equivalent: The central S atom is in the oxidation state +6, and the terminal S atom, −2. The structures of several other thio anions are also shown in Figure 22-15.

Thiosulfates can be prepared by boiling elemental sulfur in an alkaline solution of sodium sulfite. The sulfur is oxidized and the sulfite ion is reduced, both to thiosulfate ion.

$$SO_3^{2-}(aq) + S(s) \longrightarrow S_2O_3^{2-}(aq) \qquad \textbf{(22.29)}$$

Thiosulfate solutions are important in photographic film processing (see page 1099). They are also common analytical reagents, often used in conjunction with iodine. For example, in one method of analysis for copper, an excess of iodide ion is added to $Cu^{2+}(aq)$, producing $CuI(s)$ and triiodide ion, I_3^-.

$$2\,Cu^{2+}(aq) + 5\,I^-(aq) \longrightarrow 2\,CuI(s) + I_3^-(aq) \qquad \textbf{(22.30)}$$

The excess triiodide ion is then titrated with a standard solution of $Na_2S_2O_3(aq)$, forming I^- and $S_4O_6^{2-}$, the *tetrathionate* ion.

$$I_3^-(aq) + 2\,S_2O_3^{2-}(aq) \longrightarrow 3\,I^-(aq) + S_4O_6^{2-}(aq) \qquad \textbf{(22.31)}$$

Oxygen and Sulfur Halides

Both oxygen and sulfur form a number of interesting compounds with the halogens. Oxygen, for example, forms the fluorides OF_2 and O_2F_2, which have structures similar to those of water and hydrogen peroxide but which are much more reactive. Sulfur also forms compounds with the halogens; the analogous compounds SF_2 and S_2F_2 are known, as are the compounds SF_4 and SF_6. The reactivities of SF_4 and SF_6 are quite different. SF_6 is a colorless, odorless, and unreactive gas. It is so unreactive that it can be safely inhaled, in small quantities, resulting in a very deep voice. (As you may already know, helium gas has the opposite effect when inhaled in small quantities.) Conversely, SF_4 is a very reactive gas and a powerful fluorinating agent. In the following reaction, SF_4 converts BCl_3 to BF_3.

$$3\,SF_4 + 4\,BCl_3 \longrightarrow 4\,BF_3 + 3\,SCl_2 + 3\,Cl_2$$

Sulfur and chlorine also form the compounds S_2Cl_2 and SCl_4, but the best-known halide is SCl_2. It is a foul-smelling, red liquid (melting point, −122 °C; boiling point, 59 °C) that has been used in the production of the notorious, and highly poisonous, mustard gas, $S(CH_2CH_2Cl)_2$. The production of mustard gas is based on the following reactions:

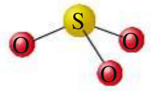
$$SCl_2 + 2\,CH_2CH_2 \longrightarrow S(CH_2CH_2Cl)_2$$

Mustard gas is not actually a gas, but a volatile liquid (melting point, 13 °C; boiling point, 235 °C). During World War I it was sprayed as a mist that stayed close to the ground and was blown by wind onto the enemy. Exposure to mustard gas causes blistering of the skin, internal and external bleeding, blindness, and, after four or five weeks, death.

SO_2 Emissions and the Environment

Industrial smog consists primarily of particles (ash and smoke), $SO_2(g)$, and H_2SO_4 mist. A variety of industrial operations produce significant quantities of $SO_2(g)$, but the main contributors to atmospheric releases of $SO_2(g)$ are power plants burning coal or high-sulfur fuel oils. SO_2 can oxidize to SO_3, especially when the reaction is catalyzed on the surfaces of airborne particles or through reaction with NO_2:

$$SO_2(g) + NO_2(g) \longrightarrow SO_3(g) + NO(g) \qquad \textbf{(22.32)}$$



SO_3^{2-}, Sulfite

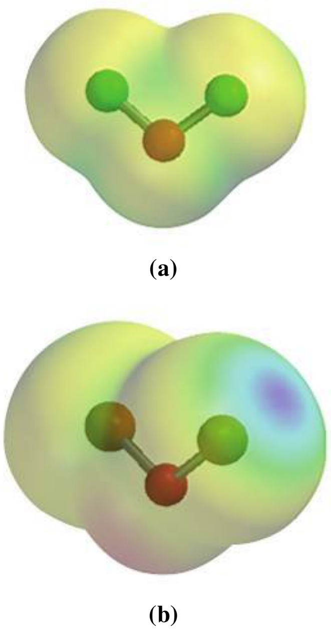
▶ FIGURE 22-16
Fluidized-bed combustion
Powdered coal, limestone, and air are introduced into a combustion chamber where water circulating through coils is converted to steam. Combustion is carried out at a relatively low temperature (760–860 °C), which minimizes the production of NO(g) from $N_2(g)$ and $O_2(g)$. At the same time, $SO_2(g)$ from sulfur in the coal reacts with CaO(s) from decomposition of the limestone, forming $CaSO_3(s)$ in a Lewis acid–base reaction.



▲ Electrostatic potential maps of **(a)** OF_2 and **(b)** OCl_2.

In turn, SO_3 can react with water vapor in the atmosphere to produce H_2SO_4 mist, a component of acid rain. Also, the reaction of H_2SO_4 with airborne NH_3 produces particles of $(NH_4)_2SO_4$. The details of the effect of low concentrations of SO_2 and H_2SO_4 on the body are not well understood, but it is clear that these substances are respiratory irritants. Levels above 0.10 ppm are considered potentially harmful.

The control of industrial smog and acid rain hinges on the removal of sulfur from fuels and the control of $SO_2(g)$ emissions. Dozens of processes have been proposed for removing SO_2 from smokestack gases, one of which is illustrated in Figure 22-16. In this process, $SO_2(g)$ from the coal reacts with CaO(s) to form deposits of $CaSO_3(s)$.

22-5 CONCEPT ASSESSMENT

Electrostatic potential maps for OF_2 and OCl_2 are shown in the margin. Explain the differences.

22-5 Group 15: The Nitrogen Family

The chemistry of the group 15 elements is an extensive subject, especially that of nitrogen and phosphorus. We will discuss the special significance of these two elements to living matter later in the text, but even here you should get a sense of the richness of their chemistry. For example, nitrogen atoms can exist in many oxidation states, which is evident from the variety of nitrogen–containing species identified in Figure 22-17.

Metallic–Nonmetallic Character in Group 15

All the elements in group 15 have the valence-shell electron configuration ns^2np^3. This configuration suggests nonmetallic behavior and doesn't give any clues as to metallic character that might exist. Table 22.11, however, indicates the usual decrease of ionization energy with increasing atomic number. These values, taken together with physical properties from the table, do suggest the order of metallic character within the group. Nitrogen and phosphorus are nonmetallic, arsenic and antimony are metalloids, and bismuth is metallic. The first ionization energy of bismuth is actually somewhat less than that of magnesium, and its third ionization energy ($2466\ \mathrm{kJ\ mol^{-1}}$) is less than the third ionization energy of aluminum ($2745\ \mathrm{kJ\ mol^{-1}}$). The electronegativities indicate a high degree of nonmetallic character for nitrogen and less so for the remaining members of the group.

Three group 15 elements—phosphorus, arsenic, and antimony—exhibit allotropy. The common forms of phosphorus at room temperature, both nonmetallic, are white and red phosphorus. For arsenic and antimony, the more stable allotropic forms are the metallic ones. These forms have high densities, moderate thermal conductivities, and limited abilities to conduct electricity. Bismuth is a metal despite its low electrical conductivity, which, nevertheless, is better than that of manganese and almost as good as that of mercury. The nonmetals and metals in group 15 are also distinguishable by their oxides. The oxides of nitrogen and phosphorus (for example, N_2O_3 and P_4O_6) are acidic

when they react with water. As with the nonmetals in groups 16 and 17, this is typical for nonmetal oxides. Arsenic(III) oxide and antimony(III) oxide are amphoteric, whereas bismuth(III) oxide acts only as a base, a property typical of metal oxides.

Occurrence, Production, and Uses

▲ Viruses for use in medical research are frozen in liquid nitrogen.

Nitrogen Nitrogen occurs mainly in the atmosphere. Its abundance in Earth's solid crust is only 0.002% by mass. The only important nitrogen-containing minerals are KNO_3 (niter, or saltpeter) and $NaNO_3$ (soda niter, or Chile saltpeter), found in a few desert regions. Other natural sources of nitrogen-containing compounds are plant and animal protein and the fossilized remains of ancient plant life, such as coal.

Until about 100 years ago, sources of pure nitrogen and its compounds were quite limited. This all changed with the invention of a process for the liquefaction of air in 1895 (see Figure 22-8) and the development of the Haber–Bosch process for converting nitrogen to ammonia in 1908 (page 1008). A host of nitrogen compounds can be made from ammonia. Nitrogen has many important uses of its own in addition to being a precursor of manufactured nitrogen compounds. Some of these uses are listed in Table 22.12.

Phosphorus Although phosphorus is the eleventh most abundant element and makes up about 0.11% of Earth's crust by mass, it was not discovered until 1669. It was originally isolated from putrefied urine—an effective if not particularly pleasant source. Today the principal source of phosphorus compounds is phosphate rock, a class of minerals known as *apatites*, such as fluorapatite $Ca_5(PO_4)_3F$ or $3\,Ca_3(PO_4)_2 \cdot CaF_2$. Elemental phosphorus is prepared by heating phosphate rock, silica (SiO_2), and coke (C) in an electric furnace. The overall change that occurs is

$$2\,Ca_3(PO_4)_2(s) + 10\,C(s) + 6\,SiO_2(s) \xrightarrow{\Delta} 6\,CaSiO_3(l) + 10\,CO(g) + P_4(g) \qquad \textbf{(22.33)}$$

The $P_4(g)$ is condensed, collected, and stored under water as white phosphorus.

Although compounds of phosphorus are vitally important to living organisms (DNA and phosphates in bones and teeth, for example), the element itself is not widely used. Almost all the elemental phosphorus produced is reoxidized to give P_4O_{10} for the manufacture of high-purity phosphoric acid. The rest is used to make organophosphorus compounds and phosphorus sulfides (P_4S_3) in match heads.

Arsenic, Antimony, and Bismuth Arsenic is obtained by heating arsenic-containing metal sulfides. For example, FeAsS yields FeS and As(g). The As(g) deposits as As(s), which can be used to make other compounds. Some arsenic is also obtained by the reduction of arsenic(III) oxide with CO(g). Antimony is obtained mainly from its sulfide ores. Bismuth is obtained as a by-product of the refining of other metals.

Both As and Sb are used in making alloys of other metals. For example, the addition of As and Sb to Pb produces an alloy that has desirable properties for use as electrodes in lead–acid batteries. Arsenic and antimony are used to produce semiconductor materials, such as GaAs, GaSb, and InSb, in electronic devices.

Nitrogen Compounds

The substance from which all nitrogen compounds are ultimately derived, $N_2(g)$, is unusually stable. One explanation of the limited reactivity of the N_2 molecule is based on its electronic structure. As discussed in Chapter 10, the bond between the two N atoms in N_2 is a *triple* covalent bond, which is unusually strong and difficult to break. In thermochemical terms, the enthalpy change associated with breaking the bonds in one mole of N_2 molecules is very high—the dissociation reaction is highly endothermic.

$$N{\equiv}N(g) \longrightarrow 2\,N(g) \qquad \Delta H^\circ = +945.4\text{ kJ}$$

Also, the Gibbs energies of formation of many nitrogen compounds are positive, which means that their formation reactions are not spontaneous. For NO(g),

$$\frac{1}{2}N_2(g) + \frac{1}{2}O_2 \longrightarrow NO(g) \qquad \Delta G_f^\circ = 86.55\text{ kJ}$$

Reactions with a positive Gibbs energy, such as the formation of NO(g) from its elements, do not occur to any significant extent at normal temperatures and atmospheric conditions. Just imagine the situation if $\Delta G_f^\circ[NO(g)] = -86.55\text{ kJ mol}^{-1}$ instead of $+86.55\text{ kJ mol}^{-1}$. The reaction of $N_2(g)$ and $O_2(g)$ to form NO(g) would proceed to a far greater extent. With an atmosphere depleted in $O_2(g)$ and rich in noxious NO(g), life as we know it would not be possible.

Nitrides Nitrogen forms binary compounds with most other elements, and these compounds can be grouped into four categories. In ionic (salt-like) nitrides, the nitrogen is present as the N^{3-} ion. These compounds form with lithium and the group 2 metals. Thus, when magnesium is burned in air (see Figure 2-1), a small quantity of magnesium nitride forms, together with the principal product, magnesium oxide.

$$3\,Mg(s) + N_2(g) \xrightarrow{\Delta} Mg_3N_2(s) \qquad \textbf{(22.34)}$$

The nitride ion is a very strong base. In aqueous solution, it accepts protons from water molecules to form ammonia molecules and hydroxide ions.

$$N^{3-}(aq) + 3\,H_2O(l) \longrightarrow NH_3(aq) + 3\,OH^-(aq)$$

In the reaction of magnesium nitride with water, magnesium and hydroxide ions combine to form insoluble $Mg(OH)_2$, and the ammonia is released as a gas, which is easily detectable by its odor.

$$Mg_3N_2(s) + 6\,H_2O(l) \longrightarrow 3\,Mg(OH)_2(s) + 2\,NH_3(g)$$

When nitrogen combines with other typical nonmetals, it does so by forming covalent bonds, yielding covalent nitrides. Bonding in these nitrides can be described in terms of the general principles presented in Chapters 10 and 11. Some binary covalent nitrides are $(CN)_2$, P_3N_5, As_4N_4, S_2N_2, and S_4N_4. Nitrogen combines with elements of group 13, producing compounds of the form MN (where M = B, Al, Ga, In, or Tl). These compounds have solid structures that resemble those of graphite or diamond, with M and N atoms bonded to form planes of hexagonal rings (the graphite-like form) or a diamond-like lattice. A fourth type of binary nitrides are the metallic nitrides with formulas such as MN, M_3N, and M_4N. These are *interstitial compounds*, in which N atoms occupy some or all of the interstices (voids) in the structure of the metal. They are hard, chemically inert, high-melting-point solids often used to harden and protect surfaces. Typical examples are TiN, VN, and UN, with melting points of 2950 °C, 2050 °C, and 2800 °C, respectively.

NOBELPRIS 1918
1 30
HABER
SVERIGE

▲ **Fritz Haber (1868–1934)** Haber's perfection of the ammonia synthesis reaction, which made the manufacture of inexpensive explosives possible, was of critical importance to Germany during World War I. After the war, Haber again applied his chemical knowledge for his country's benefit by attempting, unsuccessfully, to extract gold from seawater for use in paying war reparations. Despite his past services, this Jewish scientist was driven from his academic post by the Nazi regime in 1933.

Ammonia and Related Compounds The Haber–Bosch process for the synthesis of ammonia involves the reaction below:

$$N_2(g) + 3\,H_2(g) \rightleftharpoons 2\,NH_3(g) \qquad \textbf{(22.35)}$$

As we noted in an earlier encounter with this reaction (see Focus On 15, www.masteringchemistry.com), a high yield of ammonia requires (1) a high temperature (400 °C), (2) a catalyst to speed up the reaction, and (3) a high pressure (about 200 atm). The key to achieving essentially 100% yield is continuous removal of NH_3 and recycling of the unreacted $N_2(g)$ and $H_2(g)$. The NH_3 is removed by liquefaction. The Haber–Bosch process is outlined in Figure 22-18. A critical aspect of the process is having a source of $H_2(g)$. Mostly, this is made by the re-forming of natural gas (see page 956).

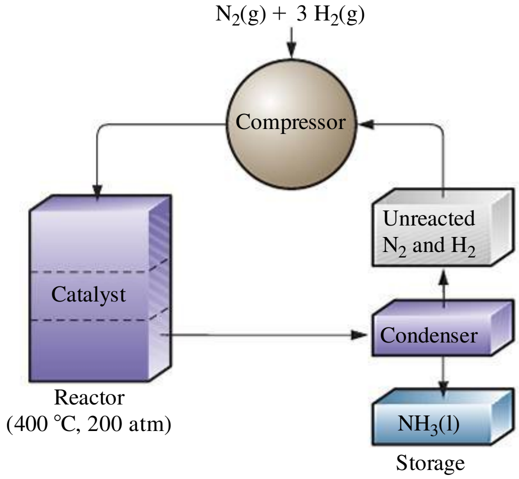
Ammonia is the starting material in the manufacture of most other nitrogen compounds, but it has some direct uses of its own. Its most important use is as a fertilizer. The highest concentration in which nitrogen fertilizer can be applied to fields is as pure liquid NH_3, known as "anhydrous ammonia." $NH_3(aq)$ is also applied in a variety of household cleaning products, such as commercial glass cleaners. In these products, the ammonia acts as an inexpensive base to produce $OH^-(aq)$. The $OH^-(aq)$ reacts with grease and oil molecules to convert them into compounds that are more soluble in water. In addition, the aqueous ammonia solution dries quickly, leaving few streaks on glass.

Because ammonia is a base, a simple approach to producing certain nitrogen compounds is to neutralize ammonia with an appropriate acid. The acid–base reaction that forms ammonium sulfate, an important solid fertilizer, is

$$2\,NH_3(aq) + H_2SO_4(aq) \longrightarrow (NH_4)_2SO_4(aq) \qquad \textbf{(22.36)}$$

Ammonium chloride, made by the reaction of $NH_3(aq)$ and HCl(aq), is used in the manufacture of dry-cell batteries, in cleaning metals, and as an agent to help solder flow smoothly when soldering metals. Ammonium nitrate, made by the reaction of $NH_3(aq)$ and $HNO_3(aq)$, is used both as a fertilizer and as an explosive. The explosive power of ammonium nitrate was not fully appreciated until a shipload of this material exploded in Texas City Texas, in 1947, killing many people. More recently, mixtures of ammonium

▲ Anhydrous liquid ammonia being applied directly to the soil.



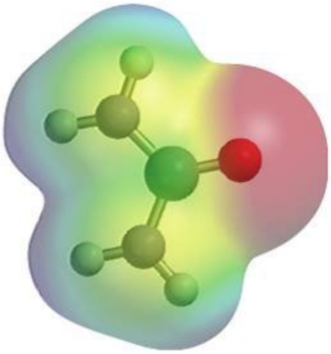
▲ FIGURE 22-18
Ammonia synthesis reaction—the Haber–Bosch process
The gaseous N_2–H_2 mixture is introduced into a reactor at high temperature and pressure in the presence of a catalyst. The gaseous N_2–H_2–NH_3 mixture leaves the reactor and is cooled as it passes through a condenser. Liquefied NH_3 is removed, and the remaining N_2–H_2 mixture is compressed and returned to the reactor. The yield is essentially 100%.

nitrate and fuel oil were used as explosives in the terrorist attacks on the World Trade Center in New York City in 1993 and the Murrah Federal Building in Oklahoma City in 1995. The reaction of $NH_3(aq)$ and $H_3PO_4(aq)$ yields ammonium phosphates, such as $NH_4H_2PO_4$ and $(NH_4)_2HPO_4$. These compounds are good fertilizers because they supply two vital plant nutrients, N and P; they are also used as fire retardants.

Urea, which contains 46% nitrogen by mass, is often manufactured at ammonia synthesis plants by using the following reaction:

$$2\,NH_3 + CO_2 \longrightarrow CO(NH_2)_2 + H_2O \qquad \textbf{(22.37)}$$

The structure of the urea molecule is shown in the margin. Urea is an excellent fertilizer, either as a pure solid, as a solid mixed with ammonium salts, or in a very concentrated aqueous solution mixed with NH_4NO_3 or NH_3 (or both). Urea is also used as a feed supplement for cattle and in the production of polymers and pesticides.



▲ Urea.

Other Hydrides of Nitrogen A great deal has been said in this text about the principal hydride of nitrogen: ammonia, NH_3. Here we describe some lesser-known hydrides. If a H atom in NH_3 is replaced by the group $—NH_2$, the resulting molecule is $H_2N—NH_2$ or N_2H_4, *hydrazine* ($pK_{b_1} = 6.07$; $pK_{b_2} = 15.05$). Replacement of a H atom in NH_3 by $—OH$ produces NH_2OH, *hydroxylamine* ($pK_b = 8.04$). Hydrazine and hydroxylamine are weak bases. Because it has two N atoms, N_2H_4 ionizes in two steps. Hydrazine and hydroxylamine form salts analogous to ammonium salts, such as $N_2H_5{}^+NO_3{}^-$, $N_2H_6{}^{2+}SO_4{}^{2-}$, and $NH_3OH^+Cl^-$. As expected, these salts hydrolyze in water to yield acidic solutions.

Hydrazine and some of its derivatives burn in air with the evolution of large quantities of heat; they are used as rocket fuels (see margin). For the combustion of hydrazine,

$$N_2H_4(l) + O_2(g) \longrightarrow N_2(g) + 2\,H_2O(l) \qquad \Delta H° = -622.2\text{ kJ} \qquad \textbf{(22.38)}$$

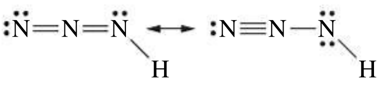
▲ The lifting thrusters of a space shuttle, shown here in an in-flight test, use methylhydrazine, CH_3NHNH_2, as a fuel.

Reaction (22.38) can also be used to remove dissolved $O_2(g)$ from boiler water. Hydrazine is particularly valued for this purpose because no salts (ionic compounds) form that would be objectionable in the water. The industrial preparation of hydrazine is described in Focus On 4, www.masteringchemistry.com.

Both hydrazine and hydroxylamine can act as either oxidizing or reducing agents (usually the latter), depending on the pH and the substances with which they react. The oxidation of hydrazine in acidic solution by nitrite ion produces *hydrazoic acid*, $HN_3(aq)$.

$$N_2H_5{}^+(aq) + NO_2{}^-(aq) \longrightarrow HN_3(aq) + 2\,H_2O(l) \qquad \textbf{(22.39)}$$

Pure HN_3 is a colorless liquid that boils at 37 °C. It is very unstable and will detonate when subjected to shock. Resonance structures for the HN_3 molecule are shown below:



In aqueous solution, HN_3 is a weak acid; its salts are called *azides*. Azides contain the azide ion, $N_3{}^-$, and resemble chlorides in some properties (for instance, AgN_3 is insoluble in water), but they are unstable. Some azides (such as lead azide) are used to make detonators. The release of $N_2(g)$ by the decomposition of sodium azide, NaN_3, is the basis of the air-bag safety system in automobiles (page 210).

Oxides of Nitrogen

Nitrogen forms a series of oxides in which the oxidation state of N can have every value ranging from +1 to +5 (Table 22.13). All these oxides are gases at

TABLE 22.13 Oxides of Nitrogen

O.S. of N	Formula
+1	N_2O
+2	NO
+3	N_2O_3
+4	NO_2
+4	N_2O_4
+5	N_2O_5

TABLE 22.14 Preparation of Oxides of Nitrogen

Oxide	A Method of Preparation
N_2O	$NH_4NO_3(s) \xrightarrow{\Delta} N_2O(g) + 2\,H_2O(g)$
NO	$3\,Cu(s) + 8\,H^+(aq) + 2\,NO_3^-(aq) \longrightarrow 3\,Cu^{2+}(aq) + 2\,NO(g) + 4\,H_2O(l)$
N_2O_3	$2\,NO(g) + N_2O_4(g) \xrightarrow{-20\,°C} 2\,N_2O_3(l)$
NO_2	$2\,Pb(NO_3)_2(s) \xrightarrow{\Delta} 2\,PbO(s) + 4\,NO_2(g) + O_2(g)$
	$2\,NO(g) + O_2(g) \rightleftharpoons 2\,NO_2(g) \qquad K_p = 1.6 \times 10^{12}$ (at 298 K)
N_2O_4	$2\,NO_2(g) \rightleftharpoons N_2O_4(g) \qquad K_p = 8.84$ (at 298 K)
N_2O_5	$4\,HNO_3(l) + P_4O_{10}(s) \xrightarrow{-10\,°C} 4\,HPO_3(s) + 2\,N_2O_5(s)$

25 °C, except N_2O_5, which is a solid with a sublimation pressure of 1 atm at 32.5 °C. It is impossible to obtain either brown $NO_2(g)$ or its colorless dimer, $N_2O_4(g)$, as a pure gas at temperatures between about −10 °C and 140 °C because of the equilibrium between them (review Example 15-9). At lower temperatures, N_2O_4 can be obtained as a pure solid, and above 140 °C, the gas-phase equilibrium strongly favors $NO_2(g)$. In the solid state, N_2O_3 is pale blue; in the liquid state, it is bright blue.

All nitrates decompose on heating, but only NH_4NO_3 yields $N_2O(g)$. Nitrates of active metals, such as $NaNO_3$, yield the corresponding nitrite, such as $NaNO_2$, and $O_2(g)$. Nitrates of less active metals, such as $Pb(NO_3)_2$, yield the metal oxide, NO(g) and $O_2(g)$. These methods of preparing oxides of nitrogen are outlined in Table 22.14.

As mentioned in our assessment of the metallic–nonmetallic character of the group 15 elements, the oxides of nitrogen are acidic, and they react with water to give acidic solutions. For example, the reaction of N_2O_5 and H_2O yields HNO_3, as shown below, and thus N_2O_5 is the acid anhydride of HNO_3.

$$N_2O_5(s) + H_2O(l) \longrightarrow 2\,HNO_3(aq)$$

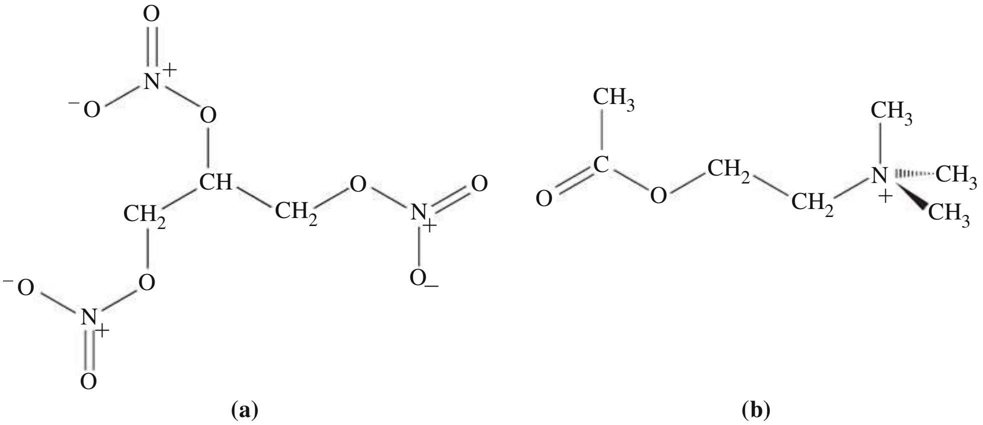
The acid anhydride of nitrous acid, HNO_2, is N_2O_3. Nitrogen dioxide, NO_2, produces both HNO_3 and NO when it reacts with water. But N_2O is not an acid anhydride in the usual sense; it is related to *hyponitrous* acid, $H_2N_2O_2$ (HON=NOH), which yields N_2O and H_2O on decomposition.

$$H_2N_2O_2 \longrightarrow N_2O + H_2O$$

Among the oxides of nitrogen, N_2O (laughing gas) has anesthetic properties and finds some use in dentistry and in providing pain relief during childbirth. N_2O has also been used as a propellant in pressured cans of fats (such as whipped cream) and as a power booster in combustion engines. The power-boosting capability of N_2O arises because at high temperatures—such as those in a combustion chamber—two moles of N_2O decompose to give a total of three moles of N_2 and O_2. The increase in the number of moles of gas increases the force on the pistons in the engine, leading ultimately to increased acceleration.

Other oxides of nitrogen include NO_2, which is employed in the manufacture of nitric acid; N_2O_4, which is used extensively as an oxidizer in rocket fuels; and NO, which is arguably the most important oxide of nitrogen, at least from a biological standpoint. Among its many biological functions, NO helps to protect the heart, stimulate the brain, and kill bacteria. It has been called the "miracle molecule" because it helps to regulate the health of almost every cell in the body.

The discovery of the role of NO in biological systems followed a somewhat tortuous route. In 1829, it was discovered that the compound trinitroglycerine, $C_3H_5(NO_3)_3$, a highly explosive compound, helped dilate (enlarge) blood vessels and relieved symptoms of a heart attack. Later acetylcholine, $C_7H_{16}NO_2^+$,



▲ Lewis structures of **(a)** trinitroglycerine, and **(b)** acetylcholine.

was discovered to have a similar effect on blood vessels. Lewis structures of these two dissimilar molecular species are shown above. Surprisingly, the link between them and their action on blood vessels was not explained until 1987. In that year, two reports were published by two research groups, one lead by Louis Ignarro in the United States and the other lead by Salvador Moncada in the United Kingdom, which demonstrated that the link is the nitric oxide molecule, NO. It is now known that acetylcholine causes enzymes in the blood vessel to release NO, which in turn causes other enzymes to relax the muscle of the vessel. Trinitroglycerine is converted to NO(g) by metabolic processes and NO(g) acts as a signaling agent in blood vessels and causes the muscle in the vessels to relax.

The NO molecule has also been implicated in the human response to infection. When infection occurs, the immune system produces both NO and O_2^-. These two radicals react as follows to produce the peroxynitrite anion, ONO_2^-:

$$NO + O_2^- \longrightarrow O{=}N{-}O{-}O^-$$

The peroxynitrite anion is a strong and versatile oxidant that can break down the structures of, and thus kill, cells of invading species. Over time, excess peroxynitrite anions isomerizes to harmless nitrate anions.

One of the interesting features of the oxides of nitrogen is that their free energies of formation are all *positive* quantities. This feature suggests that the oxides, such as $N_2O(g)$, are thermodynamically unstable, and that decomposition to the elements is spontaneous under standard conditions.

$$2\,N_2O(g) \longrightarrow 2\,N_2(g) + O_2(g) \qquad \Delta G^\circ = -208\text{ kJ (at 298 K)} \qquad \textbf{(22.40)}$$

▲ The combustion of copper gauze in $N_2O(g)$.

Actually, $N_2O(g)$ is quite stable at room temperature because the activation energy for its decomposition is very high—about 250 kJ mol^{-1}. At higher temperatures (about 600 °C), its rate of decomposition becomes appreciable. Reaction (22.40) accounts for the ability of N_2O to support combustion because the $O_2(g)$ necessary for the combustion is produced by the decomposition of N_2O. Overall reactions of the following sort occur.

$$H_2(g) + N_2O(g) \longrightarrow H_2O(l) + N_2(g)$$
$$Cu(s) + N_2O(g) \longrightarrow CuO(s) + N_2(g)$$

Notice that one of the combustion products is the normal combustion product and the other is N_2.

Nitrogen monoxide (nitric oxide), NO(g), is produced commercially by the Ostwald process, in which $NH_3(g)$ is oxidized in the presence of a catalyst:

$$4\,NH_3(g) + 5\,O_2(g) \xrightarrow[850\,^\circ C]{Pt} 4\,NO(g) + 6\,H_2O(g) \qquad \textbf{(22.41)}$$

The oxidation of NH_3 to NO is the first step in converting NH_3 to a number of other nitrogen compounds.

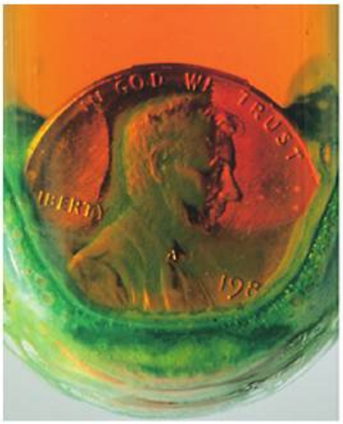
Another source of NO, usually unwanted, is in high-temperature combustion processes, such as those that occur in automobile engines and in electric power plants. At the same time that the fuel combines with oxygen from air to produce a high temperature, $N_2(g)$ and $O_2(g)$ in the hot air combine to a limited extent to form NO(g).

$$N_2(g) + O_2(g) \xrightarrow{\Delta} 2\,NO(g) \qquad \textbf{(22.42)}$$

Brown nitrogen dioxide, $NO_2(g)$, is often seen in reactions involving nitric acid. An example is the reaction of Cu(s) with warm concentrated $HNO_3(aq)$.

$$Cu(s) + 4\,H^+(aq) + 2\,NO_3^-(aq) \longrightarrow Cu^{2+}(aq) + 2\,H_2O(l) + 2\,NO_2(g) \qquad \textbf{(22.43)}$$

Of particular interest to atmospheric chemists is the key role of $NO_2(g)$ in the formation of photochemical smog (page 636).



▲ A copper penny reacting with nitric acid. The reaction is that given by equation (22.43). The blue-green color of the solution is due to $Cu^{2+}(aq)$, and the reddish brown color is that of nitrogen dioxide, $NO_2(g)$.

Nitric Acid and Nitrates The commercial synthesis of nitric acid does not use N_2O_5, as might be expected. It involves the following three reactions, the first of which—the Ostwald process—was described previously. NO(g) from reaction (22.45) is recycled into reaction (22.44).

$$4\,NH_3(g) + 5\,O_2(g) \xrightarrow[850\ ^\circ C]{Pt} 4\,NO(g) + 6\,H_2O(g) \qquad \textbf{(22.41)}$$
$$2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g) \qquad \textbf{(22.44)}$$
$$3\,NO_2(g) + H_2O(l) \longrightarrow 2\,HNO_3(aq) + NO(g) \qquad \textbf{(22.45)}$$

Nitric acid is used in the preparation of various dyes; drugs; fertilizers (ammonium nitrate); and explosives, such as nitroglycerin, nitrocellulose, and trinitrotoluene (TNT). It is also used in metallurgy and in reprocessing spent nuclear fuels. Nitric acid is about twelfth, by mass, among the top chemicals produced in the United States.

Nitric acid is also a good oxidizing agent. For example, copper reacts with dilute $HNO_3(aq)$, producing primarily NO or, with concentrated $HNO_3(aq)$, NO_2 (reaction 22.43). With a more active metal, such as Zn, the reduction product has N in one of its lower oxidation states, for example, NH_4^+. Nitrates can be made by neutralizing nitric acid with appropriate bases.

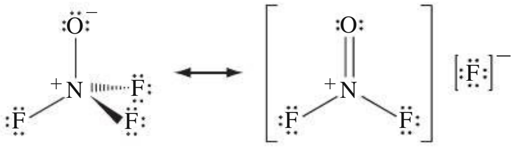
▲ Flash paper is used by magicians for dramatic effect. It can be made by treating paper with nitric and sulfuric acids. This process converts the cellulose fibers into nitrocellulose, which burns cleanly and rapidly.

Nitrogen Halides

Nitrogen forms halides with the elements of group 17. Nitrogen trifluoride, NF_3, can be made by the fluorination of ammonia in the presence of a Cu catalyst.

$$4\,NH_3(g) + 3\,F_2(g) \xrightarrow{Cu} NF_3(g) + 3\,NH_4F(s)$$

Nitrogen trifluoride is a colorless, odorless gas and is one of the few nitrogen compounds that is thermodynamically stable with respect to the elements ($\Delta G_f^\circ = -83.3\ kJ\ mol^{-1}$). Although the nitrogen atom in NF_3 has a lone pair of electrons, NF_3 has very little tendency to act as a Lewis base, unlike ammonia, but it can be made to react, in the gas phase, with oxygen to give NF_3O, a stable but somewhat unusual molecule. In the NF_3O molecule, the nitrogen atom is the central atom, and the nitrogen–oxygen bond is much shorter than the nitrogen-fluorine bonds. The following resonance structures have been proposed, and the structure on the right appears to be an important contributor.



In contrast to nitrogen trifluoride, nitrogen trichloride, NCl_3, is neither a gas nor stable. It is an oily, yellow, highly explosive liquid and care must be taken in handling or making this compound. Its explosive nature can be attributed to its endothermic enthalpy of formation ($\Delta H_f^\circ = 230.0 \text{ kJ mol}^{-1}$), which indicates that the decomposition to $N_2(g)$ and $Cl_2(g)$ is highly exothermic and thermodynamically favorable. Nitrogen trichloride is not prepared from the direct reaction of $N_2(g)$ and $Cl_2(g)$ but from the reaction of ammonium chloride with chlorine, as shown below:

$$NH_4Cl(s) + 3\,Cl_2(g) \rightleftharpoons NCl_3(l) + 4\,HCl(g)$$

The equilibrium is shifted to the right-hand side by dissolving the NCl_3 in an organic solvent. In contrast to NF_3, nitrogen trichloride reacts with water to give ammonia.

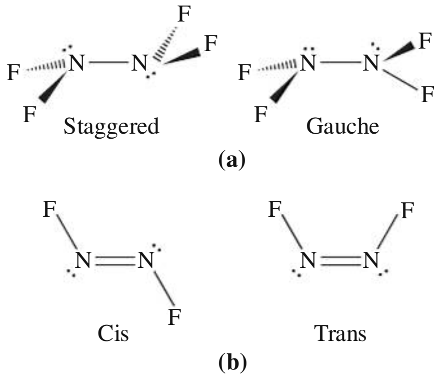
$$NCl_3(aq) + 3\,H_2O(l) \longrightarrow NH_3(aq) + 3\,HOCl(aq)$$

This reaction produces HOCl, a bleaching agent, and thus nitrogen trichloride, diluted in air, has been used to bleach flour. The compounds NBr_3 and NI_3 are also known, and are even more reactive and explosive (and thus, more dangerous to handle) than NCl_3. NI_3 is so unstable that it detonates with the slightest contact, even if touched with a feather or breathed on.

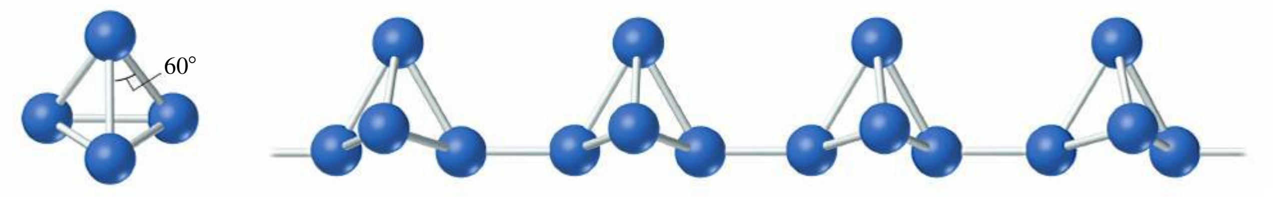
Two other fluorides of nitrogen are known: N_2F_4 and N_2F_2. The structures of the N_2F_4 and N_2F_2 molecules are shown in Figure 22-19. Dinitrogen tetrafluoride, N_2F_4, interconverts between two conformations—staggered and gauche—because the two NF_2 units can rotate independently about the N—N bond. (We will encounter these conformations again in organic chemistry in Chapters 26 and 27.) Dinitrogen difluoride, N_2F_2, exists in two geometrical forms, called geometrical isomers, that are not easily interconverted. Because the double bond prevents twisting of the molecule about the nitrogen– nitrogen bond axis, the N_2F_2, molecule exists as either the *cis* isomer or the *trans* isomer. The *cis* isomer has both fluorine atoms on the same side of the double bond, whereas the *trans* isomer has the fluorine atoms on opposite sides of the double bond. (We will meet this type of isomerism again in Chapter 26.)

Allotropes of Phosphorus

White phosphorus is a white, waxy, phosphorescent solid that can be cut with a knife. (A phosphorescent material glows in the dark.) It is a nonconductor of electricity, can ignite spontaneously in air (hence it is stored under water), and is insoluble in water but soluble in some nonpolar solvents, such as CS_2. The solid has P_4 molecules as its basic structural units (Fig. 22-20a). The P_4 molecule is tetrahedral, with a P atom at each corner. The phosphorus-to-phosphorus bonds in P_4 appear to involve the overlap of 3*p* orbitals almost exclusively. Such overlap normally produces 90° bond angles, but in P_4 the P—P—P bond angles are 60°. The bonds are strained, and as might be expected, species with strained bonds are reactive.

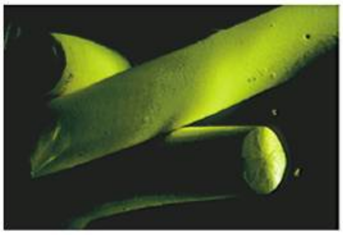


◀ FIGURE 22-19
Structures of N_2F_4 and N_2F_2
(a) In the staggered conformation of N_2F_4, the lone pairs on the nitrogen atoms are diametrically opposed to each other. The gauche conformation is obtained from the staggered conformation by rotating one NF_2 group by 60° with respect to the other. **(b)** Because the double bond prevents the molecule from twisting about the nitrogen–nitrogen bond axis, there are two geometrical isomers for the F—N=N—F molecule.



(a) White phosphorus **(b)** Red phosphorus

▲ FIGURE 22-20
Two forms of phosphorus
(a) Structure of white phosphorus: the P_4 molecule. **(b)** Structure of red phosphorus.



▲ The glow of white phosphorus gave the element its name—*phos*, light, and *phorus*, bringing. The solid has a relatively high vapor pressure, and the glow results from the slow reaction between phosphorus vapor and oxygen in air.

When white phosphorus is heated to about 300 °C out of contact with air, it transforms to *red phosphorus*. What appears to happen is that one P—P bond per P_4 molecule breaks, and the resulting fragments join together into long chains, as suggested in Figure 22-20(b). Red P is less reactive than white P. Because they have a different atomic arrangement in their basic structural units, red and white phosphorus are allotropic forms of phosphorus rather than just different solid phases. These two allotropes of phosphorus are shown in the photograph below. The triple point of red phosphorus is 590 °C and 43 atm. Thus, red phosphorus sublimes without melting (at about 420 °C).

Despite the fact that white P is the form obtained by condensing $P_4(g)$ and that the conversion of white P to red P is a very slow process at ambient temperatures, red P is actually the more thermodynamically stable of the two forms at 298.15 K. Nevertheless, white P is assigned values of 0 for ΔH_f° and ΔG_f°, and for red P, these values are negative.

Phosphorus Compounds

In Chapter 28 we will discover that compounds of phosphorus are essential to all living organisms. However, there is also a significant "inorganic" chemistry of phosphorus, as we will see in this section.

▶ Phosphine is extremely poisonous and has been used as a fumigant against rodents and insects.

Phosphine The most important compound of phosphorus and hydrogen is phosphine, PH_3. This compound is analogous to ammonia in that it acts as a base and forms phosphonium (PH_4^+) compounds. Unlike ammonia, PH_3 is thermally unstable. Phosphine is produced by the disproportionation of P_4 in aqueous base.

$$P_4(s) + 3\,OH^-(aq) + 3\,H_2O(l) \longrightarrow 3\,H_2PO_2^-(aq) + PH_3(g)$$

Phosphorus Trichloride Another phosphorus(III) compound is phosphorus trichloride, PCl_3. One typical reaction of PCl_3 is its hydrolysis, which produces hydrochloric and phosphorous acids.

$$PCl_3(l) + 6\,H_2O(l) \longrightarrow H_3PO_3(aq) + 3\,H_3O^+(aq) + 3\,Cl^-(aq)$$

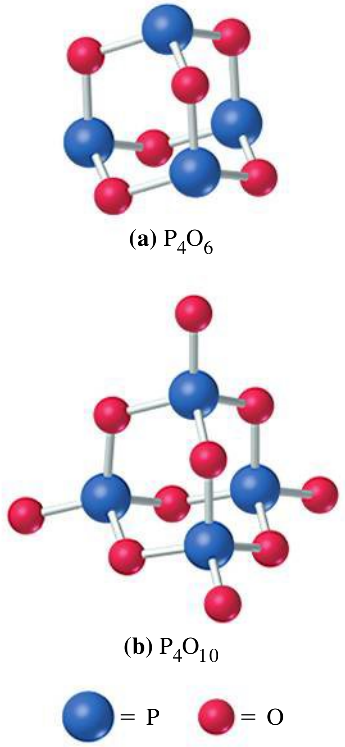
▶ The white and red allotropes of phosphorus.

PCl_3 is the most important phosphorus halide, and a variety of phosphorus(III) compounds are made from it. It is produced by the direct action of $Cl_2(g)$ on elemental phosphorus. Although you may never see PCl_3, chemicals made from it are everywhere—soaps and detergents, plastics and synthetic rubber, nylon, motor oils, and insecticides and herbicides. A variety of organic groups can replace one or more chlorine atoms of PCl_3 to give a family of phosphine-like compounds. These are good Lewis bases and can act as ligands in complex-ion formation.

The halide PCl_5 is obtained by the reaction of Cl_2 with PCl_3 in tetrachloromethane (CCl_4). In the gas phase, PCl_5 exists as discrete trigonal bipyramidal molecules. In the solid state, it exists as $[PCl_4]^+[PCl_6]^-$, in which the ions are tetrahedral and octahedral, respectively.

22-6 CONCEPT ASSESSMENT

In the solid phase, PCl_5 forms $PCl_4{}^+$ and $PCl_6{}^+$. However, PBr_5 forms $PBr_4{}^+Br^-$. Suggest a reason for this difference in structure.



(a) P_4O_6

(b) P_4O_{10}

▲ FIGURE 22-21
Molecular structures of P_4O_6 and P_4O_{10}

Oxides of Phosphorus The simplest formulas we can write for the oxides that have phosphorus in the oxidation states +3 and +5 are P_2O_3 and P_2O_5, respectively. The corresponding names are "phosphorus trioxide" and "phosphorus pentoxide." P_2O_3 and P_2O_5 are only empirical formulas, however. The true molecular formulas of the oxides are double those—that is, P_4O_6 and P_4O_{10}.

The structure of each oxide molecule is based on the P_4 tetrahedron and so must have *four* P atoms, not two. As shown in Figure 22-21(a), in P_4O_6 one O atom bridges each pair of P atoms in the P_4 tetrahedron, which means that there are *six* O atoms per P_4 tetrahedron. The structure of P_4O_{10} is shown in Figure 22-21(b). In addition to the six bridging O atoms, one O atom is bonded to each corner P atom. This means that there are a total of *ten* O atoms per P_4 tetrahedron.

The reaction of P_4 with a limited quantity of $O_2(g)$ produces P_4O_6. If an excess of $O_2(g)$ is used, P_4O_{10} is obtained. Both oxides react with water to form oxoacids—both are *acid anhydrides.*

$$P_4O_6(l) + 6\,H_2O(l) \longrightarrow \underset{\text{phosphorous acid}}{4\,H_3PO_3(aq)}$$

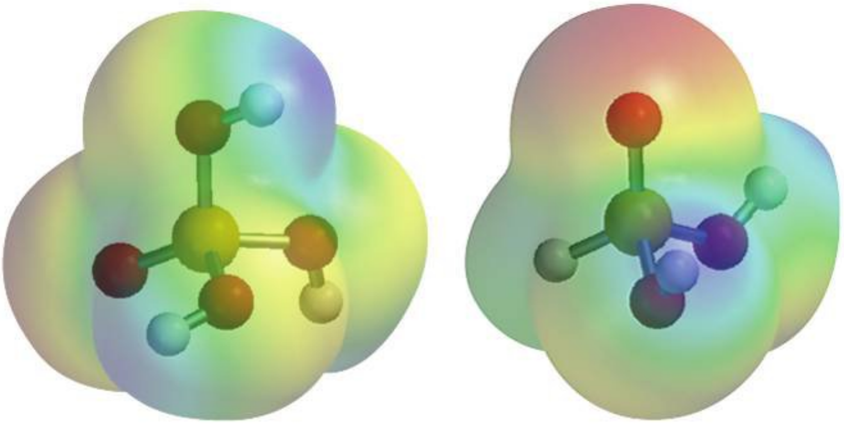
$$P_4O_{10}(s) + 6\,H_2O(l) \longrightarrow \underset{\text{phosphoric acid}}{4\,H_3PO_4(aq)} \qquad \textbf{(22.46)}$$

Because the formulas of phosphoric acid (H_3PO_4) and phosphorous acid (H_3PO_3) are very similar, it is tempting to think that the acids are somewhat similar. It turns out that these two acids have structures that are different in a very significant way. The structures and electrostatic potential maps of H_3PO_4 and H_3PO_3 are shown on page 1016. In H_3PO_4, the P atom is bonded to four oxygen atoms and each of the H atoms is bonded to an oxygen atom, but in H_3PO_3, the P atom is bonded to three oxygen atoms and one H atom. All three H atoms in phosphoric acid are ionizable, and so H_3PO_4 is a triprotic acid. Only two of the H atoms in H_3PO_3 are ionizable and so H_3PO_3 is a diprotic acid.

◀ Ionizable H atoms in oxoacids are associated with the linkage E—O—H. See page 729.

22-7 CONCEPT ASSESSMENT

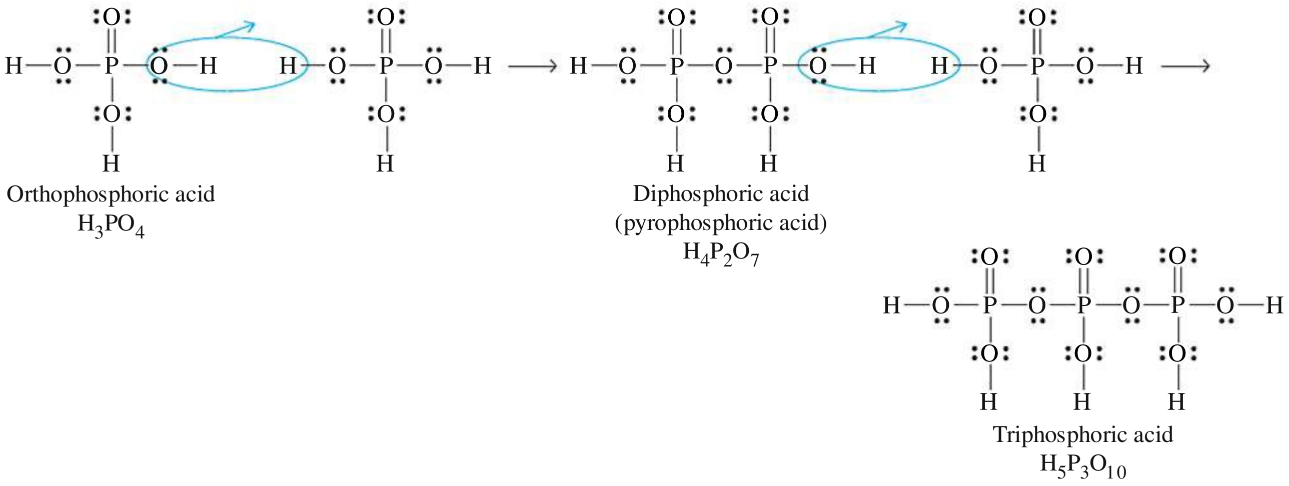
Write condensed structural formulas for phosphoric acid and phosphorous acid. Condensed structural formulas are discussed on page 70.



▶ Phosphoric and phosphorous acids.

Phosphoric Acid Phosphoric acid, H_3PO_4, ranks about seventh among the chemicals manufactured in the United States, with an annual production of more than 13 million tons. It is used mainly to make fertilizers, but it is also used to treat metals to make them more corrosion-resistant. Phosphoric acid has many uses in the food industry: It is used to make baking powders and instant cereals, in cheese making, in curing hams, and in soft drinks to impart tartness.

If P_4O_{10} and H_2O are combined in a 1 : 6 mole ratio in reaction (22.46), the liquid product should be pure H_3PO_4, that is, 100% H_3PO_4, a compound called *orthophosphoric* acid. An analysis of the liquid, however, shows it to be only about 87.3% H_3PO_4. The "missing" phosphorus is still present in the liquid, but as $H_4P_2O_7$, a compound called either *diphosphoric acid* or *pyrophosphoric acid*. A molecule of diphosphoric acid forms when a molecule of H_2O is eliminated from between two molecules of orthophosphoric acid, as shown in Figure 22-22. If a third molecule of orthophosphoric acid joins in by the elimination of another H_2O molecule, the product is $H_5P_3O_{10}$, triphosphoric acid, and so on. As a class, the chain-like phosphoric acid structures are called *polyphosphoric* acids, and their salts are called *polyphosphates*. Two especially important derivatives of the polyphosphoric acids present in living organisms are the substances known as ADP and ATP. The "A" portion of the acronym stands for adenosine, a combination of an organic base called adenine and a



▲ FIGURE 22-22
Formation of polyphosphoric acids
Removal of H_2O molecules results in P—O—P bridges.

five-carbon sugar called ribose. If this adenosine combination is linked to a diphosphate ion, the product is ADP, adenosine diphosphate. Addition of a phosphate ion to ADP yields ATP; adenosine triphosphate. These polyphosphates are described in more detail in Chapter 28.

Most phosphoric acid is made by the action of sulfuric acid on phosphate rock. The chemical equation for the reaction is given below:

$$\underset{\text{Fluorapatite}}{3\,Ca_3(PO_4)_2 \cdot CaF_2(s)} + 10\,H_2SO_4(\text{concd aq}) + 20\,H_2O(l) \longrightarrow 6\,H_3PO_4(aq) + \underset{\text{Gypsum}}{10\,CaSO_4 \cdot 2\,H_2O(s)} + 2\,HF(aq) \qquad \textbf{(22.47)}$$

The HF is converted to insoluble Na_2SiF_6, and the gypsum is filtered off along with other insoluble impurities. The phosphoric acid is concentrated by evaporation. Phosphoric acid obtained by this “wet process” contains a variety of metal ions as impurities and is dark green or brown. Nevertheless, it is satisfactory for the manufacture of fertilizers and for metallurgical operations.

If H_3PO_4 from reaction (22.47) is used in place of H_2SO_4 to treat phosphate rock, the principal product is calcium dihydrogen phosphate. This compound, a fertilizer containing 20–21% P, is marketed under the name *triple superphosphate*:

$$3\,Ca_3(PO_4)_2 \cdot CaF_2(s) + 14\,H_3PO_4(\text{concd aq}) + 10\,H_2O(l) \longrightarrow \underset{\text{Triple superphosphate}}{10\,Ca(H_2PO_4)_2 \cdot H_2O(s)} + 2\,HF(aq) \qquad \textbf{(22.48)}$$

Phosphorus and the Environment

Phosphates are widely used as fertilizers because phosphorus is an essential nutrient for plant growth. However, heavy fertilizer use may lead to phosphate pollution of lakes, ponds, and streams, causing an explosion of plant growth, particularly algae. The algae deplete the oxygen content of the water, eventually killing fish. This type of change, occurring in freshwater bodies as a result of their enrichment by nutrients, is called **eutrophication**. Eutrophication is a natural process that occurs over geological time periods, but it can be greatly accelerated by human activities, as shown in the photograph in the margin.

▲ The natural eutrophication of a lake is greatly accelerated by phosphates in wastewater and the agricultural runoff of fertilizers.

Natural sources of plant nutrients include animal wastes, decomposition of dead organic matter, and natural nitrogen fixation. Human sources include industrial wastes and municipal sewage plant effluents, in addition to fertilizer runoff. One way to reduce phosphate discharges into the environment is to remove them from the wastewater in sewage treatment plants. In the processing of sewage, polyphosphates are degraded to orthophosphates by bacterial action. The orthophosphates can then be precipitated, either as iron(III) phosphates, aluminum phosphates, or as calcium phosphate or hydroxyapatite $[Ca_5(OH)(PO_4)_3]$. The precipitating agents are generally aluminum sulfate, iron(III) chloride, or calcium hydroxide (slaked lime). In a fully equipped modern sewage treatment plant, up to 98% of the phosphates in sewage can be removed.

22-6 Hydrogen: A Unique Element

The first period has only two elements: hydrogen and helium. Hydrogen is quite reactive, but helium is inert. In the case of helium there is no difficulty relating its electronic structure and chemical properties to those of the other noble gases in group 18. Conversely, the chemical and physical properties of hydrogen cannot be correlated with any of the main groups in the periodic table. Hydrogen is truly unique and is best considered on its own.

The ground state electron configuration of a hydrogen atom ($1s^1$) is similar to that of the alkali metal atoms (ns^1), so it seems logical to place hydrogen in group 1. However, such a placement suggests that hydrogen will have properties similar to those of the alkali metals. This is not the case. Alkali metal atoms show a tendency to form M^+ ions. Although H^+ is known in acid–base chemistry, a hydrogen atom has a much greater tendency to form a covalent bond through the sharing of a pair of electrons. Hydrogen's electron configuration also resembles that of the halogens in being just one electron short of that of a noble gas. But unlike the halogens hydrogen rarely form H^- ions, except with the most active metals.

In still other ways hydrogen is like the group 14 elements—both have half-filled valence shells and similar electronegativity values. Thus, the groups $H—$ and $CH_3—$ have one unpaired electron and can form compounds such as LiH and $LiCH_3$. In spite of all of this, hydrogen is best treated as a group on its own.

Think how important hydrogen has been in the study of chemistry. John Dalton based atomic masses on a value of 1 for the H atom. Humphry Davy (1810) proposed that hydrogen is the key element in acids. We saw in Chapter 8 that theoretical studies of the H atom provided us with our modern view of atomic structure. In Chapter 11 we found that the H_2 molecule was the starting point for modern theories of chemical bonding. For all of its theoretical significance, though, hydrogen is also of great practical importance, as we will emphasize in this section.

Occurrence and Preparation

Hydrogen is a very minor component of the atmosphere, about 0.5 ppm at Earth's surface. At altitudes above 2500 km, the atmosphere is mostly atomic hydrogen at extremely low pressures. In the universe as a whole, hydrogen accounts for about 90% of the atoms and 75% of the mass. On Earth, *hydrogen occurs in more compounds than does any other element.*

The free element can easily be produced, but from only a few of its compounds. Our first choice might be H_2O—the most abundant hydrogen compound. To extract hydrogen from water means reducing the oxidation state of H from +1 in H_2O to 0 in H_2. This requires an appropriate *reducing* agent, such as carbon (coal or coke), carbon monoxide, or a hydrocarbon—particularly methane (natural gas). The first pair of reactions that follow are called the **water gas** reactions; they represent a way of making combustible gases—CO and H_2—from steam.

Water gas reactions:
$$C(s) + H_2O(g) \longrightarrow CO(g) + H_2(g) \qquad \textbf{(22.49)}$$
$$CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g) \qquad \textbf{(22.50)}$$

Re-forming of methane:
$$CH_4(g) + H_2O(g) \longrightarrow CO(g) + 3\,H_2(g)$$

Another source of $H_2(g)$ is as a by-product in petroleum refining.

Often we use methods in the chemical laboratory that are not commercially feasible. Electrolysis of water is one useful laboratory method for producing small quantities of $H_2(g)$. Another involves the reaction of active metals (recall the list in Table 5.3) in acidic solutions, an example of which is given below.

$$Zn(s) + 2\,H^+(aq) \longrightarrow Zn^{2+}(aq) + H_2(g)$$

Hydrogen Compounds

Hydrogen forms binary compounds, called **hydrides**, with most of the other elements. Binary hydrides are usually grouped into three broad categories: covalent, ionic, and metallic. *Covalent hydrides* are those formed between hydrogen and nonmetals. Some of these hydrides are simple molecules that can be formed by the direct union of hydrogen and the second element. Two examples are given below:

$$H_2(g) + Cl_2(g) \longrightarrow 2\,HCl(g)$$
$$3\,H_2(g) + N_2(g) \longrightarrow 2\,NH_3(g)$$

Ionic hydrides form between hydrogen and the most active metals, particularly those of groups 1 and 2. In these compounds hydrogen exists as the hydride *ion*, H^-.

$$\underset{\text{(M is any group 1 metal)}}{2\,M(s) + H_2(g) \longrightarrow 2\,MH(s)} \qquad \underset{\text{(M is Ca, Sr, or Ba)}}{M(s) + H_2(g) \longrightarrow MH_2(s)}$$

Ionic hydrides react vigorously with water to produce $H_2(g)$. CaH_2, a gray solid, has been used as a portable source of $H_2(g)$ for filling weather observation balloons.

$$CaH_2(s) + 2\,H_2O(l) \longrightarrow Ca(OH)_2(s) + 2\,H_2(g) \qquad \textbf{(22.51)}$$

The reaction between CaH_2 and water is highlighted in the margin.

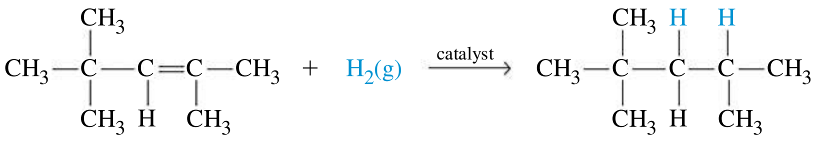
Metal hydrides feature prominently in organic chemistry. For example, because CaH_2 reacts readily with water, it is often used to remove water from organic solvents. Sodium hydride (NaH) is used as a strong base in the synthesis of many organic compounds. Lithium hydride (LiH) is used to make lithium aluminum hydride ($LiAlH_4$), a powerful reducing agent used in organic chemistry (see page 1282).

Metallic hydrides are commonly formed with the transition elements—groups 3 to 12. A distinctive feature of these hydrides is that in many cases they are *nonstoichiometric*—the ratio of H atoms to metal atoms is variable, not fixed. This is because H atoms can enter the voids or holes among the metal atoms in a crystalline lattice and fill some but not others.

▲ **Reaction of CaH_2 with water**
The pink color of phenolphthalein indicator added to the water signals the production of $Ca(OH)_2$ in reaction (22.51).

Uses of Hydrogen

Hydrogen is not listed among the top chemicals produced, because only a small percentage is ever sold to customers. Most hydrogen is produced and used on the spot. In these terms, its most important use (about 42%) is in the manufacture of NH_3 (reaction 22.35). The next most important use of H_2 (about 38%) is in petroleum refining, where it is produced in some operations and consumed in others, such as in the production of the high-octane gasoline component, isooctane, from diisobutylene.



$$CH_3-\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}-\underset{\underset{\displaystyle H}{|}}{C}=\underset{\underset{\displaystyle CH_3}{|}}{C}-CH_3 + H_2(g) \xrightarrow{\text{catalyst}} CH_3-\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}-\underset{\underset{\displaystyle H}{|}}{\overset{\overset{\displaystyle H}{|}}{C}}-\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle H}{|}}{C}}-CH_3$$

Diisobutylene

Isooctane

In similar reactions, called **hydrogenation reactions**, hydrogen atoms, in the presence of a catalyst, can be added to double or triple bonds in other molecules. This type of reaction, for example, converts liquid oleic acid, $C_{17}H_{33}COOH$, to solid stearic acid, $C_{17}H_{35}COOH$.

$$\underset{\text{Oleic acid}}{CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH} + H_2(g) \xrightarrow{\text{Ni}} \underset{\text{Stearic acid}}{CH_3(CH_2)_{16}COOH} \qquad \textbf{(22.52)}$$

Similar reactions serve as the basis for converting oils that contain carbon-carbon double bonds, such as vegetable oils, into solid or semisolid fats, such as shortening, as described in the margin.

Crisco
All-Vegetable
Crisco
Pure Vegetable Oil

▲ Liquid vegetable oils contain long molecules with some carbon-to-carbon double bonds. When some of these double bonds in the molecules are hydrogenated to give carbon-to-carbon single bonds, the result is conversion of the liquid to a solid "partially hydrogenated vegetable oil."

TABLE 22.15 Some Uses of Hydrogen

Synthesis of
  ammonia, NH_3
  hydrogen chloride, HCl
  methanol, CH_3OH

Hydrogenation reactions in
  petroleum refining
  converting oils to fats

Reduction of metal oxides, such as those of iron, cobalt, nickel, copper, tungsten, molybdenum
Metal cutting and welding with atomic and oxyhydrogen torches
Rocket fuel, usually $H_2(l)$ in combination with $O_2(l)$
Fuel cells for generating electricity, in combination with $O_2(g)$

Another important chemical manufacturing process that uses hydrogen is the synthesis of methyl alcohol (methanol), an alternative fuel.

$$CO(g) + 2\,H_2(g) \xrightarrow{\text{catalyst}} CH_3OH(g)$$

Hydrogen gas is an excellent reducing agent and in some cases is used to produce metals from their oxide ores. For example, the following reaction is used, at 850 °C, to produce tungsten metal from its oxide:

$$WO_3(s) + 3\,H_2(g) \longrightarrow W(s) + 3\,H_2O(g)$$

The uses of hydrogen described here, together with several others, are listed in Table 22.15.

Hydrogen and the Environment—A Hydrogen Economy

As we contemplate the eventual decline of the world's supplies of fossil fuels, hydrogen emerges as an attractive means of storing, transporting, and using energy. For example, when an automobile engine burns hydrogen rather than gasoline, its exhaust is essentially pollution free. The range of supersonic aircraft could be increased if they used liquid hydrogen as a fuel. A hypersonic airplane (the space plane) might also become possible. As we learned in Chapter 20, one method of using hydrogen that is already available combines H_2 and O_2 to form H_2O in an electrochemical fuel cell, which converts chemical energy directly to electricity. The subsequent conversion of electrical energy to mechanical energy (work) can be carried out much more efficiently than can the conversion of heat to mechanical energy.

The basic problems are in finding a cheap source of hydrogen and an effective means of storing it. One possibility is to use hydrogen made by the electrolysis of seawater. This possibility requires an abundant energy source, however—perhaps nuclear fusion energy if it can be developed. Another alternative is the thermal decomposition of water. The problem here is that even at 2000 °C, water is only about 1% decomposed. What is needed is a thermochemical cycle, a series of reactions that have as their overall reaction: $2\,H_2O(l) \longrightarrow 2\,H_2(g) + O_2(g)$. Ideally, no single reaction in the cycle would require a very high temperature. Still another alternative being studied involves the use of solar energy to decompose water—photodecomposition.

Storage of gaseous hydrogen is difficult because of the bulk of the gas. When liquefied, hydrogen occupies a much smaller volume, but because of its very low boiling point (-253 °C), the $H_2(l)$ must be stored at very low temperatures. Also, hydrogen must be maintained out of contact with oxygen or air, with which it forms explosive mixtures. One approach may be to dissolve

$H_2(g)$ in a metal or metal alloy, such as an iron–titanium alloy. The gas can be released by mild heating. In an automobile, this storage system would replace the gasoline tank. The heat required to release hydrogen from the metal would come from the engine exhaust.

If the problems described here can be solved, not only could hydrogen be used to supplant gasoline as a fuel for transportation but it could also replace natural gas for space heating. Because H_2 is a good reducing agent, it could replace carbon (as coal or coke) in metallurgical processes and, of course, it would be abundantly available for reaction with N_2 to produce NH_3 for the manufacture of fertilizers. The combination of all these potential uses of hydrogen could lead to a fundamental change in our way of life and give rise to what is called a **hydrogen economy**.

MasteringCHEMISTRY www.masteringchemistry.com

Ozone plays a vital role in protecting life on Earth because it absorbs potentially harmful ultraviolet radiation and also helps to maintain a heat balance in the atmosphere. For a discussion of some ozone-producing and ozone-destroying reactions occurring in the atmosphere, and the impact made by human activities, go to the Focus On feature for Chapter 22, The Ozone Layer and Its Environmental Role, on the MasteringChemistry site.

Summary

22-1 Periodic Trends in Bonding—The bonding in the fluorides changes from ionic bonding to covalent bonding as we move from left to right across the periodic table. In the transition from ionic bonding to covalent bonding, we pass through a group of elements that react with fluorine to give network covalent compounds. The bonding in the oxides exhibits a similar transition. The acid–base character of the oxides also changes as we move left to right across the periodic table. Oxides of the metallic elements (on the left of the periodic table) are generally basic, and oxides of nonmetallic elements are generally acidic. Between these two extremes are the amphoteric oxides derived from some of the elements in groups 2 and 13.

22-2 Group 18: The Noble Gases—The **noble gases** (group 18) form very few compounds. The chemistry of this group is concerned mainly with compounds of xenon and the two most electronegative elements, F and O.

22-3 Group 17: The Halogens—The **halogens** (group 17) are among the most reactive elements, forming compounds with all elements in the periodic table. Electrode potential diagrams are a way to summarize the oxidation–reduction chemistry of an element, and are introduced for the oxidation states of chlorine. Often electrode potentials for reduction processes not specifically represented in a diagram can be obtained by means of calculations based on the relationship $\Delta G° = -nFE°$. The oxoacids and oxoanions of chlorine are described in terms of the methods required to prepare them, their acid–base properties, their strengths as oxidizing or reducing agents, and their structures. In this group we observe several differences between the first and higher members of a group of the periodic table. Thus, for example, we note the failure of fluorine to form stable oxoacids. The later members of the group form **interhalogens**, such as ICl, and **polyhalide ions**, such as I_3^-.

22-4 Group 16: The Oxygen Family—The oxygen family (group 16) includes two reactive nonmetals (O and S), two metalloids (Se and Te), and a metal (Po). Again note the difference in properties between the first and second member of this group. The ability to form strong π bonds with $2p$ orbitals by oxygen contrasts with the single bond chain-like structures favored by sulfur. Sulfur is extracted from underground sources by the **Frasch process**. Sulfur forms the important acids H_2SO_4 and H_2SO_3. The salt $NaHSO_4$ is an example of an **acid salt** since the anion HSO_4^- possesses an ionizable proton.

22-5 Group 15: The Nitrogen Family—The nitrogen family (group 15) shows the progression of properties from nonmetallic to metallic within a group. The chemistry of nitrogen and phosphorus is wide and diverse. The ammonium salts of nitric acid are used in fertilizers. Phosphate ions are also important in fertilizers and in living systems as ADP or ATP. Also, phosphates are implicated in the pollution process of **eutrophication**.

22-6 Hydrogen: A Unique Element—Hydrogen is a unique element that does not fit into any group. Hydrogen can occur as $H^+(aq)$ in aqueous solutions and as H^- in **hydrides,** for example, NaH(s). Hydrogen is a good reducing agent and can be used in **hydrogenation reactions** (equation 22.52). Hydrogen can be obtained from water by electrolysis and also by the **water gas** reaction (equation 22.49). Hydrogen gas is potentially a very promising nonpolluting means of storing, transporting, and using energy and could lead to the so-called **hydrogen economy**.

Integrative Example

For use in analytical chemistry, sodium thiosulfate solutions must be carefully prepared. In particular, the solutions must be kept from becoming acidic. In strongly acidic solutions, thiosulfate ion disproportionates into $SO_2(g)$ and $S_8(s)$.

▲ **Decomposition of thiosulfate Ion**
When an aqueous solution of $Na_2S_2O_3$ is acidified, the sulfur is in the colloidal state when first formed (right).

Show that the disproportionation of $S_2O_3{}^{2-}(aq)$ is spontaneous for standard-state conditions in acidic solution, but not in basic solution.

Analyze

Begin by writing the half-equations and an overall equation for the disproportionation reaction. Determine E°_{cell} for the reaction and thus whether the reaction is spontaneous for standard-state conditions in acidic solution. Then make a qualitative assessment of whether the reaction is likely to be more spontaneous or less spontaneous in basic solution.

Solve

Base the overall equation on the verbal description of the reaction.

Reduction:

$$4\,S_2O_3{}^{2-}(aq) + 24\,H^+(aq) + 16\,e^- \longrightarrow S_8(s) + 12\,H_2O(l)$$

Oxidation:

$$\underline{4\{S_2O_3{}^{2-}(aq) + H_2O(l) \longrightarrow 2\,SO_2(g) + 2\,H^+(aq) + 4\,e^-\}}$$

Overall:

$$8\,S_2O_3{}^{2-}(aq) + 16\,H^+(aq) \longrightarrow S_8(s) + 8\,SO_2(g) + 8\,H_2O(l) \qquad \textbf{(22.53)}$$

To determine E°_{cell} for the reaction (22.53), use data from Figure 22-13. That figure gives an E° value for the reduction half-reaction (0.465 V) but no value for the oxidation. To obtain this missing E°, use additional data from Figure 22-13 together with the method of Example 22-1. That is, the sum of the half-equation

$$4\,SO_2(g) + 4\,H^+(aq) + 6\,e^- \longrightarrow S_4O_6{}^{2-}(aq) + 2\,H_2O(l)$$
$$\Delta G^\circ = -6FE^\circ = -6F \times 0.507\text{ V}$$

and the half-equation

$$S_4O_6{}^{2-}(aq) + 2\,e^- \longrightarrow 2\,S_2O_3{}^{2-}(aq)$$
$$\Delta G^\circ = -2FE^\circ = -2F \times 0.080\text{ V}$$

yields the desired new half-equation and its E° value.

$$4\,SO_2(g) + 4\,H^+(aq) + 8\,e^- \longrightarrow 2\,S_2O_3{}^{2-}(aq) + 2\,H_2O(l)$$
$$\Delta G^\circ = -F[(6 \times 0.507) + (2 \times 0.080)]\text{ V}$$
$$\Delta G^\circ = -8FE^\circ = -F(3.202)\text{ V}$$
$$E^\circ = (3.202/8)\text{ V} = 0.400\text{ V}$$

Now we can calculate E°_{cell} for reaction (22.53).

$$E^\circ_{cell} = E^\circ(\text{reduction}) - E^\circ(\text{oxidation})$$
$$= 0.465\text{ V} - 0.400\text{ V} = 0.065\text{ V}$$

The disproportionation is spontaneous for standard-state conditions in acidic solution.

Increasing $[OH^-]$, as would be the case in making the solution basic, means decreasing $[H^+]$. In fact, $OH^- = 1$ M corresponds to $[H^+] = 1 \times 10^{-14}$ M. Because equation (22.53) has $H^+(aq)$ on the *left* side of the equation, a decrease in $[H^+]$ favors the *reverse* reaction (by Le Châtelier's principle). At some point before the solution becomes basic, the forward reaction is no longer spontaneous.

Assess

This calculation demonstrated in a qualitative way that $S_2O_3{}^{2-}(aq)$ is stable in basic solutions and spontaneously disproportionates in acidic solutions. To determine the pH at which the disproportionation becomes spontaneous, one can use the Nernst equation, as seen in Exercise 100.

PRACTICE EXAMPLE A: Use information from Figure 22-17 to decide whether the nitrite anion, $NO_2{}^-$, disproportionates spontaneously in basic solution to $NO_3{}^-$ and NO. Assume standard-state conditions.

PRACTICE EXAMPLE B: Does HNO_2 spontaneously disproportionate to $NO_3{}^-$ and NO in acidic solution? Assume standard-state conditions. [*Hint*: Use data from Figure 22-17.]

MasteringCHEMISTRY

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

Exercises

Periodic Trends in Bonding and Acid–Base Character of Oxides

1. Give the formula of the stable fluoride formed by Li, Be, B, C, N, and O. For these fluorides, describe the variation in the bonding that occurs as we move from left to right across the period.
2. Fluorine is able to stabilize elements in very high oxidation states. For each of the elements Na, Mg, Al, Si, P, S, and Cl, give the formula of the highest-order fluoride that is known to exist. Then, describe the variation in bonding that occurs as we move from left to right across the period.
3. The oxides of the phosphorus(III), antimony(III), and bismuth(III) are P_4O_6, Sb_4O_6, and Bi_2O_3. Only one of these oxides is amphoteric. Which one? Which of these oxides is most acidic? Which is most basic?
4. The oxides of the selenium(IV) and tellurium(IV) are SeO_2 and TeO_2. One of these oxides is amphoteric and one is acidic. Which is which?

The Noble Gases

5. A 55 L cylinder contains Ar at 145 atm and 26 °C. What minimum volume of air at STP must have been liquefied and distilled to produce this Ar? Air contains 0.934% Ar, by volume.
6. Some sources of natural gas contain 8% He by volume. How many liters of such a natural gas must be processed at STP to produce 5.00 g of He? [*Hint:* What are the apparent molar masses of air and of the $He—O_2$ mixture?]
7. Use VSEPR theory to predict the probable geometric structures of **(a)** XeO_3; **(b)** XeO_4; **(c)** XeF_5^+.
8. Use VSEPR theory to predict the probable geometric structures of the molecules **(a)** O_2XeF_2; **(b)** O_3XeF_2; **(c)** $OXeF_4$.
9. Write a chemical equation for the hydrolysis of XeF_4 that yields XeO_3, Xe, O_2, and HF as products.
10. Write a chemical equation for the hydrolysis in alkaline solution of XeF_6 that yields XeO_6^{4-}, Xe, O_2, F^-, and H_2O as products.
11. Provide an explanation for the observation that helium, neon, and argon do not react directly with fluorine.
12. Provide an explanation for the inability of O_2 to react directly with xenon.

The Halogens

13. Freshly prepared solutions containing iodide ion are colorless, but over time they usually turn yellow. Describe a plausible chemical reaction (or reactions) to account for this observation.
14. Fluorine can be prepared by the reaction of hexafluoromanganate(IV) ion, MnF_6^{2-}, with antimony pentafluoride to produce manganese(IV) fluoride and SbF_6^-, followed by the disproportionation of manganese(IV) fluoride to manganese(III) fluoride and $F_2(g)$. Write chemical equations for these two reactions.
15. Make a general prediction about which of the halogen elements, F_2, Cl_2, Br_2, or I_2, displaces other halogens from a solution of halide ions. Which of the halogens is able to displace $O_2(g)$ from water? Which is able to displace $H_2(g)$ from water?
16. The following properties of astatine have been measured or estimated: **(a)** covalent radius; **(b)** ionic radius (At^-); **(c)** first ionization energy; **(d)** electron affinity; **(e)** electronegativity; **(f)** standard reduction potential. Based on periodic relationships and data in Table 22.4, what values would you expect for these properties?
17. The abundance of F^- in seawater is 1 g F^- per ton of seawater. Suppose that a commercially feasible method could be found to extract fluorine from seawater.
    (a) What mass of F_2 could be obtained from 1 km^3 of seawater $(d = 1.03 \text{ g cm}^{-3})$?
    (b) Would the process resemble that for extracting bromine from seawater? Explain.
18. Fluorine is produced chiefly from fluorite, CaF_2. Fluorine can also be obtained as a by-product of the production of phosphate fertilizers, derived from phosphate rock $[3\,Ca_3(PO_4)_2 \cdot CaF_2]$. What is the maximum mass of fluorine that could be extracted as a by-product from 1.00×10^3 kg of phosphate rock?
19. Show by calculation whether the disproportionation of chlorine gas to chlorate and chloride ions will occur under standard-state conditions in an acidic solution.
20. Show by calculation whether the reaction
    $$2\,HOCl(aq) \longrightarrow HClO_2(aq) + H^+(aq) + Cl^-(aq)$$
    will go essentially to completion as written for standard-state conditions.
21. Predict the geometric structures of **(a)** $\underline{Br}F_3$; **(b)** $\underline{I}F_5$; **(c)** $Cl_3\underline{I}F^-$. (Central atom underlined.)

22. Which of the following species has a linear structure: $\underline{Cl}F_2^+$, $\underline{I}BrF^-$, $\underline{O}Cl_2$, $\underline{Cl}F_3$, or $\underline{S}F_4$? (Central atom underlined.) Do any two of these species have the same structure?

23. When iodine is added to an aqueous solution of iodide ion, the I_3^- ion is formed, according to the reaction below:

$$I_2(aq) + I^-(aq) \rightleftharpoons I_3^-(aq)$$

The equilibrium constant for the reaction above is $K = 7.7 \times 10^2$ at 25 °C.

(a) What is $E°$ for the reaction above?

(b) If a 0.0010 mol sample of I_2 is added to 1.0 L of 0.0050 M NaI(aq) at 25 °C, then what fraction of the I_2 remains unreacted at equilibrium?

24. The trichloride ion, Cl_3^-, is not very stable in aqueous solution. The equilibrium constant for the following dissociation reaction is 5.5 at 25 °C:

$$Cl_3^-(aq) \rightleftharpoons Cl^-(aq) + Cl_2(aq)$$

(a) Draw a Lewis structure for the Cl_3^- ion and predict the geometry.

(b) Calculate the equilibrium concentration of Cl_3^- if 0.0010 moles each of KCl and Cl_2 are dissolved in water at 25 °C to make 1.0 L of solution.

Oxygen

25. Each of the following compounds decomposes to produce $O_2(g)$ when heated: **(a)** HgO(s); **(b)** $KClO_4(s)$. Write plausible equations for these reactions.

26. $O_3(g)$ is a powerful oxidizing agent. Write equations to represent oxidation of **(a)** I^- to I_2 in acidic solution; **(b)** sulfur in the presence of moisture to sulfuric acid; **(c)** $[Fe(CN)_6]^{4-}$ to $[Fe(CN)_6]^{3-}$ in basic solution. In each case $O_3(g)$ is reduced to $O_2(g)$.

27. *Without performing detailed calculations*, determine which of the following compounds has the greatest percent oxygen by mass: dinitrogen tetroxide, aluminum oxide, tetraphosphorus hexoxide, or carbon dioxide.

28. *Without performing detailed calculations*, determine which decomposition yields the most $O_2(g)$ **(a)** per mole and **(b)** per gram of substance.

(1) ammonium nitrate ⟶ nitrogen + oxygen + water

(2) hydrogen peroxide ⟶ oxygen + water

(3) potassium chlorate ⟶ potassium chloride + oxygen

29. The natural abundance of O_3 in unpolluted air at ground level is about 0.04 parts per million (ppm) by volume. What is the approximate partial pressure of O_3 under these conditions, expressed in millimeters of mercury?

30. A typical concentration of O_3 in the ozone layer is 5×10^{12} O_3 molecules cm^{-3}. What is the partial pressure of O_3, expressed in millimeters of mercury, in that layer? Assume a temperature of 220 K.

31. Explain why the volumes of $H_2(g)$ and $O_2(g)$ obtained in the electrolysis of water are not the same.

32. In the electrolysis of a sample of water 22.83 mL of $O_2(g)$ was collected at 25.0 °C at an oxygen partial pressure of 736.7 mmHg. Determine the mass of water that was decomposed.

33. Hydrogen peroxide is a somewhat stronger acid than water. For the ionization

$$H_2O_2(aq) + H_2O(l) \longrightarrow H_3O^+(aq) + HO_2^-(aq)$$

$pK_a = 11.75$. Calculate the expected pH of a typical antiseptic solution that is 3.0% H_2O_2 by mass.

34. In water, O^{2-} is a strong base. If 50.0 mg of Li_2O is dissolved in 750.0 mL of aqueous solution, what will be the pH of the solution?

35. The conversion of $O_2(g)$ to $O_3(g)$ can be accomplished in an electric discharge, $3\,O_2(g) \longrightarrow 2\,O_3(g)$. Use a bond dissociation energy of 498 kJ mol^{-1} for $O_2(g)$ and data from Appendix D to calculate an average oxygen-to-oxygen bond energy in $O_3(g)$.

36. Estimate the average bond energy in $O_3(g)$ from the structure on page 416 and data in Table 10.3. Compare this result with that of Exercise 35.

37. Use Lewis structures and other information to explain the observation that

(a) H_2S is a gas at room temperature, whereas H_2O is a liquid.

(b) O_3 is diamagnetic.

38. Use Lewis structures and other information to explain the observation that

(a) the oxygen-to-oxygen bond lengths in O_2, O_3, and H_2O_2 are 121, 128, and 148 pm, respectively.

(b) the oxygen-to-oxygen bond length of O_2 is 121 pm and for O_2^+ is 112 pm. Why is the bond length for O_2^+ so much shorter than for O_2?

39. Which of the following reactions are likely to go to completion or very nearly so?

(a) $H_2O_2(aq) + 2\,I^-(aq) + 2\,H^+(aq) \longrightarrow I_2(s) + 2\,H_2O(l)$

(b) $O_2(g) + 2\,H_2O(l) + 4\,Cl^-(aq) \longrightarrow 2\,Cl_2(g) + 4\,OH^-(aq)$

(c) $O_3(g) + Pb^{2+}(aq) + H_2O(l) \longrightarrow PbO_2(s) + 2\,H^+(aq) + O_2(g)$

(d) $HO_2^-(aq) + 2\,Br^-(aq) + H_2O(l) \longrightarrow 3\,OH^-(aq) + Br_2(l)$

40. Each of the following compounds produces $O_2(g)$ when strongly heated: **(a)** HgO(s); **(b)** $KClO_4(s)$; **(c)** $Hg(NO_3)_2(s)$; **(d)** $H_2O_2(aq)$. Write a plausible equation for the reaction that occurs in each instance.

41. In the laboratory, small quantities of oxygen gas can be prepared by heating potassium chlorate, $KClO_3(s)$, in the presence of $MnO_2(s)$, a catalyst. What volume of oxygen, measured at 25 °C and 101 kPa, is obtained from the decomposition of 1.0 g $KClO_3(s)$? [*Hint:* The other product of the reaction is KCl(s).]

42. Joseph Priestley, a British chemist, was credited with the discovering oxygen in 1774. In his experiments, he generated oxygen gas by heating HgO(s). The other product of the decomposition reaction is Hg(l). What volume of wet $O_2(g)$ is obtained from the decomposition of 1.0 g HgO(s), if the gas is collected over water at 25 °C and a barometric pressure of 756 mmHg? The vapor pressure of water is 23.76 mmHg at 25 °C.

Sulfur

43. Give an appropriate name to each of the following compounds: **(a)** ZnS; **(b)** $KHSO_3$; **(c)** $K_2S_2O_3$; **(d)** SF_4.

44. Give an appropriate formula for each of the following compounds: **(a)** calcium sulfate dihydrate; **(b)** hydrosulfuric acid; **(c)** sodium hydrogen sulfate; **(d)** disulfuric acid.

45. Give a specific example of a chemical equation that illustrates the
    (a) reaction of a metal sulfide with HCl(aq);
    (b) action of a *nonoxidizing* acid on a metal sulfite;
    (c) oxidation of $SO_2(aq)$ to $SO_4^{2-}(aq)$ by $MnO_2(s)$ in acidic solution;
    (d) disproportionation of $S_2O_3^{2-}$ in acidic solution.

46. Show how you would use elemental sulfur, chlorine gas, metallic sodium, water, and air to produce aqueous solutions containing **(a)** Na_2SO_3; **(b)** Na_2SO_4; **(c)** $Na_2S_2O_3$. [*Hint:* You will have to use information from other chapters as well as this one.]

47. Describe a chemical test you could use to determine whether a white solid is Na_2SO_4 or $Na_2S_2O_3$. Explain the basis of this test using a chemical equation or equations.

48. Explain why sulfur can occur naturally as sulfates, but not as sulfites.

49. Salts like $NaHSO_4$ are called *acid* salts because their anions undergo further ionization. What is the pH of 250 mL of water solution containing 12.5 g $NaHSO_4$? [*Hint:* Use data from Chapter 16, as necessary.]

50. What mass of Na_2SO_3 was present in a sample that required 26.50 mL of 0.0510 M $KMnO_4$ for its oxidation to Na_2SO_4 in an acidic solution? MnO_4^- is reduced to Mn^{2+}.

51. A 1.100 g sample of copper ore is dissolved, and the $Cu^{2+}(aq)$ is treated with excess KI. The liberated I_3^- requires 12.12 mL of 0.1000 M $Na_2S_2O_3$ for its titration. What is the mass percent copper in the ore?

52. A 25.0 L sample of a natural gas, measured at 25 °C. and 740.0 Torr, is bubbled through $Pb^{2+}(aq)$, yielding 0.535 g of PbS(s). What mass of sulfur can be recovered per cubic meter of this natural gas?

53. What is the oxidation state of sulfur in the following compounds? **(a)** SF_4; **(b)** S_2F_{10}; **(c)** H_2S; **(d)** $CaSO_3$.

54. What is the oxidation state of sulfur in the following compounds? **(a)** S_2Br_2; **(b)** SCl_2; **(c)** $Na_2S_2O_3$; **(d)** $(NH_4)_2S_4O_6$.

Nitrogen Family

55. Write balanced equations for the following important commercial reactions involving nitrogen and its compounds.
    (a) the principal artificial method of fixing atmospheric N_2
    (b) oxidation of ammonia to NO
    (c) preparation of nitric acid from NO

56. When heated, each of the following substances decomposes to the products indicated. Write balanced equations for these reactions.
    (a) $NH_4NO_3(s)$ to $N_2(g)$, $O_2(g)$, and $H_2O(g)$
    (b) $NaNO_3(s)$ to sodium nitrite and oxygen gas
    (c) $Pb(NO_3)_2(s)$ to lead(II) oxide, nitrogen dioxide, and oxygen

57. Sodium nitrite can be made by passing oxygen and nitrogen monoxide gases into an aqueous solution of sodium carbonate. Write a balanced equation for this reaction.

58. Concentrated $HNO_3(aq)$ used in laboratories is usually 15 M HNO_3 and has a density of 1.41 g mL^{-1}. What is the percent by mass of HNO_3 in this concentrated acid?

59. In 1968, before pollution controls were introduced, over 75 billion gallons of gasoline were used in the United States as a motor fuel. Assume an emission of oxides of nitrogen of 5 grams per vehicle mile and an average mileage of 15 miles per gallon of gasoline. How many kilograms of nitrogen oxides were released into the atmosphere in the United States in 1968?

60. One reaction that competes with reaction (22.41), the Ostwald process, is the reaction of gaseous ammonia and nitrogen monoxide to produce gaseous nitrogen and gaseous water. Use data from Appendix D to determine $\Delta H°$ for this reaction, per mole of ammonia consumed.

61. Use information from this chapter and previous chapters to write chemical equations to represent the following:
    (a) equilibrium between nitrogen dioxide and dinitrogen tetroxide in the gaseous state
    (b) the reduction of nitrous acid by $N_2H_5^+$ forming hydrazoic acid, followed by the reduction of additional nitrous acid by the hydrazoic acid, yielding nitrogen and dinitrogen monoxide
    (c) the neutralization of $H_3PO_4(aq)$ to the second equivalence point by $NH_3(aq)$

62. Use information from this chapter and previous chapters to write plausible chemical equations to represent the following:
    (a) the reaction of silver metal with $HNO_3(aq)$
    (b) the complete combustion of the rocket fuel, unsymmetrical dimethylhydrazine, $(CH_3)_2NNH_2$
    (c) the preparation of sodium triphosphate by heating a mixture of sodium dihydrogen phosphate and sodium hydrogen phosphate.

63. Draw plausible Lewis structures for
    (a) dimethylhydrazine, $(CH_3)_2NNH_2$
    (b) nitryl chloride, $ClNO_2$ (Central atom is N)
    (c) phosphorous acid, a *diprotic* acid with the empirical formula H_3PO_3

64. Both nitramide and hyponitrous acid have the formula $H_2N_2O_2$. Hyponitrous acid is a weak diprotic acid; nitramide contains the amide group $(-NH_2)$. Draw plausible Lewis structures for these two substances.

65. Supply an appropriate name for each of the following: **(a)** HPO_4^{2-}; **(b)** $Ca_2P_2O_7$; **(c)** $H_6P_4O_{13}$.

66. Write an appropriate formula for each of the following: **(a)** hydroxylamine; **(b)** calcium hydrogen phosphate; **(c)** lithium nitride.

67. Use Figure 22-17 to establish $E°$ for the reduction of N_2O_4 to NO in an acidic solution.

68. Use Figure 22-17 to establish $E°$ for the reduction of NO_3^- to NO_2^- in a basic solution.

69. All the group 15 elements form trifluorides, but nitrogen is the only group 15 element that does not form a pentafluoride.
(a) Suggest a reason why nitrogen does not form a pentafluoride.
(b) The observed bond angle in NF_3 is approximately 102.5 °C. Use VSEPR theory to rationalize the structure of the NF_3 molecule.

70. The structures of the NH_3 and NF_3 molecules are similar, yet the dipole moment for the NH_3 molecule is rather large (1.47 debye) and that of the NF_3 molecule is rather small (0.24 debye). Provide an explanation for this difference in the dipole moments.

Hydrogen

71. Use data from Table 7.2 (page 269) to calculate the standard enthalpies of combustion of the four alkane hydrocarbons listed there.

72. Based on the results of Exercise 71, which alkane evolves the greatest amount of heat upon combustion on **(a)** a *per mole* basis and **(b)** a *per gram* basis? Which is the most desirable alkane from the standpoint of reducing the emission of carbon dioxide to the atmosphere? Explain.

73. Write chemical equations for the following reactions:
(a) the displacement of $H_2(g)$ from HCl(aq) by Al(s)
(b) the re-forming of propane gas (C_3H_8) with steam
(c) the reduction of $MnO_2(s)$ to Mn(s) with $H_2(g)$

74. Write equations to show how to prepare $H_2(g)$ from each of the following substances: **(a)** H_2O; **(b)** HI(aq); **(c)** Mg(s); **(d)** CO(g). Use other common laboratory reactants as necessary, that is, water, acids or bases, metals, and so on.

75. $CaH_2(s)$ reacts with water to produce $Ca(OH)_2$ and $H_2(g)$. Ca(s) reacts with water to produce the same products. Na(s) reacts with water to form NaOH and $H_2(g)$. *Without doing detailed calculations,* determine **(a)** which of these reactions produces the most H_2 per liter of water used, and **(b)** which solid—CaH_2, Ca, or Na—produces the most $H_2(g)$ *per gram* of the solid.

76. What volume of $H_2(g)$ at 25 °C and 752 mmHg is required to hydrogenate oleic acid, $C_{17}H_{33}COOH(l)$, to produce one mole of stearic acid, $C_{17}H_{35}COOH(s)$? Assume reaction (22.52) proceeds with a 95% yield.

77. *Without doing detailed calculations,* explain in which of the following materials you would expect to find the greatest mass percent of hydrogen: seawater, the atmosphere, natural gas (CH_4), ammonia.

78. How many grams of $CaH_2(s)$ are required to generate sufficient $H_2(g)$ to fill a 235 L weather observation balloon at 722 mmHg and 19.7 °C?

$$CaH_2(s) + 2\,H_2O(l) \longrightarrow Ca(OH)_2(aq) + 2\,H_2(g)$$

79. The amide anion NH_2^- is a very strong base. On the basis of molecular orbital theory, would you expect NH_2^- to be linear or bent?

80. On the basis of molecular orbital theory, would you expect NH_2^+ to be linear or bent?

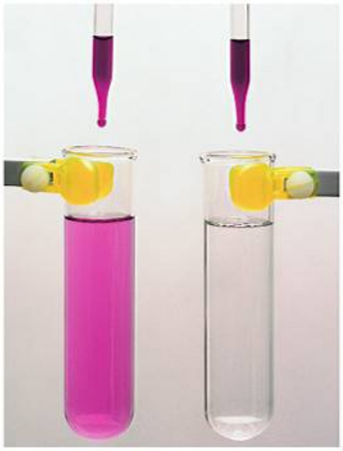
Integrative and Advanced Exercises

81. The boiling points of oxygen and argon are −183 °C and −189 °C, respectively. Because the boiling points are so similar, argon obtained from the fractional distillation of liquid air is contaminated with oxygen. The following three-step procedure can be used to obtain pure argon from the oxygen-contaminated sample:
(1) Excess hydrogen is added to the mixture and then the mixture is ignited.
(2) The mixture from step (1) is then passed over hot copper(II) oxide.
(3) The mixture from step (2) is passed over a dehydrated zeolite material (see Chapter 21).
Explain the purpose of each step, writing chemical equations for any reactions that occur.

82. In 1988, G. J. Schrobilgen, professor of chemistry at McMaster University in Canada, reported the synthesis of an ionic compound, $[HCNKrF][AsF_6]$, which consists of $HCNKrF^+$ and AsF_6^- ions. In the $HCNKrF^+$ ion, the krypton is covalently bonded to both fluorine and nitrogen. Draw Lewis structures for these ions, and estimate the bond angles.

83. Suppose that no attempt is made to separate the $H_2(g)$ and $O_2(g)$ produced by the electrolysis of water. What volume of a $H_2—O_2$ mixture, saturated with $H_2O(g)$ and collected at 23 °C and 755 mmHg, would be produced by electrolyzing 17.3 g water? Assume that the water vapor pressure of the dilute electrolyte solution is 20.5 mmHg.

84. The photograph was taken after a few drops of a deep-purple acidic solution of $KMnO_4(aq)$ were added to $NaNO_3(aq)$ (left) and to $NaNO_2(aq)$ (right). Explain the difference in the results shown.



85. Zn can reduce NO_3^- to $NH_3(g)$ in basic solution. (The following equation is not balanced.)

$$NO_3^-(aq) + Zn(s) + OH^-(aq) + H_2O(l) \longrightarrow [Zn(OH)_4]^{2-}(aq) + NH_3(g)$$

The NH_3 can be neutralized with an excess of HCl(aq). Then, the unreacted HCl can be titrated with NaOH. In this way a quantitative determination of NO_3^- can be achieved. A 25.00 mL sample of nitrate solution was treated with zinc in basic solution. The $NH_3(g)$ was passed into 50.00 mL of 0.1500 M HCl. The excess HCl required 32.10 mL of 0.1000 M NaOH for its titration. What was the $[NO_3^-]$ in the original sample?

86. Oxygen atoms are an important constituent of the thermosphere, a layer of the atmosphere with temperatures up to 1500 K. Calculate the average translational kinetic energy of O atoms at 1500 K.

87. One reaction for the production of adipic acid, $HOOC(CH_2)_4COOH$, used in the manufacture of nylon, involves the oxidation of cyclohexanone, $C_6H_{10}O$, in a nitric acid solution. Assume that dinitrogen monoxide is also formed, and write a balanced equation for this reaction.

88. Despite the fact that it has the higher molecular mass, XeO_4 exists as a gas at 298 K, whereas XeO_3 is a solid. Give a plausible explanation for this observation.

89. The text mentions that ammonium perchlorate is an explosion hazard. Assuming that NH_4ClO_4 is the sole reactant in the explosion, write a plausible equation(s) to represent the reaction that occurs.

90. The following bond energies are given for 298 K: O_2, 498; N_2, 946; F_2, 159; Cl_2, 243; ClF, 251; OF (in OF_2), 213; ClO (in Cl_2O), 205; and NF (in NF_3), 280 kJ mol^{-1}. Calculate ΔH_f° at 298 K for 1 mol of **(a)** ClF(g); **(b)** $OF_2(g)$; **(c)** $Cl_2O(g)$; **(d)** $NF_3(g)$.

91. The standard electrode potential of fluorine cannot be measured directly because F_2 reacts with water, displacing O_2. Using thermodynamic data from Appendix D, obtain a value of $E^\circ_{F_2/F^-}$.

92. Polonium is the only element known to crystallize in the simple cubic form. In this structure, the interatomic distance between a Po atom and each of its six nearest neighbors is 335 pm. Use this description of the crystal structure to estimate the density of polonium.

93. Refer to Figure 11-26 to arrange the following species in the expected order of increasing **(a)** bond length and **(b)** bond strength (energy): $O_2, O_2^+, O_2^-, O_2^{2-}$. State the basis of your expectation.

94. One reaction of a chlorofluorocarbon implicated in the destruction of stratospheric ozone is $CFCl_3 + h\nu \longrightarrow CFCl_2 + Cl$.

(a) What is the energy of the photons $(h\nu)$ required to bring about this reaction, expressed in kilojoules per mole?

(b) What is the frequency and wavelength of the light necessary to produce the reaction? In what portion of the electromagnetic spectrum is this light found?

95. The composition of a phosphate mineral can be expressed as % P, % P_4O_{10}, or % BPL [bone phosphate of lime, $Ca_3(PO_4)_2$].

(a) Show that % P = 0.436 × (% P_4O_{10}) and % BPL = 2.185 × (% P_4O_{10}).

(b) What is the significance of a % BPL greater than 100?

(c) What is the % BPL of a typical phosphate rock?

96. Estimate the percent dissociation of $Cl_2(g)$ into Cl(g) at 1 atm total pressure and 1000 K. Use data from Appendix D and equations found elsewhere in this text, as necessary.

97. *Peroxonitrous acid* is an unstable intermediate formed in the oxidation of HNO_2 by H_2O_2. It has the same formula as *nitric acid*, HNO_3. Show how you would expect peroxonitrous and nitric acids to differ in structure.

98. The structure of $N(SiH_3)_3$ involves a planar arrangement of N and Si atoms, whereas that of the related compound $N(CH_3)_3$ has a pyramidal arrangement of N and C atoms. Propose bonding schemes for these molecules that are consistent with this observation.

99. In the extraction of bromine from seawater (reaction 22.3), seawater is first brought to a pH of 3.5 and then treated with $Cl_2(g)$. In practice, the pH of the seawater is adjusted with H_2SO_4, and the mass of chlorine used is 15% in excess of the theoretical. Assuming a seawater sample with an initial pH of 7.0, a density of 1.03 g cm^{-3}, and a bromine content of 70 ppm by mass, what masses of H_2SO_4 and Cl_2 would be used in the extraction of bromine from 1.00×10^3 L of seawater?

100. Refer to the Integrative Example on page 1022. Assume that the disproportionation of $S_2O_3^{2-}$ is no longer spontaneous when the partial pressure of $SO_2(g)$ above a solution with $[S_2O_3^{2-}] = 1$ M has dropped to 1×10^{-6} atm. Show that this condition is reached while the solution is still acidic.

101. The bond energies of Cl_2 and F_2 are 243 and 159 kJ mol^{-1}, respectively. Use these data to explain why XeF_2 is a much more stable compound than $XeCl_2$. [*Hint:* Recall that Xe exists as a monatomic gas.]

102. Write plausible half-equations and a balanced oxidation–reduction equation for the disproportionation of XeF_4 to Xe and XeO_3 in aqueous acidic solution. Xe and XeO_3 are produced in a 2:1 mol ratio, and $O_2(g)$ is also produced.

103. A handbook gives the value $E^\circ = 0.174$ V for the reduction half-reaction $S + 2H^+ + 2e^- \longrightarrow H_2S(g)$. In Figure 22-13, the value given for the segment $S—H_2S(aq)$ is 0.144 V. Why are these E° values different? Can both be correct?

104. The solubility of $Cl_2(g)$ in water is 6.4 g L^{-1} at 25 °C. Some of this chlorine is present as Cl_2, and some is found as HOCl or Cl^-. For the hydrolysis reaction

$$Cl_2(aq) + 2H_2O(l) \longrightarrow HOCl(aq) + H_3O^+(aq) + Cl^-(aq) \qquad K_c = 4.4 \times 10^{-4}$$

For a saturated solution of Cl_2 in water, calculate $[Cl_2]$, $[HOCl]$, $[H_3O^+]$, and $[Cl^-]$.

105. Not shown in Figure 22-17 are electrode potential data involving hydrazoic acid. Given that $E^\circ = -3.09$ V for the reduction of HN_3 to N_2 in acidic solution, what is E° for the reduction of HN_3 to NH_4^+ in acidic solution?

106. The heavier halogens (Cl, Br, and I) form compounds in which the central halogen atom, X, is bonded directly to oxygen and to fluorine. Several examples are known, including those with formulas of the type FXO_2, FXO_3, and F_3XO. The structures of these molecules are all consistent with the VSEPR model. Draw Lewis structures and predict the geometries of **(a)** chloryl fluoride, $FClO_2$; **(b)** perchloryl fluoride, $FClO_3$; **(c)** F_3ClO.

107. Draw Lewis structures for O_3 and SO_2. In what ways are the structures similar? In what ways do they differ?

108. Chemists have successfully synthesized the ionic compound $[N_5][SbF_6]$, which consists of N_5^+ and SbF_6^- ions. Draw Lewis structures for these ions and assign formal charges to the atoms in your structures. Describe the structures of these ions. [*Hint:* The skeleton structure for N_5^+ is N—N—N—N—N and several resonance structures can be drawn.]

109. Refer to Figure 22-3 and then construct an enthalpy diagram for forming $XeO_3(g)$ from Xe(g) and $O_2(g)$. For XeO_3, the average bond enthalpy is about 36 kJ mol^{-1}, and for O_2, the bond enthalpy is 498 kJ mol^{-1}. What is ΔH_f° for $XeO_3(g)$? Does your result support the observation that Xe(g) does not react directly with $O_2(g)$ to form $XeO_3(g)$?

Feature Problems

110. Various thermochemical cycles are being explored as possible sources of $H_2(g)$. The object is to find a series of reactions that can be conducted at moderate temperatures (about 500 °C) and that results in the decomposition of water into H_2 and O_2. Show that the following series of reactions meets these requirements.

$$FeCl_2 + H_2O \longrightarrow Fe_3O_4 + HCl + H_2$$
$$Fe_3O_4 + HCl + Cl_2 \longrightarrow FeCl_3 + H_2O + O_2$$
$$FeCl_3 \longrightarrow FeCl_2 + Cl_2$$

111. The decomposition of aqueous hydrogen peroxide is catalyzed by $Fe^{3+}(aq)$. A proposed mechanism for this catalysis involves two reactions. In the first reaction, Fe^{3+} is reduced by H_2O_2. In the second, the iron is oxidized back to its original form, while hydrogen peroxide is reduced. Write an equation for the overall reaction and show that the overall reaction is indeed spontaneous. What are the minimum and maximum values of E° for a catalyst to function in this way? Which of the following should be able to catalyze the decomposition of hydrogen peroxide by the mechanism outlined here: **(a)** Cu^{2+}; **(b)** Br_2; **(c)** Al^{3+}; **(d)** Au^{3+}? In the reaction between iodic acid and hydrogen peroxide in the presence of starch indicator, the color of the reaction mixture oscillates between deep blue and colorless. What is the basis of these changes in color? Will this oscillation of color continue indefinitely? Explain. [*Hint:* Refer to Problem 97 in Chapter 14, particularly to equation (c).]

112. Both in this chapter and in Chapter 20, we have stressed the relationship between E° values and thermodynamic properties. We can use this relationship to add some missing features to an electrode potential diagram. For example, note that $ClO_2(g)$, which has Cl in the oxidation state +4, is not included in Figure 22-4. Using data from Figure 22-4 and Appendix D, add $ClO_2(g)$ to the electrode potential diagram for acidic solutions, and indicate the E° values that link $ClO_2(g)$ to $ClO_3^-(aq)$ and to $HClO_2(aq)$.

113. Figure 15-1 (page 656) shows that I_2 is considerably more soluble in $CCl_4(l)$ than it is in $H_2O(l)$. The concentration of I_2 in its saturated aqueous solution is 1.33×10^{-3} M, and the equilibrium achieved when I_2 distributes itself between H_2O and CCl_4 is

$$I_2(aq) \rightleftharpoons I_2(CCl_4) \qquad K_c = 85.5$$

(a) A 10.0 mL sample of saturated $I_2(aq)$ is shaken with 10.0 mL CCl_4. After equilibrium is established, the two liquid layers are separated. How many milligrams of I_2 will be in the aqueous layer?
(b) If the 10.0 mL of aqueous layer from part (a) is extracted with a second 10.0 mL portion of CCl_4, how many milligrams of I_2 will remain in the aqueous layer when equilibrium is reestablished?
(c) If the 10.0 mL sample of saturated $I_2(aq)$ in part (a) had originally been extracted with 20.0 mL CCl_4, would the mass of I_2 remaining in the aqueous layer have been less than, equal to, or greater than that in part (b)? Explain.

114. The so-called pyroanions, $X_2O_7{}^{n-}$, form a series of structurally similar polyatomic anions for the elements Si, P, and S.
(a) Draw the Lewis structures of these anions, and predict the geometry of the anions. What is the maximum number of atoms that can lie in a plane?
(b) Each pyroanion in part (a) corresponds to a pyroacid, $X_2O_7H_n$. Compare each pyroacid to the acid containing only one atom of the element in its maximum oxidation state. From this comparison, suggest a strategy for the preparation of these pyroacids.
(c) What is the chlorine analogue of the pyroanions? For which acid is this species the anhydride?

115. A description of bonding in XeF_2 based on the valence bond model requires the 5*d* orbitals of Xe. A more satisfactory description uses a molecular orbital approach involving three-center bonds. Assume that bonding involves the $5p_z$ orbital of Xe and the $2p_z$ orbitals of the two F atoms. These three atomic orbitals combine to give three molecular orbitals: one bonding, one nonbonding, and one antibonding. Recall that for bonding to occur, atomic orbitals with the same phase must overlap to form bonding molecular orbitals (see Chapter 11).
(a) Construct diagrams similar to Figure 11-33 to indicate the overlap of the three atomic orbitals in

forming the three molecular orbitals. Assume that the order of energy of the molecular orbitals is bonding MO < nonbonding MO < antibonding MO.

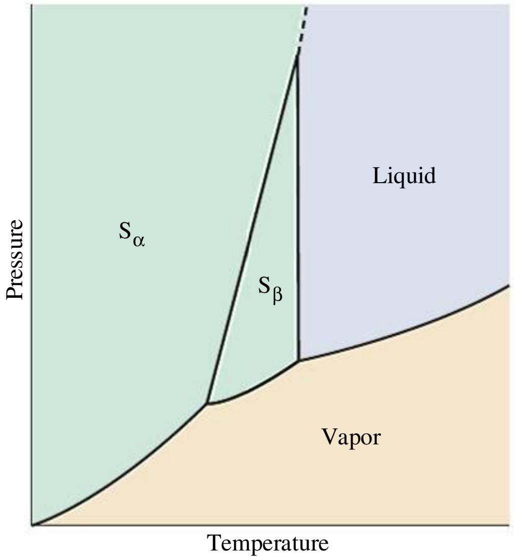
(b) Sketch a molecular orbital energy-level diagram, and assign the appropriate number of electrons from fluorine and xenon to the molecular orbitals. What is the bond order?

(c) With the aid of VSEPR theory, show that this molecular orbital description based on three-center bonds works well for XeF_4 but not for XeF_6.

116. The sketch is a portion of the phase diagram for the element sulfur. The transition between solid orthorhombic (S_α) and solid monoclinic (S_β) sulfur, in the presence of sulfur vapor, is at 95.3 °C. The triple point involving monoclinic sulfur, liquid sulfur, and sulfur vapor is at 119 °C.

(a) How would you modify the phase diagram to represent the melting of orthorhombic sulfur that is sometimes observed at 113 °C? [*Hint:* What would the phase diagram look like if the monoclinic sulfur did not form?]

(b) Account for the observation that if a sample of rhombic sulfur is melted at 113 °C and then heated, the liquid sulfur freezes at 119 °C upon cooling.



Self-Assessment Exercises

117. In your own words, define the following terms: **(a)** polyhalide ion; **(b)** polyphosphate; **(c)** interhalogen; **(d)** disproportionation.

118. Briefly describe each of the following terms: **(a)** Frasch process; **(b)** water gas reactions; **(c)** eutrophication; **(d)** electrode potential diagram.

119. Explain the important distinctions between each pair of terms: **(a)** acid salt and acid anhydride; **(b)** azide and nitride; **(c)** white phosphorus and red phosphorus; **(d)** ionic hydride and metallic hydride.

120. To displace Br_2 from an aqueous solution of Br^-, add **(a)** $I_2(aq)$; **(b)** $Cl_2(aq)$; **(c)** $H_2(g)$; **(d)** $Cl^-(aq)$; **(e)** $I_3^-(aq)$.

121. All of the following compounds yield $O_2(g)$ when heated to about 1000 K except **(a)** $KClO_3$; **(b)** $KClO_4$; **(c)** N_2O; **(d)** $CaCO_3$; **(e)** $Pb(NO_3)_2$.

122. All of the following substances are bases except for **(a)** H_2NNH_2; **(b)** NH_3; **(c)** HN_3; **(d)** NH_2OH; **(e)** CH_3NH_2.

123. The best reducing agent of the following substances is **(a)** H_2S; **(b)** O_3; **(c)** H_2SO_4; **(d)** NaF; **(e)** H_2O.

124. Of the following substances the one that is unimportant is the production of fertilizers is **(a)** NH_3; **(b)** phosphate rock; **(c)** HNO_3; **(d)** Na_2CO_3; **(e)** H_2SO_4.

125. All of the following have a tetrahedral shape except **(a)** SO_4^{2-}; **(b)** XeF_4; **(c)** CCl_4; **(d)** XeO_4; **(e)** NH_4^+.

126. Two of the following, through a reaction occurring in a weakly acidic solution, produce the same gaseous product. They are **(a)** $CaH_2(s)$; **(b)** $Na_2O_2(s)$; **(c)** NaOH(s); **(d)** Al(s); **(e)** $NaHCO_3(s)$; **(f)** $N_2H_4(l)$

127. Write a plausible chemical equation to represent the reaction of **(a)** $Cl_2(g)$ with cold NaOH(aq); **(b)** NaI(s) with hot H_2SO_4(concd aq); **(c)** $Cl_2(g)$ with $KI_3(aq)$; **(d)** NaBr(s) with hot H_3PO_4 (concd aq); **(e)** $NaHSO_3(aq)$ with $MnO_4^-(aq)$ in dilute $H_2SO_4(aq)$.

128. Give a practical laboratory method that you might use to produce small quantities of the following gases and comment on any difficulties that might arise: **(a)** O_2; **(b)** NO; **(c)** H_2; **(d)** NH_3; **(e)** CO_2.

129. Complete and balance equations for these reactions.

(a) $LiH(s) + H_2O(l) \longrightarrow$

(b) $C(s) + H_2O(g) \xrightarrow{\Delta}$

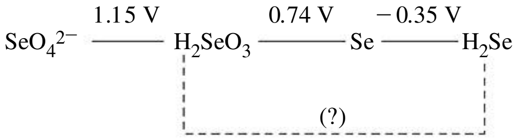
(c) $NO_2(g) + H_2O(l) \longrightarrow$

130. If Br^- and I^- occur together in an aqueous solution, I^- can be oxidized to IO_3^- with an excess of $Cl_2(aq)$. Simultaneously, Br^- is oxidized to Br_2, which is extracted with $CS_2(l)$. Write chemical equations for the reactions that occur.

131. Suppose that the sulfur present in seawater as SO_4^{2-} (2650 mg L^{-1}) could be recovered as elemental sulfur. If this sulfur were then converted to H_2SO_4, how many cubic kilometers of seawater would have to be processed to yield the average U.S. annual consumption of about 45 million tons of H_2SO_4?

132. Although relatively rare, all of the following compounds exist. Based on what you know about related compounds (for example, from the periodic table), propose a plausible name or formula for each compound: **(a)** silver(I) astatide; **(b)** Na_4XeO_6; **(c)** magnesium polonide; **(d)** H_2TeO_3; **(e)** potassium thioselenate; **(f)** $KAtO_4$.

133. A portion of the standard electrode potential diagram of selenium is given below. What is the $E°$ value for the reduction of H_2SeO_3 to H_2Se?



134. What is the acid anhydride of **(a)** H_2SO_4; **(b)** H_2SO_3; **(c)** $HClO_4$; **(d)** HIO_3?

135. Use the following electrode potential diagram for basic solutions to classify each of the statements below as true or false. Assume standard conditions.

$$SO_4^{2-} \xrightarrow{-0.936\text{ V}} SO_3^{2-} \xrightarrow{-0.576\text{ V}}$$

$$S_2O_3^{2-} \xrightarrow{-0.74\text{ V}} S \xrightarrow{-0.476\text{ V}} S^{2-}$$

(a) Sulfate (SO_4^{2-}) is a stronger oxidant than thiosulfate ($S_2O_3^{2-}$) in basic solution.

(b) S^{2-} can be used as a reducing agent in basic solutions.

(c) $S_2O_3^{2-}$ is stable with respect to disproportionation to SO_3^{2-} and S in basic solution.

The Transition Elements

Whiskers of rutile, TiO_2, in quartz (left) and titanium ore (right), a source of rutile. Titanium metal, obtained from rutile, is used in industry because it has low density and high strength. Pure TiO_2 is a bright white pigment used in paints and specialty papers.

There are more transition elements—members of the *d* and *f* blocks—than main-group elements. Although some of the transition elements are rare and of limited use, others play crucial roles in many aspects of modern life. All the transition elements are metals; among them are both the chief structural metal, iron (Fe), and important alloying metals in the manufacture of steel (V, Cr, Mn, Co, Ni, Mo, W). The best electrical conductors (Ag, Cu) are transition metals. The compounds of several transition metals (Ti, Fe, Cr) are the primary constituents of paint pigments. Compounds of silver (Ag) provide the essential material for photographic film. Specialized materials for modern applications, such as color television screens, use compounds of the *f*-block elements (lanthanide oxides). Nine of the transition metals are essential elements for living organisms.

The chemistry of the *d*-block and *f*-block elements has both theoretical and practical significance. These elements and their compounds provide insight into fundamental aspects of bonding, magnetism, and reaction chemistry.

23-1 General Properties

The high melting points, good electrical conductivity, and moderate-to-extreme hardness of the transition elements result from the ready availability of electrons and orbitals for metallic bonding (see Section 11-7). Some similarities are found among the transition elements, but each element also has some unique properties that make it and its compounds useful in particular ways. Table 23.1 lists properties of the fourth-period transition elements—the first transition series.

Atomic (Metallic) Radii

In Table 23.1, with the exception of Sc and Ti, we find little variation among the atomic radii across the first transition series. The chief difference in atomic structure between successive elements involves one unit of positive charge on the nucleus and one electron in an orbital of an *inner* electron shell. This is not a major difference and does not cause much of a change in atomic radius, especially in the middle of the series.

When an element of the first transition series is compared with elements of the second and third series within the same group, important differences appear. Consider the members of group 6—Cr, Mo, and W. As we might expect, the atomic radius of Mo is larger than that of Cr; but contrary to our expectation, the atomic radius of W is the same as that of Mo, not larger. In the aufbau process, 18 electrons are added in progressing from Cr to Mo, and all of them enter *s*, *p*, and *d* subshells. Between Mo and W, however, 32 electrons must be added, and 14 of them enter the $4f$ subshell. Electrons in an f subshell are not very effective in screening outer-shell electrons from the nucleus. As a result, the outer-shell electrons are held more tightly by the nucleus than we would otherwise expect. Atomic radii do not increase. In fact, in the series of elements in which the $4f$ subshell is filled, atomic radii decrease somewhat. This phenomenon occurs in the lanthanide series ($Z = 58$ to 71) and is called the **lanthanide contraction**. The lanthanide contraction is made more apparent in the graphs in Figure 23-1.

◀ FIGURE 23-1
Atomic radii of the *d*-block elements
The radii of the fourth-period transition elements (blue) are smaller than those of the corresponding group members in the succeeding periods. This trend is not seen between the fifth-period (black) and sixth-period (red) members, illustrating the contraction in atomic radii associated with the lanthanide series.

Electron Configurations and Oxidation States

The elements of the first transition series have electron configurations with the following characteristics:

- an inner core of electrons in the argon configuration
- two electrons in the 4s orbital for eight members and one 4s electron for the remaining two (Cr and Cu)
- a number of 3*d* electrons, ranging from one in Sc to ten in Cu and Zn

As we have seen for some of the main-group elements in Chapters 21 and 22, an element may display several oxidation states. Often, however, one particular oxidation state is the most common for an element. Ti atoms, with the electron configuration $[\mathrm{Ar}]3d^2 4s^2$, tend to use all four electrons beyond the argon core in compound formation and display the oxidation state +4. It is also possible, however, for Ti atoms to use fewer electrons, as through the loss of the $4s^2$ electrons to form the ion Ti^{2+}. With Ti, then, we note two features: (1) several possible oxidation states, as shown in Figure 23-2, and (2) a maximum oxidation state corresponding to the group number, 4. These two features continue with V, Cr, and Mn, for which the maximum oxidation states are +5, +6 and +7, respectively. A shift in behavior occurs in groups 8–12, however. Thus, although Fe, Co, and Ni can all exist in more than one oxidation state, they do not display the wide variety found in the earlier members of the first transition series. Nor do they exhibit a maximum oxidation state corresponding to their group number. In crossing the first transition series, the nuclear charge, number of *d* electrons, and energy requirement for the successive ionization of d electrons increase. Involvement of a large number of *d* electrons in bond formation becomes increasingly unfavorable energetically, and only the lower oxidation states are commonly encountered for these later elements of the first transition series.

Although the transition elements display a variety of oxidation states, they differ in the ease with which these oxidation states can be attained and in their stabilities. The stability of an oxidation state for a given transition metal depends on a number of factors—other atoms to which the transition metal atom is bonded; whether the compound is in solid form or in solution; and the pH of the solution. For example, $\mathrm{TiCl_2}$ is a well-characterized compound as a solid, but the Ti^{2+} ion is oxidized to Ti^{3+} by dissolved oxygen in aqueous solutions and even by the water itself. Conversely, $\mathrm{Co}^{3+}(\mathrm{aq})$ readily oxidizes water to $\mathrm{O_2(g)}$ and is itself reduced to $\mathrm{Co}^{2+}(\mathrm{aq})$. $\mathrm{Co}^{3+}(\mathrm{aq})$ can be stabilized, however, in certain

▶ FIGURE 23-2
Positive oxidation states of the elements of the first transition series
Common oxidation states are shown in red and less common ones in gray. Some oxidation states are rather rare, and a zero or negative oxidation state is occasionally found, chiefly in transition metal complexes. For example, the oxidation state of Cr is −2 in $Na_2[Cr(CO)_5]$, −1 in $Na_2[Cr_2(CO)_{10}]$, and 0 in $Cr(CO)_6$.

complex ions. Generally speaking, higher oxidation states in transition metals are stabilized when oxide or fluoride ions are bound to the metal. In Figure 23-2 and elsewhere, the term *common* oxidation state refers to an oxidation state often found in aqueous solution.

Another feature of the transition metals is the progressively increasing stability of higher oxidation states in descending a group of the periodic table, the reverse of the trend often seen for main-group elements. Consider Cr, Mo, and W in group 6, all of which can exhibit oxidation states ranging from +6 to −2. The number of compounds with Cr in the +6 oxidation state is rather limited, whereas those of Mo and W abound. Chromium is encountered in the oxidation states +5 and +4 mostly in unstable intermediates, whereas Mo and W exhibit a rich chemistry in these states. The most stable oxidation state of chromium is +3. Although it is a strong reducing agent, $Cr^{2+}(aq)$ nevertheless is readily obtainable, whereas Mo and W are not obtainable as the simple +2 cation. This trend favoring lower oxidation states for the first group member and higher oxidation states for the later members is also found in other groups of transition metals. For instance, although Fe does not exhibit an oxidation state corresponding to the group number, Os does form the stable oxide OsO_4 with Os in the +8 oxidation state.

Ionization Energies and Electrode Potentials

Ionization energies are fairly constant across the first transition series. Values of the first ionization energies are about the same as for the group 2 metals. Standard electrode potentials gradually increase in value across the series. With the exception of the oxidation of Cu to Cu^{2+}, however, all these elements are more readily oxidized than hydrogen. This means that the metals displace $H_2(g)$ from $H^+(aq)$. Additional comments on electrode potentials, some supported by electrode potential diagrams, are found throughout the chapter.

Ionic and Covalent Compounds

We tend to think of metals as forming ionic compounds with nonmetals. This is certainly the case with group 1 and most group 2 metal compounds. However, some metal compounds have significant covalent character; $BeCl_2$ and $AlCl_3(Al_2Cl_6)$, for example, are molecular compounds. Transition metal compounds display both ionic and covalent character. In general, compounds with the transition metal in lower oxidation states are essentially ionic, while those in higher oxidation states have covalent character. As an example, MnO is a green ionic solid with a melting point of 1785 °C, whereas Mn_2O_7 is a dark red, oily, molecular liquid that boils at room temperature and is highly explosive. Another feature of ionic compounds of the transition

▶ The oxidation state of manganese is +7 in Mn_2O_7. The bonding in this compound is not ionic, because an ion with a charge of +7 would have a very high charge density and would be strongly polarizing. Mn_2O_7 is a molecular compound with covalent bonds between Mn and O atoms.

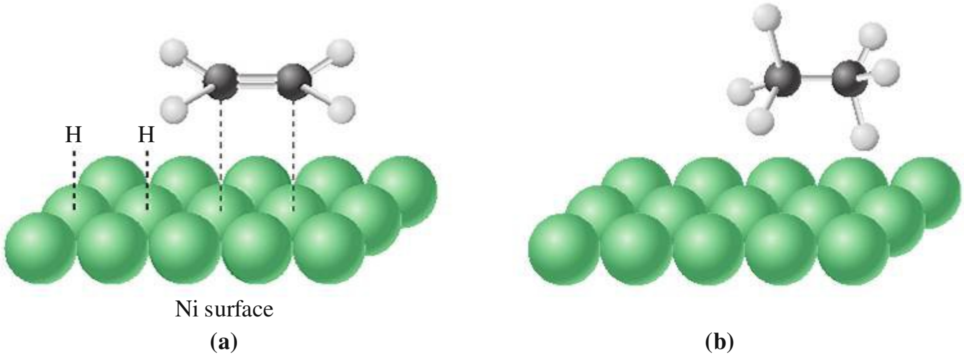
metals is that the metal atoms often occur in polyatomic cations or anions rather than as the simple monatomic ion. Some common examples are VO_2^+, MnO_4^-, and $Cr_2O_7^{2-}$.

Catalytic Activity

An unusual ability to adsorb gaseous species makes some transition metals, such as Ni and Pt, good heterogeneous catalysts. The possibility of multiple oxidation states seems to account for the ability of some transition metal ions to serve as catalysts in certain oxidation–reduction reactions. In still other types of catalysis, complex-ion formation may play an important role. As we saw in a limited way in Chapter 18 and will explore more fully in Chapter 24, complex-ion formation is a particularly distinctive feature of transition metal chemistry.

Catalysis is an essential aspect of about 90% of all chemical manufacturing processes, and the transition metals are often the key elements in the catalysts used. For example, Ni is used in the hydrogenation of oils (page 1019); Pt, Pd, and Rh are used in catalytic converters in automobiles (page 636); Fe_3O_4 is the main component of the catalyst used in the synthesis of ammonia (Focus On 15, www.masteringchemistry.com) and V_2O_5 is used in the conversion of $SO_2(g)$ to $SO_3(g)$ in the manufacture of sulfuric acid (page 1001).

Transition metal catalysts are used in both homogeneous and heterogeneous catalysis. In homogeneous catalysis (page 637), the reactants, products, and catalyst are all in the same phase (often liquid or gas) and the transition metal is part of a compound or a complex. In homogeneous catalysis, the transition metal atoms or ions serve as electron banks that lend out electrons at the appropriate time or store them for later use. In heterogeneous catalysis (page 638), the catalyst is in a different phase from the reactants or the products, and, typically, the catalyst provides a surface on which the reaction occurs. The hydrogenation of oils (page 1019) makes use of heterogeneous catalysis. The details concerning how a catalyst functions in a hydrogenation reaction depend not only on the metal used but also on the experimental conditions (for example, the amounts of reactants used and the temperature). In Figure 23-3, the events that are believed to occur in the hydrogenation of C_2H_4 are illustrated. A C_2H_4 molecule is adsorbed onto the metal surface, with electron density being transferred from the π bond in C_2H_4 to metal atoms in the surface (a Lewis acid–base reaction). Hydrogen molecules may also be adsorbed onto the surface near the C_2H_4 molecule, causing a weakening of the H—H bond. Hydrogen atoms are then transferred to the carbon atoms in the C_2H_4 molecule, producing C_2H_6 molecules, which detach from the metal surface.



▲ FIGURE 23-3
Schematic representation of the metal-catalyzed hydrogenation of C_2H_4
(a) H_2 and C_2H_4 molecules adsorb onto the metal surface, causing weakening of the H—H bond and the π bond in C_2H_4. **(b)** H atoms become bonded to carbon atoms, converting C_2H_4 to C_2H_6, which desorbs from the metal surface. The exact details of the mechanism are a matter of debate.

Color and Magnetism

▲ Color-enhanced image of magnetic domains in a ferromagnetic garnet film.

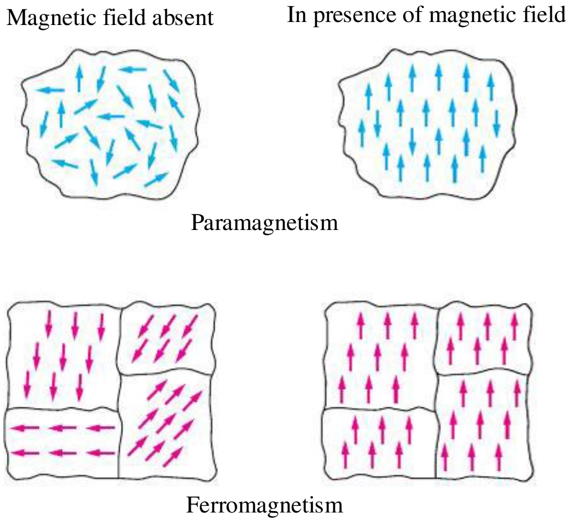
As we will explain in Section 24-6, the five *d* orbitals in a transition metal atom (or ion) do not all have the same energy when the atom is part of a compound. Electronic transitions that occur within the *d* orbitals impart color to transition compounds and their solutions. Consequently, transition metal compounds and their solutions exhibit a wide variety of colors.

Because most transition elements have partially filled *d* subshells, many transition metals and their compounds are paramagnetic—that is, they have unpaired electrons. This description certainly fits Fe, Co, and Ni, but these three metals are unique among the elements in displaying a special magnetic property: the ability to be made into permanent magnets, a property known as **ferromagnetism**. A key feature of ferromagnetism is that in the solid state, the metal atoms are thought to be grouped together into small regions—called *domains*—containing rather large numbers of atoms. Instead of the individual magnetic moments of the atoms within a domain being randomly oriented, all the magnetic moments are directed in the same way. In an unmagnetized piece of iron, the domains are oriented in several directions and their magnetic effects cancel. When the metal is placed in a magnetic field, however, the domains line up and a strong resultant magnetic effect is produced. This alignment of domains may actually involve the growth of domains with favorable orientations at the expense of those with unfavorable orientations (rather like a recrystallization of the material). The ordering of domains can persist when the object is removed from the magnetic field, and thus permanent magnetism results. Paramagnetism and ferromagnetism are compared in Figure 23-4.

The key factors in ferromagnetism are that (1) the atoms involved have unpaired electrons (a property possessed by many atoms), and (2) interatomic distances are of just the right magnitude to make possible the ordering of atoms into domains. If atoms are too large, interactions among them are too weak to produce this ordering. With small atoms, the tendency is for atoms to pair and their magnetic moments to cancel. This critical factor of atomic size is just met in Fe, Co, and Ni. It is possible, however, to prepare *alloys* of other metals in which this condition is also met. Some examples are Al–Cu–Mn, Ag–Al–Mn, and Bi–Mn.

Comparison of Transition and Main-Group Elements

With the main-group elements, the *s* and *p* orbitals of the outermost electron shell are the most important in determining the nature of the chemical bonding that occurs. Participation in bonding by *d* orbitals is essentially nonexistent for



▶ FIGURE 23-4
Ferromagnetism and paramagnetism compared
In a paramagnetic material, the effect of a magnetic field is to align the magnetic moments of the individual atoms. In a ferromagnetic material, the magnetic moments are aligned within domains even in the absence of a magnetic field, but the direction of the alignment varies from one domain to another. The effect of the magnetic field is to change the orientation of these varied alignments into a single direction—the direction of the magnetic field.

second-period elements and for group 1 and 2 metals. With the transition elements, *d* orbitals are as important as *s* and *p* orbitals. Most of the observed behavioral differences between the transition and main-group elements—multiple versus single oxidation states, complex-ion formation, color, magnetic properties, and catalytic activity—can be traced to the orbitals that are most involved in bond formation.

23-1 CONCEPT ASSESSMENT

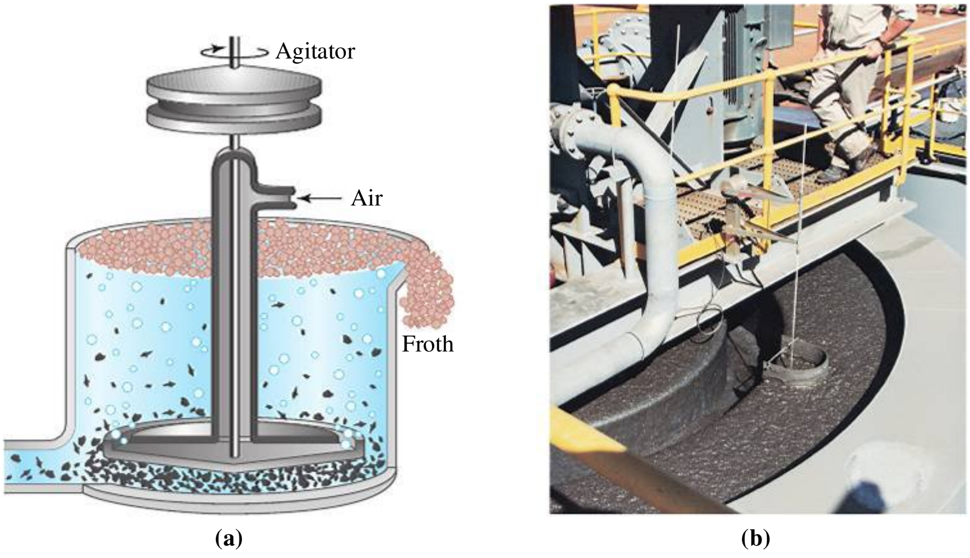
Why is +3 the most stable oxidation state for Fe, while it is +2 for Co and Ni?

23-2 Principles of Extractive Metallurgy

Many of the transition elements have important uses related to their metallic properties—iron for its structural strength and copper for its excellent electrical conductivity, for example. Unlike the more chemically reactive metals of groups 1 and 2 and aluminum in group 3, which are produced mainly by modern methods of electrolysis, the transition metals are obtained by procedures developed over many centuries.

The term *metallurgy* describes the general study of metals. **Extractive metallurgy** describes the winning of metals from their ores. There is no single method of extractive metallurgy, but a few basic operations generally apply. Let us illustrate them with the extractive metallurgy of zinc.

Concentration In mining operations, the desired mineral from which a metal is to be extracted often constitutes only a small percentage (or occasionally just a fraction of a percent) of the material mined. It is necessary to separate the desired ore from waste rock before proceeding with other metallurgical operations. One useful method, *flotation*, is described in Figure 23-5.



▲ FIGURE 23-5
Concentration of an ore by flotation
(a) Powdered ore is suspended in water in a large vat, together with suitable additives, and the mixture is agitated with air. Particles of ore become attached to air bubbles, rise to the top of the vat, and are collected in the overflow froth. Particles of undesired waste rock (gangue) fall to the bottom. **(b)** The froth formed in the flotation process.

Roasting An ore is roasted (heated to a high temperature) to convert a metal compound to its oxide, which can then be reduced. For zinc, the commercially important ores are $ZnCO_3$ (smithsonite) and ZnS (sphalerite). $ZnCO_3(s)$, like the carbonates of the group 2 metals, decomposes to ZnO(s) and $CO_2(g)$ when it is strongly heated. When strongly heated in air, ZnS(s) reacts with $O_2(g)$, producing ZnO(s) and $SO_2(g)$. In modern smelting operations, $SO_2(g)$ is converted to sulfuric acid rather than being vented to the atmosphere.

$$\mathrm{ZnCO_3(s) \xrightarrow{\Delta} ZnO(s) + CO_2(g)} \qquad \textbf{(23.1)}$$

$$\mathrm{2\,ZnS(s) + 3\,O_2(g) \xrightarrow{\Delta} 2\,ZnO(s) + 2\,SO_2(g)} \qquad \textbf{(23.2)}$$

Reduction Because it is inexpensive and easy to handle, carbon, in the form of coke or powdered coal, is used as the reducing agent whenever possible. Several reactions occur simultaneously in which both C(s) and CO(g) act as reducing agents. The reduction of ZnO is carried out at about 1100 °C, a temperature above the boiling point of zinc. The zinc is obtained as a vapor and condensed to the liquid.

$$\mathrm{ZnO(s) + C(s) \xrightarrow{\Delta} Zn(g) + CO(g)} \qquad \textbf{(23.3)}$$

$$\mathrm{ZnO(s) + CO(g) \xrightarrow{\Delta} Zn(g) + CO_2(g)} \qquad \textbf{(23.4)}$$

Refining The metal produced by chemical reduction is usually not pure enough for its intended uses. Impurities must be removed; that is, the metal must be refined. The refining process chosen depends on the nature of the impurities. The impurities in zinc are mostly Cd and Pb, which can be removed by the fractional distillation of liquid zinc.

Most of the zinc produced worldwide, however, is refined electrolytically, usually in a process that combines reduction and refining. ZnO from the roasting step is dissolved in $H_2SO_4(aq)$. This is represented by the ionic equation

$$\mathrm{ZnO(s) + 2\,H^+(aq) + SO_4{}^{2-}(aq) \longrightarrow Zn^{2+}(aq) + SO_4{}^{2-}(aq) + H_2O(l)} \qquad \textbf{(23.5)}$$

Powdered Zn is added to the solution to displace less active metals, such as Cd. Then the solution is electrolyzed. The electrode reactions are

▶ The sulfate anion is a spectator ion in this reaction and could be cancelled.

$$\begin{array}{lrcl}
\textit{Cathode:} & \mathrm{Zn^{2+}(aq) + 2\,e^-} & \longrightarrow & \mathrm{Zn(s)} \\
\textit{Anode:} & \mathrm{H_2O} & \longrightarrow & \mathrm{\tfrac{1}{2}O_2(g) + 2\,H^+(aq) + 2\,e^-} \\
\textit{Unchanged:} & \mathrm{SO_4{}^{2-}(aq)} & \longrightarrow & \mathrm{SO_4{}^{2-}(aq)} \\
\hline
\textit{Overall:} & \multicolumn{3}{l}{\mathrm{Zn^{2+}(aq) + SO_4{}^{2-}(aq) + H_2O(l) \longrightarrow}} \\
 & \multicolumn{3}{r}{\mathrm{Zn(s) + 2\,H^+(aq) + SO_4{}^{2-}(aq) + \tfrac{1}{2}O_2(g)} \quad \textbf{(23.6)}}
\end{array}$$

Note that in the overall electrolysis reaction, Zn^{2+} is reduced to pure metallic zinc and sulfuric acid is regenerated. The acid is recycled in reaction (23.5).

Zone Refining In discussing freezing-point depression (Section 13-8), we assumed that a solute is *soluble* in a liquid solvent and *insoluble* in the solid solvent that freezes from solution. This behavior suggests a particularly simple way to purify a solid: Melt the solid and then refreeze a portion of it. Impurities remain in the liquid phase, and the solid that freezes is pure. In practice, the method is not quite so simple because the solid that freezes is wet with unfrozen liquid and thereby retains some impurities. Also, one or more solutes (impurities) might be slightly soluble in the solid solvent. In any case, the impurities do distribute themselves between the solid and liquid, concentrating in the liquid phase. If the solid that freezes from a liquid is remelted and the molten material refrozen, the solid obtained in the second freezing is purer than that in the first. Repeating the melting and refreezing procedure hundreds of times produces a very pure solid product.

EXAMPLE 23-1 Writing Chemical Equations for Metallurgical Processes

Write chemical equations to represent the **(a)** roasting of galena, PbS; **(b)** reduction of $Cu_2O(s)$ with charcoal as a reducing agent; **(c)** deposition of pure silver from an aqueous solution of Ag^+.

Analyze

When answering these questions we have to make sure we understand the meaning of the terms *roasting*, *reduction*, and *deposition*; these terms have all been discussed in the text.

Solve

(a) We expect this process to be essentially the same as reaction (23.2).

$$2\,PbS(s) + 3\,O_2(g) \xrightarrow{\Delta} 2\,PbO(s) + 2\,SO_2(g)$$

(b) The simplest possible equation is

$$Cu_2O(s) + C(s) \xrightarrow{\Delta} 2\,Cu(l) + CO(g)$$

(c) The reduction half-reaction is

$$Ag^+(aq) + e^- \longrightarrow Ag(s)$$

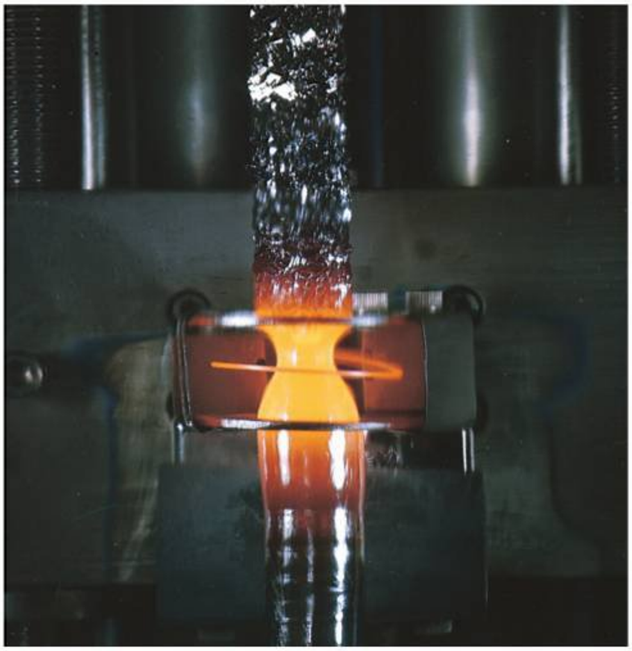
Assess

Roasting converts a metal sulfide to a metal oxide. When carbon is used as a reducing agent, CO(g) is produced, not $CO_2(g)$. The deposition of Ag(s) involves a reduction half-reaction. The accompanying oxidation half-reaction is not specified and neither is it specified whether this is an electrolysis process or whether silver is displaced by a more active metal, but these distinctions are not important in answering the question.

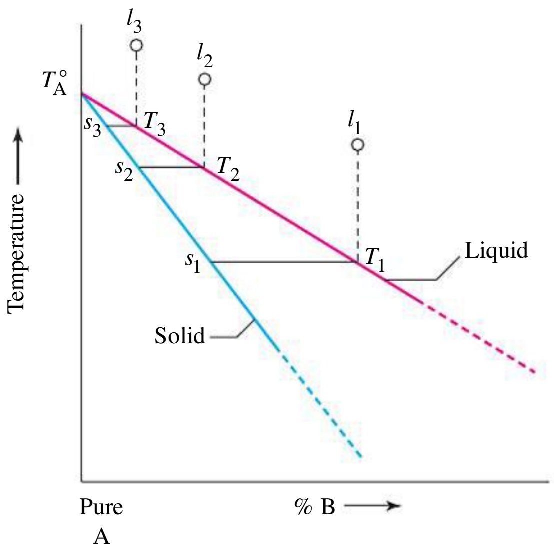
PRACTICE EXAMPLE A: Write plausible chemical equations to represent the **(a)** roasting of Cu_2S; **(b)** reduction of WO_3 with $H_2(g)$; **(c)** thermal decomposition of HgO to its elements.

PRACTICE EXAMPLE B: Write chemical equations to represent the **(a)** reduction of Cr_2O_3 to chromium with silicon as the reducing agent; **(b)** conversion of $Co(OH)_3(s)$ to $Co_2O_3(s)$ by roasting; **(c)** production of pure $MnO_2(s)$ from $MnSO_4(aq)$ at the anode in an electrolysis cell. [*Hint:* A few simple products are not specifically mentioned; propose plausible ones.]

The purification procedure just described implies that the melting and refreezing is done in batches, but in practice it is done *continuously*. In the method known as **zone refining**, a cylindrical rod of material is alternately melted and refrozen as a series of heating coils passes along the rod (Fig. 23-6). Impurities concentrate in the molten zones, and the portions of the rod behind



◀ FIGURE 23-6
Zone refining
As a heating coil moves up the rod of material, melting occurs. Impurities concentrate in the molten zone. The portion of the rod below the molten zone is purer than the portion in or above the molten zone. With each successive passage of the heating coil, the rod becomes purer.



▲ FIGURE 23-7
The principle of zone refining
The red line shows the freezing points of solutions of impurity B in substance A. The blue line gives the composition of the solid that freezes from these solutions. In some cases, the blue line is nearly coincident with the temperature axis. When a solution of composition l_1 is cooled to temperature T_1, it freezes to produce a solid of composition s_1. If a small quantity of this solid is removed from the solution and melted, it produces a new liquid, l_2. The freezing point of l_2 is T_2, and the composition of the solid freezing from the solution is s_2. When removed from the solution, a small portion of this solid produces liquid l_3 and so on. With each melting/freezing cycle, the melting point increases and the point representing the composition of the solid moves closer to pure A. In zone refining the melting/freezing cycles are conducted continuously, not in batches as described here.

these zones are somewhat purer than the portions in front of the zones. Eventually, impurities are swept to the end of the rod, which is cut off. The principle of zone refining is shown graphically in Figure 23-7. This process is capable of producing materials in which the impurity levels are as low as 10 parts per billion (ppb), a common requirement of substances used in semiconductors.

Thermodynamics of Extractive Metallurgy

It is interesting to think of the reduction of zinc oxide by carbon, as shown in reaction (23.3), as a competition between zinc and carbon for O atoms. Zinc has them initially in ZnO, and carbon acquires them in forming CO. To establish the conditions under which carbon will reduce zinc oxide to zinc, we start by comparing the relative tendencies for zinc and carbon to undergo oxidation. We can assess these tendencies through Gibbs energy changes.

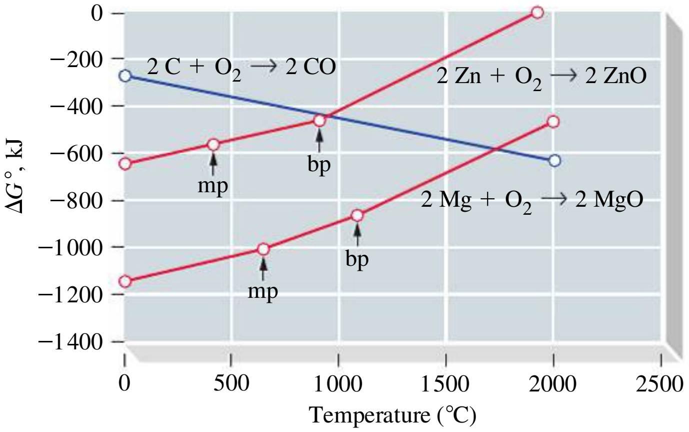
KEEP IN MIND

that a nonspontaneous process can sometimes be achieved by *coupling* with a spontaneous process. In the reduction of ZnO with C, the nonspontaneous $2\,ZnO \longrightarrow 2\,Zn + O_2$ is coupled with the spontaneous $2\,C + O_2 \longrightarrow 2\,CO$.

$$\begin{array}{llr} \text{(a)} & 2\,C(s) + O_2(g) \longrightarrow 2\,CO(g) & \Delta G^\circ_{(a)} \\ \text{(b)} & 2\,Zn(g) + O_2(g) \longrightarrow 2\,ZnO(s) & \Delta G^\circ_{(b)} \end{array}$$

To determine if the reduction of zinc oxide to zinc by carbon is a spontaneous reaction, we need the value of ΔG° for the overall reaction, represented below by reversing equation (b) and adding it to equation (a).

$$\begin{array}{llr} \text{(a)} & 2\,C(s) + O_2(g) \longrightarrow 2\,CO(g) & \Delta G^\circ_{(a)} \\ -\text{(b)} & 2\,ZnO(s) \longrightarrow 2\,Zn(s) + O_2(g) & -\Delta G^\circ_{(b)} \\ \hline \textit{Overall:} & 2\,ZnO(s) + 2\,C(s) \longrightarrow 2\,Zn(s) + 2\,CO(g) & \Delta G^\circ = \Delta G^\circ_{(a)} - \Delta G^\circ_{(b)} \end{array}$$



◀ FIGURE 23-8

$\Delta G°$ as a function of temperature for some reactions of extractive metallurgy

The points on the lines marked by arrows indicate the melting points and boiling points of Zn and Mg. At these points, the states of matter in which the metal exists change from (s) to (l) and from (l) to (g), respectively.

We still need some numerical data to complete our assessment. In Figure 23-8, the blue line gives $\Delta G°_{(a)}$ as a function of temperature, and the top red line gives $\Delta G°_{(b)}$.

Figure 23-8 shows that at low temperatures, $\Delta G°_{(b)}$ is much more negative than $\Delta G°_{(a)}$. This makes $\Delta G°$ for the overall reaction positive and the reaction *nonspontaneous*. At high temperatures, the situation is reversed: $\Delta G°_{(a)}$ is more negative than $\Delta G°_{(b)}$, and the overall reaction is *spontaneous*. The switchover from nonspontaneous to spontaneous occurs at the point of intersection of the blue line and the red line—about 950 °C. There, $\Delta G°$ for the overall reaction is *zero*.

When we make a similar assessment for the reduction $2\,MgO(s) + 2\,C(s) \longrightarrow 2\,Mg(g) + 2\,CO(g)$, we conclude that the reaction does not become spontaneous until a temperature in excess of 1700 °C is reached. This is an exceedingly high temperature at which to carry out a chemical reaction, and it is not used in the metallurgy of magnesium.

Alternative Methods in Extractive Metallurgy Some common variations of the methods previously discussed are worth mentioning. First, many ores contain several metals, and it is not always necessary to separate them. For example, a major use of vanadium, chromium, and manganese is in making alloys with iron. Obtaining each metal by itself is not commercially important. Thus, the principal chromium ore *chromite*, $Fe(CrO_2)_2$, can be reduced to give an alloy of Fe and Cr called *ferrochrome*. Ferrochrome may be added directly to iron, together with other metals, to produce one type of steel. Vanadium and manganese can be isolated as the oxides V_2O_5 and MnO_2, respectively. When iron-containing compounds are added to these oxides and the mixtures are reduced, ferrovanadium and ferromanganese alloys form.

23-1 ARE YOU WONDERING...

Why the slope of the blue line in Figure 23-8 is negative, whereas the other slopes are positive?

Recall from Chapter 19 that $\Delta G° = \Delta H° - T\,\Delta S°$ and that $\Delta H°$ does not change appreciably with temperature. Thus, the temperature variation of $\Delta G°$ is determined primarily by the $-T\,\Delta S°$ term. We expect $\Delta S°$ to be negative for the reaction $2\,Zn(s) + O_2(g) \longrightarrow 2\,ZnO(s)$, because a mole of gas is lost. The term $-T\,\Delta S°$ is *positive*, and $\Delta G°$ *increases* with temperature. Conversely, in the reaction $2\,C(s) + O_2(g) \longrightarrow 2\,CO(g)$, an additional mole of gas forms, resulting in a positive value of $\Delta S°$. As a consequence, $-T\,\Delta S°$ is *negative* and $\Delta G°$ *decreases* with temperature.

▲ Vacuum-distilled metallic titanium sponge produced by the Kroll process.

Extensive production of titanium was an important development of the latter half of the twentieth century, spurred first by the needs of the military and then by the aircraft industry. Steel is unsuitable as the structural metal for aircraft because it has a high density ($d = 7.8\ \text{g cm}^{-3}$). Aluminum has the advantage of a low density ($d = 2.70\ \text{g cm}^{-3}$), but it loses strength at high temperatures. For certain aircraft components, titanium is a good alternative to aluminum and steel because its density is moderately low ($d = 4.50\ \text{g cm}^{-3}$) and it does not lose strength at high temperatures.

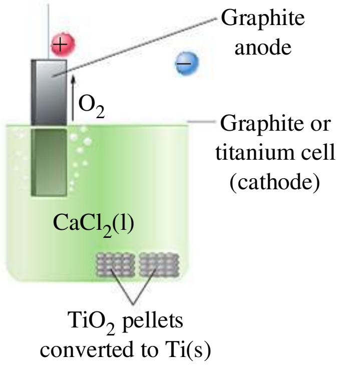
Titanium metal cannot be produced by reduction of TiO_2 with carbon because the metal and carbon react to form titanium carbides. Also, at high temperatures the metal reacts with air to form TiO_2 and TiN. The metallurgy of titanium, then, must be conducted out of contact with air and with an active metal rather than with carbon as a reducing agent.

The first step in the production of Ti is the conversion of *rutile* ore (TiO_2) to $TiCl_4$ by reaction with carbon and $Cl_2(g)$.

$$\mathrm{TiO_2(s) + 2\,C(s) + 2\,Cl_2(g) \xrightarrow{800\ °C} TiCl_4(g) + 2\,CO(g)} \qquad \textbf{(23.7)}$$

The purified $TiCl_4$ is next reduced to Ti with a good reducing agent. The *Kroll process* uses Mg.

$$\mathrm{TiCl_4(g) + 2\,Mg(l) \xrightarrow{1000\ °C} Ti(s) + 2\,MgCl_2(l)} \qquad \textbf{(23.8)}$$



Graphite anode
O$_2$
Graphite or titanium cell (cathode)
CaCl$_2$(l)
TiO$_2$ pellets converted to Ti(s)

▲ Electrolytic production of Ti(s) from $TiO_2(s)$.

The $MgCl_2(l)$ is removed and electrolyzed to produce Cl_2 and Mg, which are recycled in reactions (23.7) and (23.8), respectively. The Ti is obtained as a sintered (fused) mass called *titanium sponge*. This sponge must be subjected to further treatment and alloying with other metals before it can be used.

The Kroll process is slow; it takes a week to produce a few tons of Ti. It is also demanding in health and safety terms because it requires high-temperature vacuum distillation to remove the Mg and $MgCl_2$ from the titanium. Recently, an electrolytic process has been suggested for the production of Ti from rutile. Porous pellets of TiO_2 are placed at the cathode of an electrolytic cell containing molten calcium chloride. The pellets dissolve in the electrolyte and oxide ions (O^{2-}) are discharged as oxygen at a graphite anode. The Ti(IV) is reduced at the cathode, which is the vessel containing the electrolytic cell and is made of either graphite or titanium. The titanium metal is obtained as sponge. This method, devised by Derek Fray, George Chen, and Tom Farthing in the United Kingdom, is being developed as a commercial process for the production of Ti(s) at a substantially lower cost than the Kroll process.

▲ Slag formed during the smelting of copper one.

Metallurgy of Copper The extraction of copper from its ores (generally sulfides) is rather complicated, chiefly because the copper ores usually contain iron sulfides. The scheme of extractive metallurgy previously discussed produces copper contaminated with iron. For some metals, such as V, Cr, and Mn, contamination with iron is not a problem because the metals are mostly used in the manufacture of steel. Copper, however, is prized commercially for the properties of the pure metal. To avoid contamination with iron, several changes to the usual metallurgical methods are necessary.

Concentration of copper is done by flotation, and roasting converts iron sulfides to iron oxides. The copper remains as the sulfide if the temperature is kept below 800 °C. Smelting of the roasted ore in a furnace at 1400 °C causes the material to melt and separate into two layers. The bottom layer, called *copper matte*, consists chiefly of the molten sulfides of copper and iron. The top layer is a silicate slag formed by the reaction of oxides of Fe, Ca, and Al with SiO_2 (which typically is present in the ore or can be added). For example,

$$\mathrm{FeO(s) + SiO_2(s) \xrightarrow{\Delta} FeSiO_3(l)} \qquad \textbf{(23.9)}$$

A process called *conversion* is carried out in another furnace, where air is blown through the molten copper matte. First, the remaining iron sulfide is converted to the oxide, followed by formation of slag [$FeSiO_3(l)$]. The slag is poured off, and air is again blown through the furnace. The following reactions occur and yield a product that is about 98%–99% Cu:

$$2\,Cu_2S(l) + 3\,O_2(g) \xrightarrow{\Delta} 2\,Cu_2O(l) + 2\,SO_2(g) \qquad \textbf{(23.10)}$$

$$2\,Cu_2O(l) + Cu_2S(l) \xrightarrow{\Delta} 6\,Cu(l) + SO_2(g) \qquad \textbf{(23.11)}$$

The product of reaction (23.11) is called *blister copper* because frozen bubbles of $SO_2(g)$ are present. Blister copper can be used where high purity is not required (as in plumbing).

Refining blister copper to obtain high-purity copper is done electrolytically by the method outlined on page 901. High-purity copper is essential in electrical applications.

Pyrometallurgical Processes The metallurgical method based on roasting an ore, followed by reduction of the oxide to the metal, is called **pyrometallurgy**, the prefix *pyro-* suggesting that high temperatures are involved. Some of the characteristics of pyrometallurgy are as follows:

- large quantities of waste materials produced in concentrating low-grade ores
- high energy consumption to maintain high temperatures necessary for roasting and reduction of ores
- gaseous emissions that must be controlled, such as $SO_2(g)$ in roasting

Many of the metallurgical processes described earlier fall into this category.

Hydrometallurgical Processes In **hydrometallurgy**, the materials handled are water and aqueous solutions at moderate temperatures rather than dry solids at high temperatures. Generally, three steps are involved in hydrometallurgy:

1. *Leaching:* Metal ions are extracted (leached) from the ore by a liquid. Leaching agents include water, acids, bases, and salt solutions. Oxidation–reduction reactions may also be involved.
2. *Purification and concentration:* Impurities are separated, and the solution produced by leaching may be made more concentrated. Methods include the adsorption of impurities on the surface of activated charcoal, ion exchange, and the evaporation of water.
3. *Precipitation:* The desired metal ions are either precipitated in an ionic solid or reduced to the free metal, often electrolytically.

Hydrometallurgy has long been used in obtaining silver and gold from natural sources. A typical gold ore currently being processed in the United States has only about 10 g Au per metric ton of ore. The leaching step in gold processing is known as *cyanidation*. The process is based on the following reaction:

$$4\,Au(s) + 8\,CN^-(aq) + O_2(g) + 2\,H_2O(l) \longrightarrow 4[Au(CN)_2]^-(aq) + 4\,OH^-(aq) \qquad \textbf{(23.12)}$$

The $[Au(CN)_2]^-(aq)$ is then filtered and concentrated. This is followed by displacement of Au(s) from solution by an active metal, such as zinc.

$$2[Au(CN)_2]^-(aq) + Zn(s) \longrightarrow 2\,Au(s) + [Zn(CN)_4]^{2-}(aq) \qquad \textbf{(23.13)}$$

In one hydrometallurgical process for zinc, a zinc sulfide ore is leached with a sulfuric acid solution at 150 °C and an oxygen pressure of about 7 atm. The overall reaction is

$$ZnS(s) + H_2SO_4(aq) + \tfrac{1}{2}O_2(g) \longrightarrow ZnSO_4(aq) + S(s) + H_2O(l) \qquad \textbf{(23.14)}$$

In this process, there is no $SO_2(g)$ emission. Also, mercury impurities in the ZnS ore are retained in the leaching solution rather than being emitted with $SO_2(g)$ as in the traditional roasting process. Following the leaching process,

$ZnSO_4(aq)$ is electrolyzed to produce pure Zn at the cathode, and $H_2SO_4(aq)$ is regenerated; see reaction (23.6). The $H_2SO_4(aq)$ is recycled into the leaching operation.

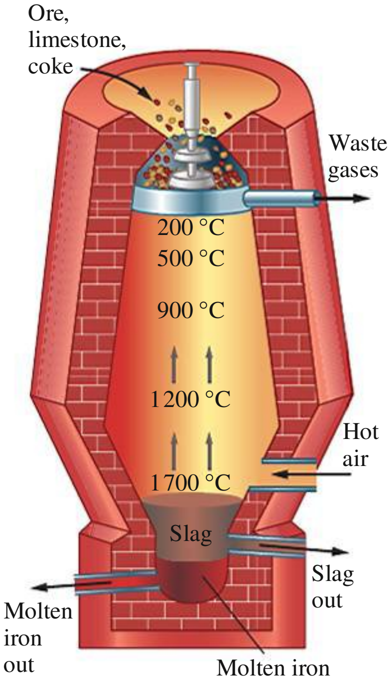
23-2 CONCEPT ASSESSMENT

The text describes the production of pure zinc from zinc sulfide ore both by a pyrometallurgical and by a hydrometallurgical process. Which aspects of the two processes are different and which are similar?

23-3 Metallurgy of Iron and Steel

▶ In the United States, slightly more than half of all iron and steel production comes from recycled iron and steel.

Iron is the most widely used metal from Earth's crust, and for this reason, we use this section to explore the metallurgy of iron and its principal alloy—steel—somewhat more fully. A type of steel called *wootz steel* was first produced in India about 3000 years ago; that same steel became famous in ancient times as Damascus steel, prized for making swords because of its suppleness and ability to hold a cutting edge. Many technological advances have been made since ancient times. These include introduction of the blast furnace around AD 1300, the Bessemer converter in 1856, the open-hearth furnace in the 1860s, and the basic oxygen furnace in the 1950s. A true understanding of the iron- and steelmaking processes has developed only within the past few decades, however. This understanding is based on concepts of thermodynamics, equilibrium, and kinetics.



▲ FIGURE 23-9
Typical blast furnace
Iron ore, coke, and limestone are added at the top of the furnace, and hot air is introduced through the bottom. Maximum temperatures are attained near the bottom of the furnace where molten iron and slag are drained off. The principal reactions occurring in the blast furnace are outlined in Table 23.2.

Pig Iron

The reactions that occur in a blast furnace are complex. A highly simplified representation of the reduction of iron ore to impure iron is

$$Fe_2O_3(s) + 3\,CO(g) \longrightarrow 2\,Fe(l) + 3\,CO_2(g) \qquad \textbf{(23.15)}$$

A more complete description of the blast furnace reactions, including the removal of impurities as slag, is given in Table 23.2. Approximate temperatures are given for these reactions so that you can key them to regions of the blast furnace pictured in Figure 23-9.

TABLE 23.2 Some Blast Furnace Reactions

Formation of gaseous reducing agents $CO(g)$ and $H_2(g)$:
$C + H_2O \longrightarrow CO + H_2\ (> 600\,°C)$
$C + CO_2 \longrightarrow 2\,CO\ (1700\,°C)$
$2\,C + O_2 \longrightarrow 2\,CO\ (1700\,°C)$
Reduction of iron oxide:
$3\,CO + Fe_2O_3 \longrightarrow 2\,Fe + 3\,CO_2\ (900\,°C)$
$3\,H_2 + Fe_2O_3 \longrightarrow 2\,Fe + 3\,H_2O\ (900\,°C)$
Slag formation to remove impurities from ore:
$CaCO_3 \longrightarrow CaO + CO_2\ (800–900\,°C)$
$CaO + SiO_2 \longrightarrow CaSiO_3(l)\ (1200\,°C)$
$6\,CaO + P_4O_{10} \longrightarrow 2\,Ca_3(PO_4)_2(l)\ (1200\,°C)$
Impurity formation in the iron:
$MnO + C \longrightarrow Mn + CO\ (1400\,°C)$
$SiO_2 + 2\,C \longrightarrow Si + 2\,CO\ (1400\,°C)$
$P_4O_{10} + 10\,C \longrightarrow 4\,P + 10\,CO\ (1400\,°C)$

The blast furnace charge—that is, the solid reactants—consists of iron ore, coke, a slag-forming flux, and perhaps some scrap iron. The exact proportions depend on the composition of the iron ore and its impurities. The common ores of iron are the oxides and carbonate: hematite (Fe_2O_3), magnetite (Fe_3O_4), limonite ($2\,Fe_2O_3 \cdot 3\,H_2O$), and siderite ($FeCO_3$). The purpose of the flux is to maintain the proper ratio of acidic oxides (SiO_2, Al_2O_3, and P_4O_{10}) to basic oxides (CaO, MgO, and MnO) to obtain an easily liquefied silicate, aluminate, or phosphate slag. Because acidic oxides predominate in most ores, the flux generally employed is limestone, $CaCO_3$, or dolomite, $CaCO_3 \cdot MgCO_3$.

▲ Pouring pig iron.

The iron obtained from a blast furnace is called **pig iron**. It contains about 95% Fe, 3%–4% C, and varying quantities of other impurities. *Cast iron* can be obtained by pouring pig iron directly into molds of the desired shape. Cast iron is very hard and brittle and is used only where it is not subjected to mechanical or thermal shock, such as in engine blocks, brake drums, and transmission housings in automobiles.

◀ Thermal shock occurs when an object undergoes a rapid change of temperature. Engine blocks get quite hot, but because they cool slowly, they are not usually subject to thermal shock.

Steel

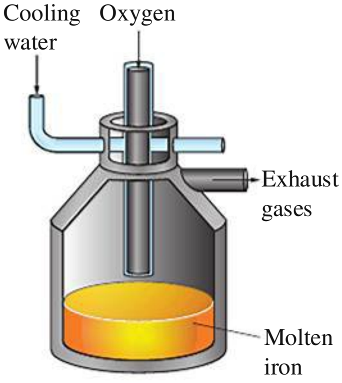
Three fundamental changes must be made to convert pig iron to **steel**:

1. reduction of the carbon content from 3%–4% in pig iron to 0%–1.5% in steel
2. removal, through slag formation, of Si, Mn, and P (each present in pig iron to the extent of 1% or so), together with other minor impurities
3. addition of alloying elements (such as Cr, Ni, Mn, V, Mo, and W) to give the steel its desired end properties

◀ Steel made with 18% Cr and 8% Ni resists corrosion and is commonly known as *stainless steel*.

The most important method of steelmaking today is the **basic oxygen process**. Oxygen gas at about 10 atm pressure and a stream of powdered limestone are fed through a water-cooled tube (called a *lance*) and discharged above the molten pig iron (Fig. 23-10). The reactions that occur (Table 23.3) accomplish the first two objectives. A typical reaction time is 22 minutes. The reaction vessel is tilted to pour off the liquid slag floating on top of the iron, and then the desired alloying elements are added.

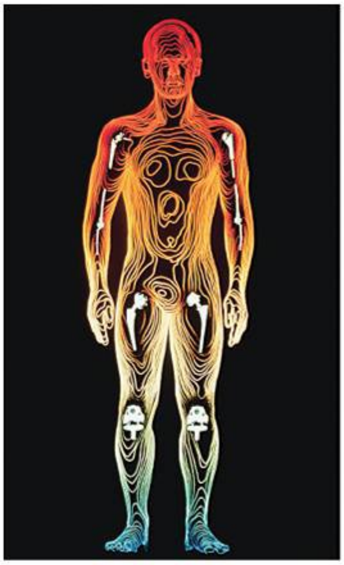
Steelmaking has been undergoing rapid technological changes. It is now possible to make iron and steel directly from iron ore in a single-step, continuous process at temperatures below the melting point of any of the materials used in the process. In the *direct reduction of iron* (DRI), $CO(g)$ and $H_2(g)$, obtained in the reaction of steam with natural gas, are used as reducing agents. The economic viability of the DRI process depends on an abundant supply of natural gas. Currently, only a small percentage of the world's iron production is by direct reduction, but this is a fast-growing component of the iron and steel industry, particularly in the Middle East and South America.



▲ FIGURE 23-10
A basic oxygen furnace

TABLE 23.3 Some Reactions Occurring in Steelmaking Processes

$2\,C + O_2 \longrightarrow 2\,CO$
$2\,FeO + Si \longrightarrow 2\,Fe + SiO_2$
$FeO + Mn \longrightarrow Fe + MnO$
$FeO + SiO_2 \longrightarrow \underset{\text{slag}}{FeSiO_3}$
$MnO + SiO_2 \longrightarrow \underset{\text{slag}}{MnSiO_3}$
$4\,P + 5\,O_2 \longrightarrow P_4O_{10}$
$6\,CaO + P_4O_{10} \longrightarrow \underset{\text{slag}}{2\,Ca_3(PO_4)_2}$



▲ A computer-generated representation of titanium joint implants at the shoulders, elbows, hips, and knees.

▲ White $TiO_2(s)$, mixed with other components to produce the desired color, is the leading pigment used in paints.

23-3 CONCEPT ASSESSMENT

Write a balanced chemical equation for the direct reduction of iron(III) oxide by hydrogen gas.

23-4 First-Row Transition Metal Elements: Scandium to Manganese

The properties and uses of the first-row transition metals span a wide range, strikingly illustrating periodic behavior despite the small variation in some of the atomic properties listed in Table 23.1. The preparation, uses, and reactions of the compounds of these metals illustrate concepts we have previously discussed, including the variability of oxidation states.

Scandium

Scandium is a rather obscure metal, though not especially rare. It constitutes about 0.0025% of Earth's crust, which makes it more abundant than many better-known metals, including lead, uranium, molybdenum, tungsten, antimony, silver, mercury, and gold. Its principal mineral form is *thortveitite*, $Sc_2Si_2O_7$. Most scandium is obtained from uranium ores, however, in which it occurs only to the extent of about 0.01% Sc by mass. The commercial uses of scandium are limited, and its production is measured in gram or kilogram quantities, not in tons. One application is in high-intensity lamps. The pure metal is usually prepared by the electrolysis of a fused mixture of $ScCl_3$ with other chlorides.

Because of its noble-gas electron configuration, the Sc^{3+} ion lacks some of the characteristic properties of transition metal ions. For instance, the ion is colorless and diamagnetic, as are most of its salts. In its chemical behavior, Sc^{3+} most closely resembles Al^{3+}, as in the hydrolysis of $[Sc(H_2O)_6]^{3+}(aq)$ to yield acidic solutions and in the formation of an amphoteric gelatinous hydroxide, $Sc(OH)_3$.

Titanium

Titanium is the ninth most abundant element, constituting 0.6% of Earth's solid crust. The metal is greatly valued for its low density, high structural strength, and corrosion resistance. The first two properties account for its extensive use in the aircraft industry and the third for its uses in the chemical industry: in pipes, component parts of pumps, and reaction vessels. Titanium is also used in dental and other bone implants. The metal provides a strong support and bone bonds directly to a titanium implant, making it a part of the body.

Several compounds of titanium are of particular commercial importance. *Titanium tetrachloride*, $TiCl_4$, is the starting material for preparing other Ti compounds and plays a central role in the metallurgy of titanium. $TiCl_4$ is also used to formulate catalysts for the production of plastics. The usual method of preparing $TiCl_4$ involves the reaction of naturally occurring rutile (TiO_2) with carbon and $Cl_2(g)$ [reaction (23.7)].

$TiCl_4$ is a colorless liquid (mp −24 °C; bp 136 °C). In the +4 oxidation state, all the valence-shell electrons of Ti atoms are employed in bond formation. In this oxidation state, Ti bears a strong resemblance to the group 14 elements, with some properties and a molecular shape (tetrahedral) similar to those of CCl_4 and $SiCl_4$. The hydrolysis of $TiCl_4$, when carried out in moist air, is the basis for a type of smoke grenade in which $TiO_2(s)$ is the smoke.

$$TiCl_4(l) + 2\,H_2O(l) \longrightarrow TiO_2(s) + 4\,HCl(g)$$

$SiCl_4$ also fumes in moist air in a similar reaction.

Titanium dioxide, TiO_2, is bright white, opaque, inert, and nontoxic. Because of these properties and its relative low cost, it is now the most widely used white pigment for paints. In this application, TiO_2 has displaced toxic basic lead carbonate—so-called white lead. TiO_2 is also used as a paper whitener and in glass, ceramics, floor coverings, and cosmetics.

To produce pure TiO_2 for these and other uses, a gaseous mixture of $TiCl_4$ and O_2 is passed through a silica tube at about 700 °C:

$$TiCl_4(g) + O_2(g) \xrightarrow{\Delta} TiO_2(s) + 2\,Cl_2(g)$$

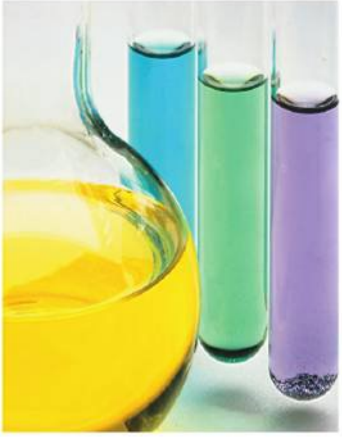
Vanadium

Vanadium is a fairly abundant element (0.02% of Earth's crust) found in several dozen ores. Its principal ores are rather complex, such as *vanadinite*, $3\,Pb_3(VO_4)_2 \cdot PbCl_2$. The metallurgy of vanadium is not simple, but vanadium of high purity (99.99%) is obtainable. For most of its applications, though, vanadium is prepared as an iron–vanadium alloy, *ferrovanadium*, containing from 35% to 95% V. About 80% of the vanadium produced is for the manufacture of steel. Vanadium-containing steels are used in applications requiring strength and toughness, such as in springs and high-speed machine tools.

The most important compound of vanadium is the pentoxide, V_2O_5, used mainly as a catalyst, as in the conversion of $SO_2(g)$ to $SO_3(g)$ in the contact method for the manufacture of sulfuric acid. The activity of V_2O_5 as an oxidation catalyst may be linked to its reversible loss of oxygen occurring from 700 to 1100 °C.

In its compounds, vanadium can exist in a variety of oxidation states. In each of these oxidation states, vanadium forms an oxide or ion. The ions display distinctive colors in aqueous solution (Fig. 23-11). The acid–base properties of vanadium oxides are in accord with factors established earlier in the text: If the central metal atom is in a low oxidation state, the oxide acts as a base; in higher oxidation states for the central atom, acidic properties become important. Vanadium oxides with V in the +2 and +3 oxidation states are basic, whereas those in the +4 and +5 oxidation states are amphoteric.

Most compounds with vanadium in its highest oxidation state (+5) are good oxidizing agents. In its +2 oxidation state, vanadium (as V^{2+}) is a good reducing agent. The oxidation–reduction relationships between the ionic species pictured in Figure 23-11 are summarized in Table 23.4.



▲ FIGURE 23-11
Some vanadium species in solution
The yellow solution has vanadium in the +5 oxidation state, as VO_2^+. In the blue solution, the oxidation state is +4, in VO^{2+}. The green solution contains V^{3+}, and the violet solution contains V^{2+}.

Chromium

Although it is found only to the extent of 122 parts per million (0.0122%) in Earth's crust, chromium is one of the most important industrial metals. The production of ferrochrome from *chromite*, $Fe(CrO_2)_2$, was discussed in Section 23-2. Chromium metal is hard and maintains a bright surface through the protective action of an invisible oxide coating. Because it is resistant to corrosion, chromium is extensively used in plating other metals.

◀ The word *chromium* is derived from the Greek *chroma*, meaning "color"—an apt name, given the range of colors found in chromium compounds.

TABLE 23.4 Oxidation States of Vanadium Species in Acidic Solution

O.S. Change	Reduction Half-Reaction	*E*°
+5 ⟶ +4:	$\underset{\text{(yellow)}}{VO_2^+(aq)} + 2\,H^+(aq) + e^- \longrightarrow \underset{\text{(blue)}}{VO^{2+}(aq)} + H_2O(l)$	1.000 V
+4 ⟶ +3:	$VO^{2+}(aq) + 2\,H^+(aq) + e^- \longrightarrow \underset{\text{(green)}}{V^{3+}(aq)} + H_2O(l)$	0.337 V
+3 ⟶ +2:	$V^{3+}(aq) + e^- \longrightarrow \underset{\text{(violet)}}{V^{2+}(aq)}$	−0.255 V
+2 ⟶ 0:	$V^{2+}(aq) + 2\,e^- \longrightarrow V(s)$	−1.13 V

EXAMPLE 23-2 Using Electrode Potential Data to Predict an Oxidation–Reduction Reaction

Can $MnO_4^-(aq)$ be used to oxidize $VO^{2+}(aq)$ to $VO_2^+(aq)$ for standard-state conditions in an acidic solution? If so, write a balanced equation for the redox reaction.

Analyze

We need to start by writing two half-equations, one for the reduction of MnO_4^- to Mn^{2+} the other for the oxidation of VO^{2+} to VO_2^+. Both occur in acidic solution. We find one $E°$ value in Table 23.4 and the other in Table 20.1. We then combine the $E°$ values to obtain a value for $E°_{cell}$.

$$\textit{Reduction:}\quad MnO_4^- + 8\,H^+ + 5\,e^- \longrightarrow Mn^{2+} + 4\,H_2O$$

$$\textit{Oxidation:}\quad 5(VO^{2+} + H_2O \longrightarrow VO_2^+ + 2\,H^+ + e^-)$$

$$\textit{Overall:}\quad 5\,VO^{2+}(aq) + MnO_4^-(aq) + H_2O(l) \longrightarrow 5\,VO_2^+(aq) + Mn^{2+}(aq) + 2\,H^+(aq)$$

$$E°_{cell} = E°_{MnO_4^-/Mn^{2+}} - E°_{VO_2^+/VO^{2+}} = 1.51\text{ V} - 1.000\text{ V} = 0.51\text{ V}$$

Because $E°_{cell}$ is positive, we predict that MnO_4^- should oxidize VO^{2+} to VO_2^+ for standard-state conditions in acidic solution.

Assess

By using equation (20.17), we can easily verify that K for the overall reaction is very large (greater than 1×10^{43}), which is another indication that $MnO_4^-(aq)$ could be effectively used for oxidizing $VO^{2+}(aq)$ to $VO_2^+(aq)$.

PRACTICE EXAMPLE A: Use data from Tables 20.1 and 23.4 to determine whether nitric acid can be used to oxidize $V^{3+}(aq)$ to $VO^{2+}(aq)$ for standard-state conditions. If so, write a balanced equation for the reaction.

PRACTICE EXAMPLE B: Select a *reducing agent* from Table 20.1 that can be used to reduce VO^{2+} to V^{2+} for standard-state conditions in acidic solution. Consider that the reduction occurs in two stages: $VO^{2+} \longrightarrow V^{3+} \longrightarrow V^{2+}$, but note that the V^{2+} must not be reduced to V(s).

Steel is chrome-plated from an aqueous solution containing CrO_3 and H_2SO_4. The plating obtained is thin and porous. It tends to develop cracks unless the steel is first plated with copper or nickel, which provides the true protective coating. Then chromium is plated over this layer for extra protection and decorative purposes. The efficiency of chrome-plating is limited by the fact that reduction of Cr(VI) to Cr(0) produces only $\frac{1}{6}$ mol Cr per mole of electrons. In other words, large quantities of electric energy are required for chrome-plating relative to other types of metal plating.

▶ The colors may also depend on other species present in solution. For example, if $[Cl^-]$ is high, $[Cr(H_2O)_6]^{3+}$ is converted to $[CrCl_2(H_2O)_4]^+$ and the violet color changes to green.

Chromium, like vanadium, has a variety of oxidation states in aqueous solution, each having a different color.

O.S. + 2: $[Cr(H_2O)_6]^{2+}$, blue
O.S. + 3: (acidic) $[Cr(H_2O)_6]^{3+}$, violet (basic) $[Cr(OH)_4]^-$, green
O.S. + 6: (acidic) $Cr_2O_7^{2-}$, orange (basic) CrO_4^{2-}, yellow

The oxides and hydroxides of chromium conform to the general principles of acid–base behavior: CrO is basic, Cr_2O_3 is amphoteric, and CrO_3 is acidic.

Pure chromium reacts with dilute HCl(aq) or $H_2SO_4(aq)$ to produce $Cr^{2+}(aq)$. Nitric acid and other oxidizing agents alter the surface of the metal (perhaps by formation of an oxide coating). They render the metal resistant to further attack—it becomes *passive*. A better source of chromium compounds than the pure metal is the alkali metal chromates, which contain Cr(VI) and can be obtained directly from chromite ore by reactions such as

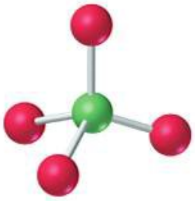
$$4\,Fe(CrO_2)_2 + 8\,Na_2CO_3 + 7\,O_2 \xrightarrow{\Delta} 2\,Fe_2O_3 + 8\,Na_2CrO_4 + 8\,CO_2 \qquad \textbf{(23.16)}$$

The *sodium chromate*, Na_2CrO_4, produced by this reaction is the source of many industrially important chromium compounds.

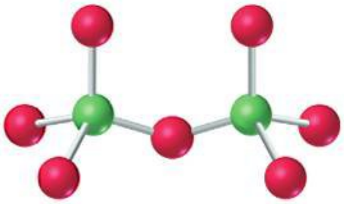
The Cr(VI) oxidation state is also observed in the red oxide, CrO_3. As expected, this oxide dissolves in water to produce a strongly acidic solution.

The product of the reaction is not the expected chromic acid, H_2CrO_4, however, which has never been isolated in the pure state. Instead, the observed reaction is

$$2\,CrO_3(s) + H_2O(l) \longrightarrow 2\,H^+(aq) + Cr_2O_7^{2-}(aq) \tag{23.17}$$



Chromate ion (CrO_4^{2-})



Dichromate ion ($Cr_2O_7^{2-}$)

It is possible to crystallize a *dichromate* salt from an aqueous solution of CrO_3. If the solution is made basic, the color turns from orange to yellow. From basic solutions, only *chromate* salts can be crystallized. Thus, whether a solution contains Cr(VI) as $Cr_2O_7^{2-}$ or CrO_4^{2-} or a mixture of the two depends on the pH. The relevant equations follow.

$$2\,CrO_4^{2-}(aq) + 2\,H^+(aq) \rightleftharpoons Cr_2O_7^{2-}(aq) + H_2O(l) \tag{23.18}$$

$$K_c = \frac{[Cr_2O_7^{2-}]}{[CrO_4^{2-}]^2[H^+]^2} = 3.2 \times 10^{14} \tag{23.19}$$

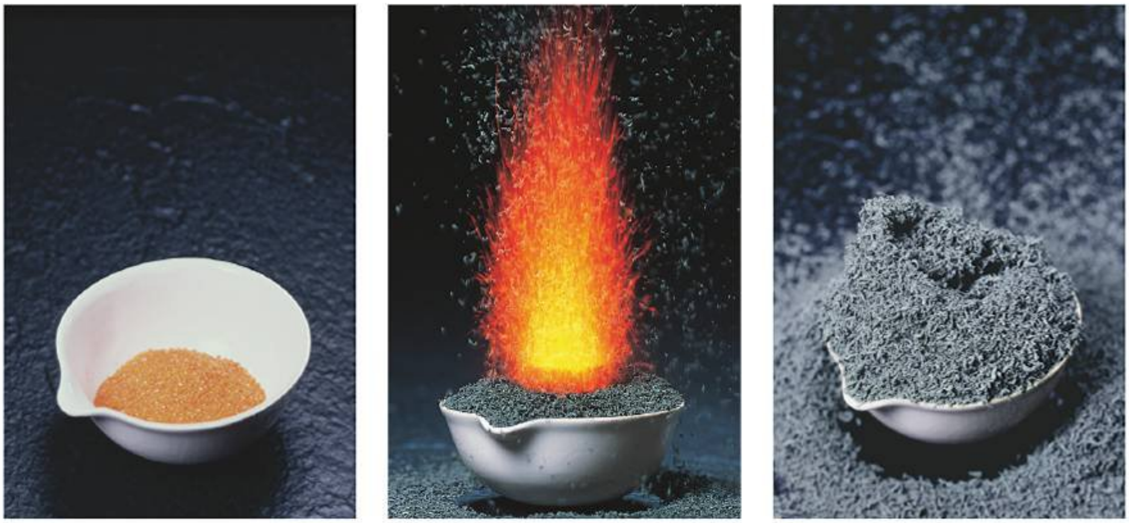
Le Châtelier's principle predicts that the forward reaction of (23.18) is favored in acidic solutions and that the predominant Cr(VI) species is $Cr_2O_7^{2-}$. In basic solution, H^+ ions are removed and the reverse reaction is favored, forming CrO_4^{2-} as the principal species. Careful control of the pH is necessary when $Cr_2O_7^{2-}$ is used as an oxidizing agent or CrO_4^{2-} as a precipitating agent. In addition, equation (23.19) can be used to calculate the relative amounts of the two ions as a function of $[H^+]$.

Chromate ion in basic solution can be used to precipitate metal chromates such as $BaCrO_4(s)$ and $PbCrO_4(s)$. It is not a good oxidizing agent, however; it is not readily reduced.

$$CrO_4^{2-}(aq) + 4\,H_2O(l) + 3\,e^- \longrightarrow [Cr(OH)_4]^-(aq) + 4\,OH^-(aq) \quad E° = -0.13\text{ V}$$

Dichromates are poor precipitating agents but excellent oxidizing agents, which are used in a variety of industrial processes. In the chrome leather tanning process, for example, animal hides are immersed in $Na_2Cr_2O_7(aq)$, which is then reduced by $SO_2(g)$ to soluble basic chromic sulfate, $Cr(OH)SO_4$. Collagen, a protein in hides, reacts to form an insoluble chromium complex. The hides become *leather*, a tough, pliable material resistant to biological attack.

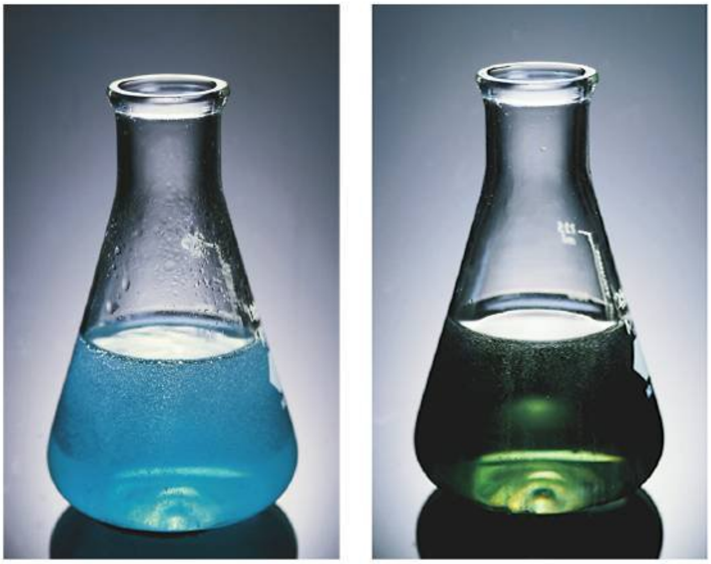
Dichromates are easily reduced to Cr_2O_3. In the case of ammonium dichromate, simply heating the compound produces Cr_2O_3 in a dramatic reaction (Fig. 23-12).



▲ FIGURE 23-12

Decomposition of $(NH_4)_2Cr_2O_7$

Ammonium dichromate (left) contains both an oxidizing agent, $Cr_2O_7^{2-}$, and a reducing agent, NH_4^+. The products of the reaction between these two ions are $Cr_2O_3(s)$ (right), $N_2(g)$, and $H_2O(g)$. Considerable heat and light are also evolved (center).



▶ FIGURE 23-13
Relationship between Cr^{2+} and Cr^{3+}
The solution on the left, containing blue $Cr^{2+}(aq)$, is prepared by dissolving chromium metal in HCl(aq). Within minutes, the $Cr^{2+}(aq)$ is oxidized to green $Cr^{3+}(aq)$ by atmospheric oxygen (right). The green color is that of the complex ion $[CrCl_2(H_2O)_4]^+(aq)$.

Chromium(II) compounds can be prepared by the reduction of Cr(III) compounds with zinc in acidic solution or electrolytically at a lead cathode. The most distinctive feature of Cr(II) compounds is their reducing power.

$$Cr^{3+}(aq) + e^- \longrightarrow Cr^{2+}(aq) \qquad E^\circ = -0.424\ V$$

That is, the oxidation of $Cr^{2+}(aq)$ occurs readily. In fact, Cr(II) solutions can be used to purge gases of trace amounts of $O_2(g)$, through the following reaction, illustrated in Figure 23-13.

$$4\,Cr^{2+}(aq) + O_2(g) + 4\,H^+(aq) \longrightarrow 4\,Cr^{3+}(aq) + 2\,H_2O(l) \qquad E^\circ_{cell} = +1.653\ V$$

Pure Cr can be obtained in small amounts by reducing Cr_2O_3 with Al in a reaction similar to the thermite reaction.

$$Cr_2O_3(s) + 2\,Al(s) \longrightarrow Al_2O_3(s) + 2\,Cr(l) \qquad \textbf{(23.20)}$$

Manganese

Manganese is a fairly abundant element, constituting about 1% of Earth's crust. Its principal ore is *pyrolusite*, MnO_2. Like V and Cr, Mn is most important in steel production, generally as the iron–manganese alloy, *ferromanganese*. Ferromanganese can be obtained by the reduction of a mixture of pyrolusite and hematite iron ores with carbon.

$$MnO_2 + Fe_2O_3 + 5\,C \xrightarrow{\Delta} \underbrace{Mn + 2\,Fe}_{\text{Ferromanganese}} + 5\,CO$$

Mn participates in the purification of iron by reacting with sulfur and oxygen and removing them through slag formation. In addition, Mn increases the hardness of steel. Steel containing high proportions of Mn is extremely tough and wear-resistant in such applications as railroad rails, bulldozers, and road scrapers.

The electron configuration of Mn is $[Ar]3d^54s^2$. By employing first the two 4s electrons and then, consecutively, up to all five of its unpaired 3*d* electrons, manganese exhibits all oxidation states from +2 to +7. The most important reactions of manganese compounds are oxidation–reduction reactions. Standard electrode potential diagrams are given in Figure 23-14. These diagrams help explain the following observations:

- $Mn^{3+}(aq)$ is unstable; that is, its disproportionation is spontaneous.

$$2\,Mn^{3+}(aq) + 2\,H_2O(l) \longrightarrow Mn^{2+}(aq) + MnO_2(s) + 4\,H^+(aq)$$
$$E^\circ_{cell} = 0.54\ V \qquad \textbf{(23.21)}$$

FIGURE 23-14
Electrode potential diagrams for manganese

- Manganate ion, MnO_4^{2-}, is also unstable in acidic solution; its disproportionation is spontaneous.

$$3\,MnO_4^{2-}(aq) + 4\,H^+(aq) \longrightarrow MnO_2(s) + 2\,MnO_4^-(aq) + 2\,H_2O(l) \qquad E^\circ_{cell} = 1.70\text{ V} \quad \textbf{(23.22)}$$

- If $[OH^-]$ is kept sufficiently high, the following reaction can be reversed; thus, manganate ion can be maintained as a stable species in a strongly basic medium.

$$3\,MnO_4^{2-}(aq) + 2\,H_2O(l) \longrightarrow MnO_2(s) + 2\,MnO_4^-(aq) + 4\,OH^-(aq) \qquad E^\circ_{cell} = 0.04\text{ V} \quad \textbf{(23.23)}$$

Manganese dioxide is used in dry-cell batteries, in glass and ceramic glazes, and as a catalyst; it is also the principal source of manganese compounds. When MnO_2 is heated in the presence of an alkali and an oxidizing agent, a manganate salt is produced.

$$3\,MnO_2 + 6\,KOH + KClO_3 \xrightarrow{\Delta} 3\,K_2MnO_4 + KCl + 3\,H_2O$$

K_2MnO_4 is extracted from the fused mass with water and can then be oxidized to $KMnO_4$, *potassium permanganate* (with Cl_2 as an oxidizing agent, for instance). Potassium permanganate, $KMnO_4$, is an important laboratory oxidizing agent. For chemical analyses, it is generally used in acidic solutions in which it is reduced to $Mn^{2+}(aq)$. In the analysis of iron by MnO_4^-, a sample of Fe^{2+} is prepared by dissolving iron in an acid and reducing any Fe^{3+} back to Fe^{2+}. Then the sample is titrated with $MnO_4^-(aq)$.

$$5\,Fe^{2+}(aq) + MnO_4^-(aq) + 8\,H^+(aq) \longrightarrow 5\,Fe^{3+}(aq) + Mn^{2+}(aq) + 4\,H_2O(l) \quad \textbf{(23.24)}$$

$Mn^{2+}(aq)$ has a barely discernible pale pink color. $MnO_4^-(aq)$ is an intense purple color. At the end point of the titration reaction (23.24), the solution acquires a lasting light purple color with just one drop of excess $MnO_4^-(aq)$ (recall Figure 5-18). $MnO_4^-(aq)$ is less satisfactory for titrations in alkaline solutions because the insoluble reduction product, brown $MnO_2(s)$, obscures the end point.

23-4 CONCEPT ASSESSMENT

The dichromate ion is formed by the condensation of chromate ion in an acidic solution. Further condensation occurs at low pH to form $[Cr_3O_{10}]^{2-}$. Suggest the structures for these anions. What other elements form similar anions?

23-5 The Iron Triad: Iron, Cobalt, and Nickel

▲ Cobalt–samarium magnets are used in high-efficiency motors.

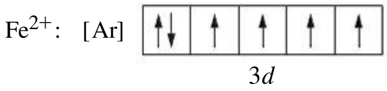
The transition elements iron, cobalt, and nickel comprise the *iron triad*. Iron, with an annual worldwide production of more than 500 million metric tons, is the most important metal in modern civilization. It is widely distributed in Earth's crust at an abundance of 4.7%. The major commercial use of iron is to make steel (see Section 23-3).

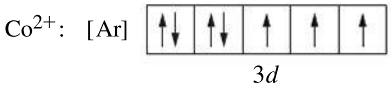
Cobalt is among the rarer elements. It comprises only about 0.0020% of Earth's crust, but it occurs in sufficiently concentrated deposits (ores) so that its annual production runs into the millions of pounds. Cobalt is used primarily in alloys with other metals. Like iron, cobalt is ferromagnetic. One alloy of cobalt, Co_5Sm, makes a particularly strong and lightweight permanent magnet. Because of the strength of its magnetic field, magnets of this alloy are used in the manufacture of miniature electronic devices.

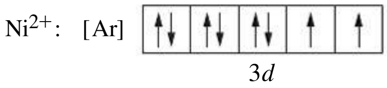
Nickel ranks twenty-fourth in abundance among the elements in Earth's crust. Its ores are mainly the sulfides, oxides, silicates, and arsenides. Particularly large deposits are found in Canada. Of the 136 million kilograms of nickel consumed annually in the United States, about 80% goes to the production of alloys. Another 15% is used in electroplating, and the remainder for miscellaneous purposes (for example, as catalysts).

Oxidation States

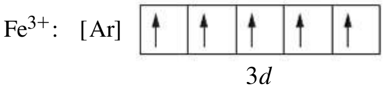
Variability of oxidation state is seen in the iron triad, even if not to the same degree as with vanadium, chromium, and manganese. The +2 oxidation state is commonly encountered in all three metals.







For cobalt and nickel, the +2 oxidation state is the most stable, but for iron, the most stable is +3.



The electron configuration of Fe^{3+} has a half-filled *d* subshell with all the *d* electrons unpaired. This type of electron configuration has a special stability. As we can see from the orbital diagrams of Co^{2+} and Ni^{2+}, neither would have a half-filled 3*d* subshell following the loss of one additional electron. Co^{3+} and

Ni^{3+} are not readily formed. To illustrate the contrast between Fe^{3+} on the one hand, and Co^{3+} and Ni^{3+}, on the other, consider the following observations.

- $Fe^{2+}(aq)$ is spontaneously oxidized to $Fe^{3+}(aq)$ by $O_2(g)$ at 1 atm in a solution with $[H^+] = 1$ M.

  $$4\,Fe^{2+}(aq) + O_2(g) + 4\,H^+(aq) \longrightarrow 4\,Fe^{3+}(aq) + 2\,H_2O(l) \qquad E^\circ_{cell} = 0.44\text{ V} \quad \textbf{(23.25)}$$

  This reaction is still spontaneous with lower O_2 partial pressures and less acidic solutions.
- For the half-reaction $Co^{3+}(aq) + e^- \longrightarrow Co^{2+}(aq)$, $E^\circ = 1.82$ V. The reduction of $Co^{3+}(aq)$ to $Co^{2+}(aq)$ occurs readily; conversely, the oxidation of $Co^{2+}(aq)$ to Co^{3+} occurs only with difficulty. As will be noted in Chapter 24, however, the oxidation state +3 can be attained when Co^{3+} is the central metal ion in very stable complex ions.
- Nickel(III) compounds are used in batteries. For example, in the nickel–cadmium (Nicad) cell, the cathode half-reaction is $NiO(OH) + H^+ + e^- \longrightarrow Ni(OH)_2$. It is the ease of this reduction, when combined with the oxidation half-reaction, $Cd(s) + 2\,OH^-(aq) \longrightarrow Cd(OH)_2(s) + 2\,e^-$, that produces a cell with a voltage of about 1.5 V.

Some Reactions of the Iron Triad Elements

The reactions of the iron triad elements are many and varied. The metals are more active than hydrogen and liberate $H_2(g)$ from an acidic solution. Hydrated Co^{2+} and Ni^{2+} are red and green, respectively. In aqueous solution, Fe^{2+} is pale green and fully hydrated Fe^{3+} is purple. Generally, however, solutions of $Fe^{2+}(aq)$ are yellow to brown, but this color probably results from the presence of species formed in the hydrolysis of $Fe^{3+}(aq)$. Like the hydrolysis of $Al^{3+}(aq)$, described on page 733, that of $Fe^{3+}(aq)$ produces an acidic solution.

$$[Fe(H_2O)_6]^{3+}(aq) + H_2O(l) \rightleftharpoons [FeOH(H_2O)_5]^{2+}(aq) + H_3O^+(aq) \qquad K_a = 8.9 \times 10^{-4} \quad \textbf{(23.26)}$$

Some reactions that can be used to identify and distinguish between $Fe^{2+}(aq)$ and $Fe^{3+}(aq)$ are summarized in Table 23.5.

◀ The blue precipitate that establishes the presence of $Fe^{2+}(aq)$ from the corroding nails in Figure 20-20 is Turnbull's blue.

An interesting set of reactions involves the complex ions $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$. These ions are commonly called *ferrocyanide* and *ferricyanide*, respectively. $Fe^{3+}(aq)$ yields a dark blue precipitate called *Prussian blue* when treated with potassium ferrocyanide, $K_4[Fe(CN)_6](aq)$, whereas $Fe^{2+}(aq)$ yields a similar blue precipitate, called *Turnbull's blue*, when treated with potassium ferricyanide, $K_3[Fe(CN)_6](aq)$. Together, these two and similar related precipitates are known commercially as *iron blue*. Iron blue is used as a pigment for paints, printing inks, laundry bluing, art colors, cosmetics (eye shadow), and blueprinting. An additional sensitive test for $Fe^{3+}(aq)$ is the formation of a blood-red complex ion with thiocyanate ion, $SCN^-(aq)$.

◀ In Chapter 24, we will learn to write the systematic names for ferrocyanide and ferricyanide ions; they are hexacyanoferrate(II) and hexacyanoferrate(III), respectively.

$$[Fe(H_2O)_6]^{3+} + SCN^-(aq) \longrightarrow [FeSCN(H_2O)_5]^{2+} + H_2O(l)$$

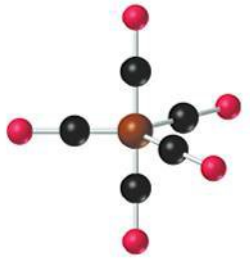
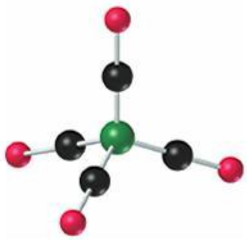
$Cr(CO)_6$



$Fe(CO)_5$



$Ni(CO)_4$

▲ FIGURE 23-15
Structure of some simple carbonyls

TABLE 23.6 Three Metal Carbonyls

	Number of e^-		
	From Metal	From CO	Total
$Cr(CO)_6$	24	12	36
$Fe(CO)_5$	26	10	36
$Ni(CO)_4$	28	8	36

With only a few exceptions, the transition metals form compounds with carbon monoxide (CO), called **metal carbonyls**. In the simple metal carbonyls listed in Table 23.6,

- each CO molecule contributes an electron pair to an empty orbital of the metal atom
- all electrons are paired (most metal carbonyls are diamagnetic)
- the metal atom acquires the electron configuration of the noble gas Kr

The structures of the simple carbonyls in Figure 23-15 are those that we would predict from VSEPR theory (based on a number of electron pairs around the central atom equal to the number of CO molecules).

Metal carbonyls are produced in several ways. Nickel combines with CO(g) at ordinary temperatures and pressures in a reversible reaction.

$$Ni(s) + 4\,CO(g) \rightleftharpoons Ni(CO)_4(l)$$

The reaction above forms the basis of an important industrial process called the Mond process for obtaining nickel metal from its oxides. In the Mond process, CO(g) is passed over a mixture of metal oxides. Nickel is carried off as $Ni(CO)_4(g)$, while the other oxides are reduced to the metals. When $Ni(CO)_4(g)$ is subsequently heated to about 250 °C, the carbonyl complex decomposes, yielding Ni(s). With iron, it is necessary to use higher temperatures (200 °C) and CO(g) pressures (100 atm).

$$Fe(s) + 5\,CO(g) \rightleftharpoons Fe(CO)_5(g)$$

In other cases, the carbonyl is obtained by reducing a metal compound in the presence of CO(g).

Carbon monoxide poisoning results from a reaction similar to carbonyl formation. CO molecules coordinate with Fe atoms in hemoglobin in the blood, displacing the O_2 molecules normally carried by hemoglobin. The metal carbonyls themselves are also very poisonous.

23-5 CONCEPT ASSESSMENT

What is the oxidation state of iron in the compound $Fe(CO)_5$?

23-6 Group 11: Copper, Silver, and Gold

Throughout the ages, Cu, Ag, and Au have been the preferred metals for coins because they are so durable and resistant to corrosion. The data in Table 23.7 help us understand why this is so. The metal ions are easy to reduce to the free metals, which means that the metals are difficult to oxidize.

In Mendeleev's periodic table, the alkali metals (group 1) and the coinage metals (group 11) appear together as group I. The only similarity between the two subgroups, however, is that both have a single *s* electron in the valence

TABLE 23.7 Some Properties of Copper, Silver, and Gold

[a] The most common oxidation states are shown in red.

shells of their atoms. More significant are the differences between the group 1 and group 11 metals. For example, the first ionization energies for the group 11 metals are much larger than for the group 1 metals, and the standard electrode potentials, $E°$, are positive for the group 11 metals and negative for the group 1 metals.

Like the other transition elements that precede them in the periodic table, the group 11 metals can use *d* electrons in chemical bonding. Thus they can exist in different oxidation states, exhibit paramagnetism and color in some of their compounds, and form complex ions. They also possess to a high degree some of the distinctive physical properties of metals—malleability, ductility, and excellent electrical and thermal conductivity.

▲ Gold leaf and copper wire

Copper, silver, and gold—the coinage metals—are used in jewelry making and the decorative arts. Gold, for instance, is extraordinarily malleable and can be pounded into thin translucent sheets known as gold leaf. The coinage metals are valued by the electronics industry for their ability to conduct electricity. Silver has the highest electrical conductivity of any pure element, but both copper and gold are more often used as electrical conductors because copper is inexpensive and gold does not readily corrode. The most important use of gold is as the monetary reserve of nations throughout the world.

Generally, the coinage metals are resistant to air oxidation, although silver will tarnish through reactions with sulfur compounds in air to produce black Ag_2S. In moist air, copper corrodes to produce green basic copper carbonate. This is the green color associated with copper roofing and gutters and bronze statues. (Bronze is an alloy of Cu and Sn.) Fortunately, this corrosion product forms a tough adherent coating that protects the underlying metal. The corrosion reaction is complex but may be summarized as

$$2\,Cu(s) + H_2O(g) + CO_2(g) + O_2(g) \longrightarrow \underset{\text{Basic copper carbonate}}{Cu_2(OH)_2CO_3(s)} \qquad \textbf{(23.27)}$$

The group 11 metals do not react with HCl(aq), but both Cu and Ag react with concentrated $H_2SO_4(aq)$ or $HNO_3(aq)$. The metals are oxidized to Cu^{2+} and Ag^+, respectively, and the reduction products are $SO_2(g)$ in $H_2SO_4(aq)$ and either NO(g) or $NO_2(g)$ in $HNO_3(aq)$.

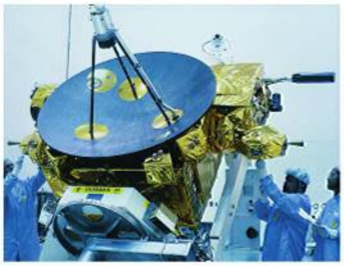
Au does not react with either acid, but it will react with "royal water"—*aqua regia* (1 part HNO_3 and 3 parts HCl). The $HNO_3(aq)$ oxidizes the metal and Cl^- from the HCl(aq) promotes the formation of the stable complex ion $[AuCl_4]^-$.

$$Au(s) + 4\,H^+(aq) + NO_3^-(aq) + 4\,Cl^-(aq) \longrightarrow [AuCl_4]^-(aq) + 2\,H_2O(l) + NO(g) \qquad \textbf{(23.28)}$$

Trace amounts of Cu are essential to life, but larger quantities are toxic, especially to bacteria, algae, and fungi. Among the many copper compounds used as pesticides are the basic acetate, carbonate, chloride, hydroxide, and sulfate. Commercially, the most important copper compound is $CuSO_4 \cdot 5\,H_2O$. In addition to its agricultural applications, $CuSO_4$ is employed in batteries and electroplating, in the preparation of other copper salts, and in a variety of industrial processes.

Silver(I) nitrate is the principal silver compound of commerce and is also an important laboratory reagent for the precipitation of anions, most of which form insoluble silver salts. These precipitation reactions can be used for the quantitative determination of anions, either gravimetrically (by weighing precipitates) or volumetrically (by titration). Most other Ag compounds are derived from $AgNO_3$. Ag compounds are used in electroplating, in the manufacture of batteries, as catalysts, and in cloud seeding (AgI). Silver halides, such as AgBr, are used in photography (see Section 24-10), although this is diminishing now because of the advent of digital cameras.

Gold compounds are used in electroplating, photography, medicinal chemistry (as anti-inflammatory agents for severe rheumatoid arthritis, for example), and the manufacture of special glasses and ceramics (such as ruby glass).



▲ Gold plating on a space antenna.

23-6 CONCEPT ASSESSMENT

What is the electron configuration of gold(III) ion?

23-7 Group 12: Zinc, Cadmium, and Mercury

The properties of the group 12 elements are consistent with elements having full subshells, $(n-1)d^{10}ns^2$; some of those properties are summarized in Table 23.8. The low melting and boiling points of the group 12 metals can probably be attributed to the fact that, with only the ns^2 electrons participating, metallic bonding is weak. Mercury is the only metal that exists as a liquid at room temperature and below (although liquid gallium can easily be supercooled to room temperature). Mercury differs from Zn and Cd in a number of ways in addition to physical appearance.

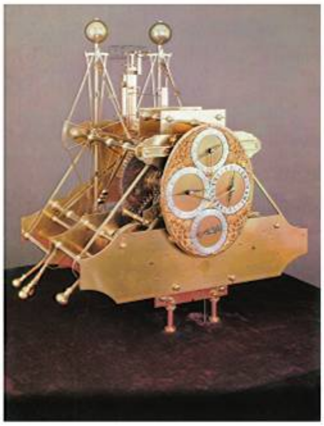
- Mercury has little tendency to combine with oxygen. Its oxide, HgO, is thermally unstable.
- Very few mercury compounds are water soluble, and most are not hydrated.

TABLE 23.8 Some Properties of the Group 12 Metals

	Zn	Cd	Hg
Density, g cm^{-3}	7.14	8.64	13.59 (liquid)
Melting point, °C	419.6	320.9	−38.87
Boiling point, °C	907	765	357
Electron configuration	$[Ar]3d^{10}4s^2$	$[Kr]4d^{10}5s^2$	$[Xe]4f^{14}5d^{10}6s^2$
Atomic radius, pm	133	149	160
Ionization energy, kJ mol^{-1}			
First	906	867	1006
Second	1733	1631	1809
Principal oxidation state(s)	+2	+2	+1, +2
Electrode potential $E°$, V			
$[M^{2+}(aq) + 2\,e^- \longrightarrow M]$	−0.763	−0.403	+0.854
$[M_2{}^{2+}(aq) + 2\,e^- \longrightarrow 2\,M]$	—	—	+0.796

- Many mercury compounds are covalent. Except for HgF_2, mercury halides are only slightly ionized in aqueous solution.
- Mercury(I) forms a common diatomic ion with a metal–metal covalent bond, Hg_2^{2+}.
- Mercury will not displace $H_2(g)$ from $H^+(aq)$.

Some of these differences exhibited by mercury can probably be attributed to the *relativistic effect* discussed in Chapter 9 (Focus On 9, www.masteringchemistry.com). Because the speed of the 6*s* electrons reaches a significant fraction of the speed of light, as they approach the high positive charge of the mercury nucleus, their masses increase (as predicted by Einstein's theory of relativity) and the 6*s* orbital shrinks in size. The closer approach of the 6*s* electrons to the nucleus subjects them to a greater attractive force than that experienced by the ns^2 electrons in Zn and Cd. As a result, for example, the first ionization energy of Hg is greater than that of Zn or Cd.



▲ A brass seagoing chronometer made by John Harrison in the eighteenth century.

Uses of the Group 12 Metals and Their Compounds

About one-third of the zinc produced is used in coating iron to give it corrosion protection (Section 20-6). The product is called *galvanized iron*. Large quantities of Zn are consumed in the manufacture of alloys. For example, about 20% of the production of Zn is used in *brass*, a copper alloy having 20%–45% Zn and small quantities of Sn, Pb, and Fe. Brass is a good electrical conductor and is corrosion resistant. Zinc is also employed in the manufacture of dry-cell batteries, in printing (lithography), in the construction industry (roofing materials), and as sacrificial anodes in corrosion protection (Section 20-6).

Although poisonous, cadmium is substituted for zinc as a shiny and protective plating on iron in special applications. It is used in bearing alloys, in low-melting solders, in aluminum solders, and as an additive to impart strength to copper. Another application, based on its neutron-absorbing capacity, is in control rods and shielding for nuclear reactors.

The principal uses of mercury take advantage of its metallic and liquid properties and its high density. It is used in thermometers, barometers, gas-pressure regulators, and electrical relays and switches, and as electrodes, as in the chlor-alkali process (Section 20-8). Mercury vapor is used in fluorescent tubes and street lamps. Mercury alloys, called **amalgams**, can be made with most metals, and some of these amalgams are of commercial importance. A silver dental filling is an amalgam of mercury with an alloy containing about 70% Ag, 26% Sn, 3% Cu, and 1% Zn.

◀ Iron is one of the few metals that does not form an amalgam. Mercury is generally stored and shipped in iron containers.

Table 23.9 lists a few important compounds of the group 12 metals and some of their uses. Some of the most interesting compounds are the

TABLE 23.9 Some Important Compounds of the Group 12 Metals

Compound	Uses
ZnO	Reinforcing agent in rubber; pigment; cosmetics; dietary supplement; photoconductors in copying machines
ZnS	Phosphors in X-ray and television screens; pigment; luminous paints
$ZnSO_4$	Rayon manufacture; animal feeds; wood preservative
CdO	Electroplating; batteries; catalyst
CdS	Solar cells; photoconductor in photocopying; phosphors; pigment
$CdSO_4$	Electroplating; standard voltaic cells (Weston cell)
HgO	Polishing compounds; dry cells; antifouling paints; fungicide; pigment
$HgCl_2$	Manufacture of Hg compounds; disinfectant; fungicide; insecticide; wood preservative
Hg_2Cl_2	Electrodes; pharmaceuticals; fungicide

semiconductors ZnO, CdS, and HgS, which are also the artist's pigments zinc white, cadmium yellow, and vermilion (red), respectively. Like all semiconductor materials, these compounds have an electronic structure consisting of a valence band and a conduction band (see Section 11-7). When light interacts with these compounds, electrons from the valence band may absorb photons and be excited into the conduction band. The energy of the light absorbed must equal or exceed the energy difference between the bands, called the *band gap*. The characteristic colors of these materials depend on the widths of the band gaps, as described in Focus On 21, www.masteringchemistry.com.

Mercury and Cadmium Poisoning

Accumulations of mercury in the body affect the nervous system and cause brain damage. One form of chronic mercury poisoning, "hatter's disease," was fairly common in the nineteenth century. Mercury compounds were used to convert fur to felt for making hats. Many hat makers of the time worked in hot, cramped spaces and used these compounds without special precautions. The hatters inadvertently ingested or inhaled the toxic mercury compounds while they worked.

One proposed mechanism of mercury poisoning, based on the fact that Hg has a high affinity for sulfur, involves interference with the functioning of sulfur-containing enzymes. Organic mercury compounds are generally more poisonous than inorganic ones and much more toxic than the element itself. An insidious aspect of mercury poisoning is that certain microorganisms have the ability to convert mercury(II) compounds to methylmercury (CH_3Hg^+) compounds, which then concentrate in the food chains of fish and other aquatic life. An early discovery of the environmental hazard of mercury was in Japan in the 1950s. Dozens of cases of mercury poisoning, including more than 40 deaths, occurred among residents of the shores of Minamata Bay. Local seafood with up to 20 ppm of mercury was a major component of the victims' diet. The source of contamination was traced to a chemical plant discharging mercury waste into the bay.

Chisso plant
Minamata
The area with outbreak of patients

▲ The area of contamination in Japan where mercury poisoning was observed.

In the free state, mercury is most poisonous as a vapor. Levels of mercury that exceed 0.05 mg Hg/m^3 air are considered unsafe. Although we think of mercury as having a low vapor pressure, the concentration of Hg in its saturated vapor far exceeds this limit, and mercury vapor levels sometimes exceed safe limits where mercury is used—as in chlor–alkali plants, thermometer factories, and smelters.

Although zinc is an essential element in trace amounts, cadmium, which so closely resembles zinc, is a poison. One effect of cadmium poisoning is an extremely painful skeletal disorder known as *itai-itai kyo* (Japanese for "ouch-ouch" disease). This disorder was discovered in an area of Japan where effluents from a zinc mine became mixed with irrigation water used in rice fields, and cadmium poisoning was discovered in people who ate the rice. Cadmium poisoning can also cause liver damage, kidney failure, and pulmonary disease. The mechanism of cadmium poisoning may involve substitution in certain enzymes of Cd (a poison) for Zn (an essential element). Concern over cadmium poisoning has increased with an awareness that some cadmium is almost always found in zinc and zinc compounds, materials that have many commercial applications.

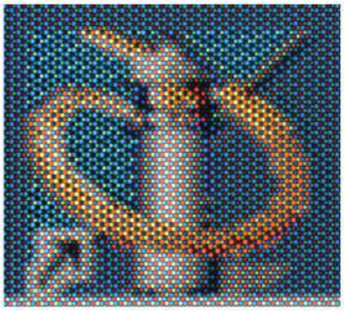
Suggest the geometry of the cadmium anion $[CdCl_5]^{3-}$.

23-8 Lanthanides

The elements from lanthanum $(Z = 57)$ through lutetium $(Z = 71)$ are variously called the *lanthanide, lanthanoid*, or *rare earth elements*. The rare earth elements are "rare" only relative to the alkaline earth metals (group 2). Otherwise, they are not particularly rare. Ce, Nd, and La, for example, are more abundant than lead, and Tm is about as abundant as iodine. The lanthanides occur primarily as oxides, and mineral deposits containing them are found in various locations. Large deposits near the California-Nevada border are being developed to provide oxides of the lanthanides for use as phosphors in color monitors and television sets. Cobalt–samarium (Co_5Sm) magnets are used in high-efficiency motors.



▲ The individual elements of a CRT computer screen are phosphors that contain the lanthanide elements. The phosphors glow red, blue, or green depending on their composition. (™ Netscape ®)

Because the differences in electron configuration among the lanthanides are mainly in $4f$ orbitals, and because $4f$ electrons play a minor role in chemical bonding, strong similarities are found among these elements. For example, $E°$ values for the reduction process $M^{3+}(aq) + 3\,e^- \longrightarrow M(s)$ do not show much variation. All fall between −2.38 V (La) and −1.99 V (Eu). The differences in properties that do exist among the lanthanides arise mostly from the lanthanide contraction discussed in Section 23-1. This contraction is best illustrated in the radii of the ions M^{3+}. These radii decrease regularly by about 1–2 pm for each unit increase in atomic number, from a radius of 106 pm for La^{3+} to 85 pm for Lu^{3+}.

The lanthanides, which we can represent by the general symbol Ln, are reactive metals that liberate $H_2(g)$ from hot water and from dilute acids by undergoing oxidation to $Ln^{3+}(aq)$. The lanthanides combine with $O_2(g)$, sulfur, the halogens, $N_2(g)$, $H_2(g)$, and carbon in much the same way as expected for metals about as active as the alkaline earths. The pure metals can be prepared by electrolytic reduction of Ln^{3+} in a molten salt.

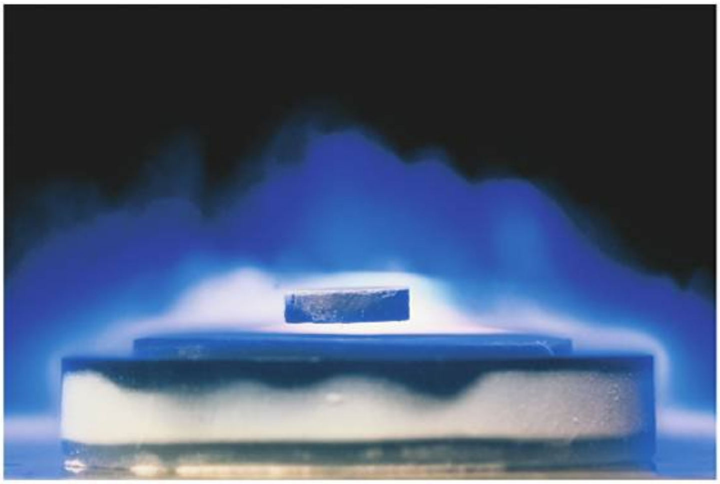
The most common oxidation state for the lanthanides is +3. About half the lanthanides can also be obtained in the oxidation state +2; the other half, +4. The special stability associated with an electron configuration involving half-filled f orbitals (f^7) may account for some of the observed oxidation states, but the reason for the predominance of the +3 oxidation state is less clear. Most of the lanthanide ions are paramagnetic and colored in aqueous solution.

The lanthanide elements are extremely difficult to extract from their natural sources and to separate from one another. All the methods for doing so are based on the following principle: Species that are strongly dissimilar can often be completely separated in a one-step process, such as separating $Ag^+(aq)$ and $Cu^{2+}(aq)$ by adding $Cl^-(aq)$; AgCl is insoluble. At best, species that are very similar can only be fractionated in a one-step process. That is, the ratio of the concentration of one species to that of another is altered slightly. To achieve a complete separation means repeating the same basic step hundreds or even thousands of times. To achieve the separation of the lanthanides, the methods of fractional crystallization, fractional precipitation, solvent extraction, and ion exchange were brought to their highest level of performance.

23-9 High-Temperature Superconductors

Magnetically levitated trains, magnetic resonance imaging (MRI) for medical diagnoses, and particle accelerators used in high-energy physics all require high magnetic fields generated by superconducting electromagnets. Superconductors offer no resistance to an electric current, so electricity is conducted with no loss of energy (Fig. 23-16).

If cooled to near absolute zero, all metals become superconducting. Several metals and alloys superconduct even at marginally higher temperatures of



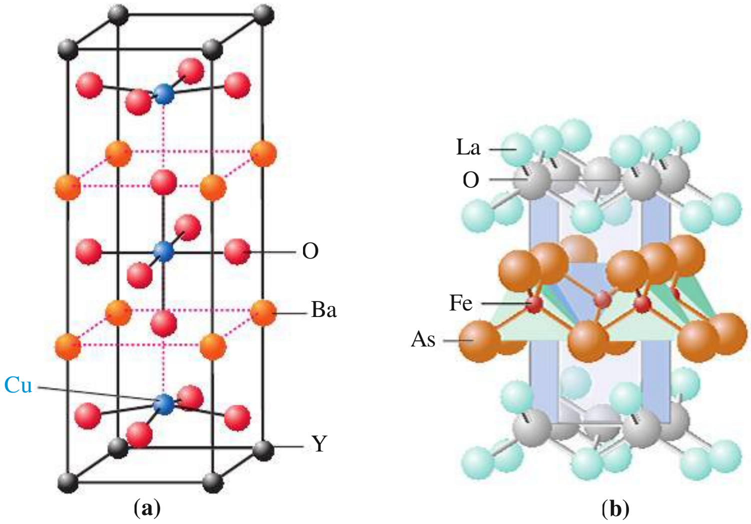
▶ FIGURE 23-16
The small magnet induces an electric current in the superconductor below it. Associated with this current is another magnetic field that opposes the field of the small magnet, causing it to be repelled. The magnet remains suspended above the superconductor as long as the superconducting current is present, and the current persists as long as the temperature of the superconductor is maintained at the boiling point of liquid nitrogen (77 K).

10–15 K. To maintain a superconductor at these extremely low temperatures requires liquid helium (bp, 4 K) as a coolant.

In the mid-1980s, materials made of lanthanum, strontium, copper, and oxygen were found to become superconducting at 30 K. This was a much higher temperature for superconductivity than had been previously achieved. More surprising, the new materials were not metals but *ceramics*! In short order, other types of ceramic superconductors were discovered.

One of these new types was particularly easy to make. When a stoichiometric mixture of yttrium oxide (Y_2O_3), barium carbonate ($BaCO_3$), and copper(II) oxide (CuO) is heated in a stream of $O_2(g)$, a ceramic is produced with the approximate formula $YBa_2Cu_3O_x$ (where x is slightly less than 7), which is an oxygen-deficient version of the ceramic $YBa_2Cu_3O_7$ shown in Figure 23-17). This so-called YBCO ceramic becomes superconducting at the remarkably high temperature of 92 K. Although a temperature of 92 K is still quite low, it is far above the boiling point of helium. In fact, it is above the boiling point of nitrogen (77 K). Thus, inexpensive liquid nitrogen can be used as the coolant.

Many variations of the basic YBCO formula are possible. Almost any lanthanide element can be substituted for yttrium, and combinations of group 2 elements can be substituted for barium. All these variations yield materials that are superconducting at relatively high temperatures, but of the group, the yttrium compound is superconducting at the highest temperature.



▶ FIGURE 23-17
Structures of $YBa_2Cu_3O_7$ and LaOFeAs
Two important classes of superconductors are based on the structures of **(a)** $YBa_2Cu_3O_7$ and **(b)** LaOFeAs.

The record high temperature for superconductivity set by the YBCO ceramics was soon eclipsed by another group of ceramics containing bismuth and copper, such as $Bi_2Sr_2CaCu_2O_8$. One of these is superconducting at 110 K, but this record was also short-lived. A ceramic containing thallium and copper, with the approximate formula $TlBa_2Ca_3Cu_4O_y$ (where y is slightly larger than 10), was found to become superconducting at 125 K. Now, the search continues for materials that might become superconducting at room temperature (about 293 K).

To date, many of the ceramic superconductors contain copper and share a common structural feature: carbon and oxygen atoms bonded together in planar sheets. In YBCO superconductors, the Cu—O planes are widely separated. In bismuth superconductors, the Cu—O planes occur in "sandwiches" consisting of two closely spaced sheets separated by a layer of group 2 ions. These sandwiches are separated from one another by several layers of bismuth oxide. In the thallium superconductors, the Cu—O planes are stacked in groups of three, like triple-decker sandwiches.

Recently,* the first copper-free ceramic superconductors were discovered. This new class of superconducting ceramics, with approximate formula $LaO_{1-x}F_xFeAs$, are based on iron, a metal that is much more abundant than copper. These superconducting materials are based on LaOFeAs, shown in Figure 23-17(b), but some of the O^{2-} ions are replaced by F^- ions. LaOFeAs has a stack of alternating layers of LaO and FeAs, as illustrated in Figure 23-17(b). The LaO layer is positively charged, consisting of La^{3+} and O^{2-} ions, and the FeAs layer is negatively charged, with the bonding between Fe and As being predominantly covalent. Replacing some of the O^{2-} ions with F^- ions gives a material that superconducts up to about 26 K. Although this temperature is not particularly high, the discovery has generated much excitement because it has opened up new possibilities for developing high-temperature superconductors.

The current theory of superconductivity, developed in the 1950s, explains the superconducting behavior of metals at very low temperatures but not the higher-temperature superconductivity of ceramics. It seems that the electrons in all known superconductors move through the material in pairs—a sort of buddy system that allows the electrons to move without resistance. The mechanism by which electron pairs form in high-temperature superconductors, however, is clearly different from that in low-temperature superconductors. Lack of a suitable theory complicates the search for higher-temperature superconductors. When the mechanism for high-temperature superconductors is better understood, new breakthroughs might be easier to accomplish. Perhaps a room-temperature superconducting material will be possible.

Despite this less-than-complete understanding of high-temperature superconductors, engineers are already building devices that use the new materials. Wires have been made that are superconducting at liquid nitrogen temperatures, and new devices for precise magnetic field measurements using ceramic superconductors are now being produced. Ultimately, ceramic superconductors may find application in low-cost, energy-efficient electric power transmission.

MasteringCHEMISTRY **www.masteringchemistry.com**

Nanoparticles are chemical structures whose dimensions are in the range 1–100 nm. One example of a nanoparticle is a quantum dot, a cluster of atoms with a diameter of tens of nanometers. For a discussion of the interesting and unusual properties of quantum dots, go to the Focus On feature for Chapter 23, Quantum Dots, on the MasteringChemistry site.

Summary

23-1 General Properties—More than half the elements are the metals known as transition elements. Most are more reactive than hydrogen. Transition metals tend to exist in several different oxidation states in their compounds (see Table 23.1), and they readily form complex ions (discussed in Chapter 24). Many transition metals and their compounds are paramagnetic, and certain of the metals (Fe, Co, and Ni) and their alloys exhibit **ferromagnetism**. Within a group of *d*-block elements, the members of the second and third transition series resemble one another more than they do the group member in the first transition series. This is a consequence of the phenomenon known as the **lanthanide contraction** occurring in the sixth period.

23-2 Principles of Extractive Metallurgy—The extraction of metals from their ores is called **extractive metallurgy**. **Pyrometallurgy** relies on roasting an ore with subsequent reduction of the oxide to the metal. In **hydrometallurgy** metal ions are leached from ores using aqueous solutions of acid or bases. Various methods can be used to refine impure metals. One technique for producing an ultrapure metal is **zone refining**, which involves the continuous melting and refreezing of the metal to concentrate the impurities in one region of the sample, which is then discarded (Fig. 23-6). The thermodynamics of metallurgy can be viewed as the appropriate coupling of reactions into a spontaneous process (Fig. 23-8).

23-3 Metallurgy of Iron and Steel—The conversion of iron(III) oxide into iron by reduction with carbon monoxide in a blast furnace (Fig. 23-9) leads to the formation of **pig iron**. Pig iron is converted to **steel** through the **basic oxygen process** (Fig. 23-10).

23-4 First-Row Transition Elements: Scandium to Manganese—Oxidation–reduction reactions are commonly encountered with transition metal compounds of Sc, Ti, V, Cr, and Mn. Two common types of oxidizing agents are the dichromates and permanganates. In aqueous solution, dichromate ion is in equilibrium with chromate ion, which is a good precipitating agent for a number of metal ions. Most oxides and hydroxides of the transition metals are basic if the metal is in one of its lower oxidation states. In higher oxidation states, some transition metal oxides and hydroxy compounds are amphoteric, and in the highest oxidation states, a few are acidic (as is CrO_3, for example).

23-5 The Iron Triad: Iron, Cobalt, and Nickel—The iron triad elements (Fe, Co, and Ni) exhibit a variability in oxidation state with +2 the most common. Like other transition elements these metals form compounds with carbon monoxide called metal **carbonyls**.

23-6 Group 11: Copper, Silver, and Gold—The metals Cu, Ag, and Au are resistant to corrosion and are widely used in coins and jewelry. These so-called coinage metals are excellent conductors of heat and electricity and are highly malleable. They also find many uses in the electronics industry.

23-7 Group 12: Zinc, Cadmium, and Mercury—These group 12 elements have chemical properties consistent with a filled *d* subshell. Zn is used in an alloy with copper to produce brass, which is a good electrical conductor and is resistant to corrosion. Most metals form alloys with mercury called **amalgams**.

23-8 Lanthanides—This first series of *f*-block elements have long been known as the rare earth elements, not because of their scarcity but because they are difficult to separate from one another. Their chemical behavior is strongly influenced by the lanthanide contraction, which produces similarities in their atomic and ionic sizes.

23-9 High-Temperature Superconductors—High-temperature superconducting materials have been made using some of the transition elements. In particular, a ceramic material that is superconducting at 92 K is made from yttrium, barium, copper, and oxygen. These ceramic materials have the potential for many applications, for example, more efficient electric power transmission.

Integrative Example

Although a number of slightly soluble copper(I) compounds (such as CuCN) can exist in contact with water, it is not possible to prepare a solution with a high concentration of Cu^+ ion.

Show that $Cu^+(aq)$ disproportionates to $Cu^{2+}(aq)$ and Cu(s), and explain why a high $[Cu^+]$ cannot be maintained in aqueous solution.

Analyze

Write a plausible equation describing the disproportionation reaction. Then determine E°_{cell} for the reaction, followed by the equilibrium constant *K*, and see what conclusions can be drawn from the numerical value of *K*.

Solve

The half-equations and overall equation for the disproportionation are

$$\begin{array}{lrcl} \textit{Reduction:} & Cu^+(aq) + e^- & \longrightarrow & Cu(s) \\ \textit{Oxidation:} & Cu^+(aq) & \longrightarrow & Cu^{2+}(aq) + e^- \\ \hline \textit{Overall:} & 2\,Cu^+(aq) & \longrightarrow & Cu^{2+}(aq) + Cu(s) \end{array}$$

Find E° values for the couples $Cu^+/Cu(s)$ and Cu^{2+}/Cu^+ in Appendix D and combine them to obtain E°_{cell}.

$$\begin{aligned} E^\circ_{cell} &= E^\circ(\text{reduction}) - E^\circ(\text{oxidation}) \\ &= E^\circ_{Cu^+/Cu(s)} - E^\circ_{Cu^{2+}/Cu^+} = 0.520\text{ V} - 0.159\text{ V} = 0.361\text{ V} \end{aligned}$$

Use equation (20.17) to obtain the value of K. In the equation $n = 1$,

$$E^\circ_{\text{cell}} = \frac{0.025693\ \text{V}}{n} \ln K$$

$$\ln K = \frac{n \times E^\circ_{\text{cell}}}{0.025693\ \text{V}} = \frac{1 \times 0.361\ \text{V}}{0.025693\ \text{V}} = 14.1$$

$$K = e^{14.1} = 1.3 \times 10^6$$

Thus, for the disproportionation reaction,

$$K = \frac{[\text{Cu}^{2+}]}{[\text{Cu}^+]^2} = 1.3 \times 10^6$$

and

$$[\text{Cu}^{2+}] = 1.3 \times 10^6 \times [\text{Cu}^+]^2$$

To maintain $[\text{Cu}^+] = 1$ M in solution, $[\text{Cu}^{2+}]$ would have to be more than 1×10^6 M—a clear impossibility.

Assess

As a practical matter, we could not maintain $[\text{Cu}^+]$ at much more than 0.002 M, for even this would require that $[\text{Cu}^{2+}] \approx 5$ M.

PRACTICE EXAMPLE A: Consider a galvanic cell based on the following half-reactions. Assuming the cell operates under standard conditions at 25 °C, what is the spontaneous cell reaction? Under what nonstandard conditions is the spontaneous formation of $[\text{PtCl}_6]^{2-}$ favored? Do you think that, in practical terms, a significant amount of PtCl_6^{2-} can be obtained by altering the concentrations in a galvanic cell?

$$\text{PtCl}_6{}^{2-} + 2\,e^- \longrightarrow \text{PtCl}_4{}^{2-} + 2\,\text{Cl}^- \qquad E^\circ = 0.68\ \text{V}$$
$$\text{V}^{3+} + e^- \longrightarrow \text{V}^{2+} \qquad E^\circ = -0.255\ \text{V}$$

PRACTICE EXAMPLE B: Because metallic titanium exhibits excellent corrosion resistance, it is often desirable to coat iron objects with a thin coating of titanium metal. One approach involves production of Ti(s) from electrolysis of molten mixtures of NaCl and TiCl_2. The production of Ti(s) involves the disproportionation of Ti^{2+} to Ti^{3+} and Ti. Write a balanced chemical equation for the disproportionation reaction and use the following half-reactions to decide whether the disproportionation reaction is spontaneous under standard conditions. $\text{Ti}^{2+} + 2e^- \longrightarrow \text{Ti}$, $E^\circ = -1.630$ V; $\text{Ti}^{3+} + e^- \longrightarrow \text{Ti}^{2+}$, $E^\circ = -0.369$ V.

Exercises

Properties of the Transition Elements

1. By means of orbital diagrams, write electron configurations for the following transition element atom and ions: **(a)** Ti; **(b)** V^{3+}; **(c)** Cr^{2+}; **(d)** Mn^{4+}; **(e)** Mn^{2+}; **(f)** Fe^{3+}.
2. Arrange the following species according to the number of unpaired electrons they contain, starting with the one that has the greatest number: Fe, Sc^{3+}, Ti^{2+}, Mn^{4+}, Cr, Cu^{2+}.
3. Describe how the transition elements compare with main-group metals (such as group 2) with respect to oxidation states, formation of complexes, colors of compounds, and magnetic properties.
4. With only minor irregularities, the melting points of the first series of transition metals rise from that of Sc to that of Cr and then fall to that of Zn. Give a plausible explanation for this phenomenon based on atomic structure.
5. Why do the atomic radii vary so much more for two main-group elements that differ by one unit in atomic number than they do for two transition elements that differ by one unit?
6. The metallic radii of Ni, Pd, and Pt are 125, 138, and 139 pm, respectively. Why is the difference in radius between Pt and Pd so much less than between Pd and Ni?
7. Which of the first transition series elements exhibits the greatest number of different oxidation states in its compounds? Explain.
8. Why is the number of common oxidation states for the elements at the beginning and those at the end of the first transition series less than for elements in the middle of the series?
9. As a group, the lanthanides are more reactive metals than are those in the first transition series. How do you account for this difference?
10. The maximum difference in standard reduction potential, $E^\circ_{\text{M}^{2+}/\text{M(s)}}$, among members of the first transition series is about 2.4 V. For the lanthanides, the maximum difference in $E^\circ_{\text{M}^{3+}/\text{M(s)}}$ is only about 0.4 V. How do you account for this fact?

Reactions of Transition Metals and Their Compounds

11. Complete and balance the following equations. If no reaction occurs, so state.

(a) $TiCl_4(g) + Na(l) \xrightarrow{\Delta}$

(b) $Cr_2O_3(s) + Al(s) \xrightarrow{\Delta}$

(c) $Ag(s) + HCl(aq) \longrightarrow$

(d) $K_2Cr_2O_7(aq) + KOH(aq) \longrightarrow$

(e) $MnO_2(s) + C(s) \xrightarrow{\Delta}$

12. By means of a chemical equation, give an example to represent the reaction of **(a)** a transition metal with a nonoxidizing acid; **(b)** a transition metal oxide with NaOH(aq); **(c)** an inner transition metal with HCl(aq).

13. Write balanced chemical equations for the following reactions described in the chapter.
(a) the reaction of $Sc(OH)_3(s)$ with HCl(aq)
(b) oxidation of $Fe^{2+}(aq)$ by $MnO_4^-(aq)$ in basic solution to give $Fe^{3+}(aq)$ and $MnO_2(s)$
(c) the reaction of $TiO_2(s)$ with molten KOH to form K_2TiO_3
(d) oxidation of Cu(s) to $Cu^{2+}(aq)$ with H_2SO_4 (concd aq) to form $SO_2(g)$

14. Write balanced equations for the following reactions described in the chapter.
(a) Sc(l) is produced by the electrolysis of Sc_2O_3 dissolved in $Na_3ScF_6(l)$.
(b) Cr(s) reacts with HCl(aq) to produce a blue solution containing $Cr^{2+}(aq)$.
(c) $Cr^{2+}(aq)$ is readily oxidized by $O_2(g)$ to $Cr^{3+}(aq)$.
(d) Ag(s) reacts with concentrated $HNO_3(aq)$, and $NO_2(g)$ is evolved.

15. Suggest a series of reactions, using common chemicals, by which each of the following syntheses can be performed.
(a) $Fe(OH)_3(s)$ from FeS(s)
(b) $BaCrO_4(s)$ from $BaCO_3(s)$ and $K_2Cr_2O_7(aq)$

16. Suggest a series of reactions, using common chemicals, by which each of the following syntheses can be performed.
(a) $Cu(OH)_2(s)$ from CuO(s)
(b) $CrCl_3(aq)$ from $(NH_4)_2Cr_2O_7(s)$

Extractive Metallurgy

17. One of the simplest metals to extract from its ores is mercury. Mercury vapor is produced by roasting cinnabar ore (HgS) in air. Alternatives to this simple roasting, designed to reduce or eliminate SO_2 emissions, is to roast the ore in the presence of a second substance. For example, when cinnabar is roasted with quicklime, the products are mercury vapor and calcium sulfide and calcium sulfate. Write equations for the two reactions described here.

18. According to Figure 23-8, $\Delta G°$ decreases with temperature for the reaction $2\,C(s) + O_2(g) \longrightarrow 2\,CO(g)$. How would you expect $\Delta G°$ to vary with temperature for the following reactions?
(a) $C(s) + O_2(g) \longrightarrow CO_2(g)$
(b) $2\,CO(g) + O_2(g) \longrightarrow 2\,CO_2(g)$

19. Calcium will reduce MgO(s) to Mg(s) at all temperatures from 0 to 2000 °C. Use this fact, together with the melting point (839 °C) and boiling point (1484 °C) of calcium, to sketch a plausible graph of $\Delta G°$ as a function of temperature for the reaction $2\,Ca(s) + O_2(g) \longrightarrow 2\,CaO(s)$.

20. One method of obtaining chromium metal from chromite ore is as follows. After reaction (23.16), sodium chromate is reduced to chromium(III) oxide by carbon. Then the chromium(III) oxide is reduced to chromium metal by silicon. Write plausible equations to describe these two reactions.

Oxidation–Reduction

21. Write plausible half-equations to represent each of the following in acidic solution.
(a) $VO^{2+}(aq)$ as an oxidizing agent
(b) $Cr^{2+}(aq)$ as a reducing agent

22. Write plausible half-equations to represent each of the following in basic solution.
(a) oxidation of $Fe(OH)_3(s)$ to FeO_4^{2-}
(b) reduction of $[Ag(CN)_2]^-$ to silver metal

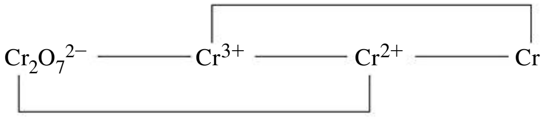
23. Use electrode potential data from this chapter or Appendix D to predict whether each of the following reactions will occur to any significant extent under standard-state conditions.
(a) $2\,VO_2^+ + 6\,Br^- + 8\,H^+ \longrightarrow 2\,V^{2+} + 3\,Br_2(l) + 4\,H_2O$
(b) $VO_2^+ + Fe^{2+} + 2\,H^+ \longrightarrow VO^{2+} + Fe^{3+} + H_2O$
(c) $MnO_2(s) + H_2O_2 + 2\,H^+ \longrightarrow Mn^{2+} + 2\,H_2O + O_2(g)$

24. You are given these three reducing agents: Zn(s), $Sn^{2+}(aq)$, and $I^-(aq)$. Use data from Appendix D to determine which of them can, under standard-state conditions in acidic solution, reduce
(a) $Cr_2O_7^{2-}(aq)$ to $Cr^{3+}(aq)$
(b) $Cr^{3+}(aq)$ to $Cr^{2+}(aq)$
(c) $SO_4^{2-}(aq)$ to $SO_2(g)$

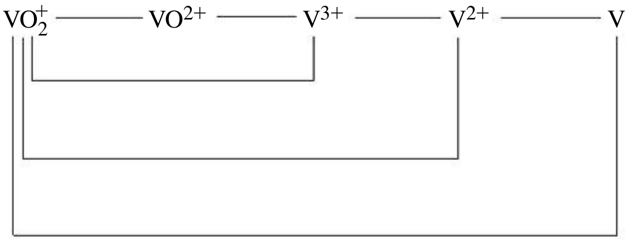
25. Refer to Example 23-2. Select a reducing agent (from Table 23.1 or Appendix D) that will reduce VO^{2+} to V^{3+} and no further in acidic solution.

26. The electrode potential diagram for manganese in acidic solutions in Figure 23-14 does not include a value of $E°$ for the reduction of MnO_4^- to Mn^{2+}. Use other data in the figure to establish this $E°$, and compare your result with the value found in Table 20.1.

27. Use data from the text to construct a standard electrode potential diagram relating the following chromium species in acidic solution.



28. Use data from the text to construct a standard electrode potential diagram relating the following vanadium species in acidic solution.



Chromium and Chromium Compounds

29. When a soluble lead compound is added to a solution containing primarily *orange* dichromate ion, *yellow* lead chromate precipitates. Describe the equilibria involved.

30. When *yellow* $BaCrO_4$ is dissolved in HCl(aq), a *green* solution is obtained. Write a chemical equation to account for the color change.

31. When Zn(s) is added to $K_2Cr_2O_7$ dissolved in HCl(aq), the color of the solution changes from orange to green, then to blue, and, over a period of time, back to green. Write equations for this series of reactions.

32. If $CO_2(g)$ under pressure is passed into $Na_2CrO_4(aq)$, $Na_2Cr_2O_7(aq)$ is formed. What is the function of the $CO_2(g)$? Write a plausible equation for the net reaction.

33. Use equation (23.19) to determine $[Cr_2O_7^{2-}]$ in a solution that has $[CrO_4^{2-}] = 0.20$ M and a pH of **(a)** 6.62 and **(b)** 8.85.

34. If a solution is prepared by dissolving 1.505 g Na_2CrO_4 in 345 mL of a buffer solution with pH = 7.55, what will be $[CrO_4^{2-}]$ and $[Cr_2O_7^{2-}]$?

35. How many grams of chromium would be deposited on an object in a chrome-plating bath (see page 1048) after 1.00 h at a current of 3.4 A?

36. How long would an electric current of 3.5 A have to pass through a chrome-plating bath (see page 1048) to produce a chromium deposit 0.0010 mm thick on an object with a surface area of 0.375 m^2? (The density of Cr is 7.14 g cm^{-3}.)

37. Why is it reasonable to expect the chemistry of dichromate ion to involve mainly oxidation–reduction reactions and that of chromate ion to involve mainly precipitation reactions?

38. What products are obtained when $Mg^{2+}(aq)$ and $Cr^{3+}(aq)$ are each treated with a limited amount of NaOH(aq)? With an excess of NaOH(aq)? Why are the results different in these two cases?

The Iron Triad

39. Will reaction (23.25) still be spontaneous in the forward direction in a solution containing equal concentrations of Fe^{2+} and Fe^{3+}, a pH of 3.25, and under an $O_2(g)$ partial pressure of 0.20 atm?

40. Based on the description of the nickel–cadmium cell on page 1053, and with appropriate data from Appendix D, estimate $E°$ for the reduction of NiO(OH) to $Ni(OH)_2$.

41. Write a net ionic equation to represent the precipitation of Prussian blue, described on page 1053.

42. The reaction to form Turnbull's blue (page 1053) appears to occur in two stages. First, $Fe^{2+}(aq)$ is oxidized to $Fe^{3+}(aq)$ and ferricyanide ion is reduced to ferrocyanide ion. Then, the $Fe^{3+}(aq)$ and ferrocyanide ion combine. Write equations for these reactions.

Group 11 Metals

43. Write plausible equations for the following reactions occurring in the hydrometallurgy of the coinage metals.

(a) Copper is precipitated from a solution of copper(II) sulfate by treatment with $H_2(g)$.

(b) Gold is precipitated from a solution of Au^+ by adding iron(II) sulfate.

(c) Copper(II) chloride solution is reduced to copper(I) chloride when treated with $SO_2(g)$ in acidic solution.

44. In the metallurgical extraction of silver and gold, an alloy of the two metals is often obtained. The alloy can be separated into Ag and Au either with concentrated HNO_3 or boiling concentrated H_2SO_4, in a process called *parting*. Write chemical equations to show how these separations work.

45. Use the result of the Integrative Example to determine whether a solution can be prepared with $[Cu^+]$ equal to **(a)** 0.20 M; **(b)** 1.0×10^{-10} M.

46. Show that the corrosion reaction in which Cu is converted to its basic carbonate (reaction 23.27) can be thought of in terms of a combination of oxidation–reduction, acid–base, and precipitation reactions.

Group 12 Metals

47. Use data from Table 23.8 to determine $E°$ for the reduction of Hg^{2+} to Hg_2^{2+} in aqueous solution.

48. At 400 °C, $\Delta G° = -25$ kJ for the reaction $2\,Hg(l) + O_2(g) \longrightarrow 2\,HgO(s)$. If a sample of HgO(s) is heated to 400 °C, what will be the equilibrium partial pressure of $O_2(g)$?

49. Use Figure 23-8 to estimate for the reaction $ZnO(s) + C(s) \rightleftharpoons Zn(l) + CO(g)$, at about 800 °C, **(a)** a value of K_p and **(b)** the equilibrium pressure of CO(g).

50. The vapor pressure of Hg(l) as a function of temperature is $\log P(\text{mmHg}) = (-0.05223a/T) + b$, where $a = 61{,}960$ and $b = 8.118$; T is the Kelvin temperature. Show that at 25 °C, the concentration of Hg(g) in equilibrium with Hg(l) greatly exceeds the maximum permissible level of 0.05 mg Hg/m^3 air.

51. In ZnO, the band gap between the valence and conduction bands is 290 kJ mol^{-1}, and in CdS it is 250 kJ mol^{-1}. Show that CdS absorbs some visible light but ZnO does not. Explain the observed colors: ZnO is white and CdS is yellow.

52. CdS is yellow, HgS is red, and CdSe is black. Which of these materials has the largest band gap? the smallest? How does the band gap relate to the observed color?

Integrative and Advanced Exercises

53. Although Au reacts with and dissolves in aqua regia (3 parts HCl + 1 part HNO_3), Ag does not dissolve. What is (are) the likely reason(s) for this difference?

54. The text mentions that scandium metal is obtained from its molten chloride by electrolysis, and that titanium is obtained from its chloride by reduction with magnesium. Why are these metals not obtained by the reduction of their oxides with carbon (coke), as are metals such as zinc and iron?

55. The text notes that in small quantities, zinc is an essential element (though it is toxic in higher concentrations). Tin is considered to be a toxic metal. Can you think of reasons why, for food storage, tinplate instead of galvanized iron is used in cans?

56. In an atmosphere polluted with industrial smog, Cu corrodes to a basic sulfate, $Cu_2(OH)_2SO_4$. Propose a series of chemical reactions to describe this corrosion.

57. What formulas would you expect for the metal carbonyls of **(a)** molybdenum, **(b)** osmium; **(c)** rhenium? Note that the simple carbonyls shown in Figure 23-15 have one metal atom per molecule. Some metal carbonyls are *binuclear*; that is, they have two metal atoms bonded together in the carbonyl structure. Also, **(d)** explain why iron and nickel carbonyls are liquids at room temperature, whereas that of cobalt is a solid, and **(e)** describe the probable nature of the bonding in the compound $Na[V(CO)_6]$.

58. For the straight-line graphs in Figure 23-8, explain why **(a)** breaks occur at the melting points and boiling points of the metals; **(b)** the slopes of the lines become more positive at these breaks; **(c)** the break at the boiling point is sharper than at the melting point.

59. Attempts to make CuI_2 by the reaction of $Cu^{2+}(aq)$ and $I^-(aq)$ produce CuI(s) and $I_3^-(aq)$ instead. Without performing detailed calculations, show why this reaction should occur.

$$2\,Cu^{2+}(aq) + 5\,I^-(aq) \longrightarrow 2\,CuI(s) + I_3^-(aq)$$

60. Without performing detailed calculations, show that significant disproportionation of AuCl occurs if you attempt to make a saturated aqueous solution. Use data from Table 23.7 and $K_{sp}(AuCl) = 2.0 \times 10^{-13}$.

61. In acidic solution, silver(II) oxide first dissolves to produce $Ag^{2+}(aq)$. This is followed by the oxidation of $H_2O(l)$ to $O_2(g)$ and the reduction of Ag^{2+} to Ag^+.

(a) Write equations for the dissolution and oxidation–reduction reactions.

(b) Show that the oxidation–reduction reaction is indeed spontaneous.

62. Equation (23.18), which represents the chromate–dichromate equilibrium, is actually the sum of two equilibrium expressions. The first is an acid–base reaction, $H^+ + CrO_4^{2-} \rightleftharpoons HCrO_4^-$. The second reaction involves elimination of a water molecule between two $HCrO_4^-$ ions (a dehydration reaction), $2\,HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O$. If the ionization constant, K_a, for $HCrO_4^-$ is 3.2×10^{-7}, what is the value of K for the dehydration reaction?

63. Show that under the following conditions, $Ba^{2+}(aq)$ can be separated from $Sr^{2+}(aq)$ and $Ca^{2+}(aq)$ by precipitating $BaCrO_4(s)$ with the other ions remaining in solution:

$$[Ba^{2+}] = [Sr^{2+}] = [Ca^{2+}] = 0.10\text{ M}$$
$$[HC_2H_3O_2] = [C_2H_3O_2^-] = 1.0\text{ M}$$
$$[Cr_2O_7^{2-}] = 0.0010\text{ M}$$
$$K_{sp}(BaCrO_4) = 1.2 \times 10^{-10}$$
$$K_{sp}(SrCrO_4) = 2.2 \times 10^{-5}$$

Use data from this and previous chapters, as necessary.

64. A 0.589 g sample of pyrolusite ore (impure MnO_2) is treated with 1.651 g of oxalic acid ($H_2C_2O_4 \cdot 2\,H_2O$) in an acidic medium (reaction 1). Following this, the excess oxalic acid is titrated with 30.06 mL of 0.1000 M $KMnO_4$ (reaction 2). What is the mass percent of MnO_2 in the pyrolusite? The following equations are neither complete nor balanced.

$$\text{(1)}\quad H_2C_2O_4(aq) + MnO_2(s) \longrightarrow Mn^{2+}(aq) + CO_2(g)$$
$$\text{(2)}\quad H_2C_2O_4(aq) + MnO_4^-(aq) \longrightarrow Mn^{2+}(aq) + CO_2(g)$$

65. Both $Cr_2O_7^{2-}(aq)$ and $MnO_4^-(aq)$ can be used to titrate $Fe^{2+}(aq)$ to $Fe^{3+}(aq)$. Suppose you have available as titrants two solutions: 0.1000 M $Cr_2O_7^{2-}(aq)$ and 0.1000 M $MnO_4^-(aq)$.

(a) For which solution would the greater volume of titrant be required for the titration of a particular sample of $Fe^{2+}(aq)$? Explain.

(b) How many mL of 0.1000 M $MnO_4^-(aq)$ would be required for a titration if the same titration requires 24.50 mL of 0.1000 M $Cr_2O_7^{2-}(aq)$?

66. The only important compounds of Ag(II) are AgF_2 and AgO. Why would you expect these two compounds to be stable, but not other silver(II) compounds such as $AgCl_2$, $AgBr_2$, and AgS?

67. A certain steel is to be analyzed for Cr and Mn. By suitable treatment, the Cr in the steel is oxidized to $Cr_2O_7^{2-}(aq)$ and the Mn to $MnO_4^-(aq)$. A 10.000 g sample of steel is used to produce 250.0 mL of a solution containing $Cr_2O_7^{2-}(aq)$ and $MnO_4^-(aq)$. A 10.00 mL portion of this solution is added to $BaCl_2(aq)$, and by proper adjustment of the pH, the chromium is completely precipitated as $BaCrO_4(s)$; 0.549 g is obtained. A second 10.00 mL portion of the solution requires exactly 15.95 mL of 0.0750 M $Fe^{2+}(aq)$ for its titration in acidic solution. Calculate the % Cr and % Mn in the steel sample. [*Hint:* In the titration $MnO_4^-(aq)$ is reduced to $Mn^{2+}(aq)$ and $Cr_2O_7^{2-}(aq)$ is reduced to $Cr^{3+}(aq)$; the $Fe^{2+}(aq)$ is oxidized to $Fe^{3+}(aq)$.]

68. Nickel can be determined as nickel dimethylglyoximate, a brilliant scarlet precipitate that has the composition 20.31% Ni, 33.26% C, 4.88% H, 22.15% O, and 19.39% N. A 15.020 g steel sample is dissolved in concentrated HCl(aq). The solution obtained is suitably treated to remove interfering ions, to establish the proper pH, and to obtain a final solution volume of 250.0 mL. A 10.00 mL sample of this solution is then treated with dimethylglyoxime. The mass of purified, dry nickel dimethylglyoximate obtained is 0.104 g.

(a) What is the empirical formula of nickel dimethylglyoximate?

(b) What is the mass percent nickel in the steel sample?

69. A solution is believed to contain one or more of the following ions: Cr^{3+}, Zn^{2+}, Fe^{3+}, Ni^{2+}. When the solution is treated with excess NaOH(aq), a precipitate forms. The solution in contact with the precipitate is colorless. The precipitate is dissolved in HCl(aq), and the resulting solution is treated with $NH_3(aq)$. No precipitation occurs. Based solely on these observations, what conclusions can you draw about the ions present in the original solution? That is, which ion(s) are likely present, which are most likely not present, and about which can we not be certain? [*Hint:* Refer to Appendix D for solubility product and complex-ion formation data.]

70. Nearly all mercury(II) compounds exhibit covalent bonding. Mercury(II) chloride is a covalent molecule that dissolves in warm water. The stability of this compound is exploited in the determination of the levels of chloride ion in blood serum. Typical human blood serum levels range from 90 to 115 mmol L^{-1}. The chloride concentration is determined by titration with $Hg(NO_3)_2$. The indicator used in the titration is diphenylcarbazone, $C_6H_5N{=}NCONHNHC_6H_5$, which complexes with the mercury(II) ion after all the chloride has reacted with the mercury(II). Free diphenylcarbazone is pink in solution, and when it is complexed with mercury(II), it is blue. Thus, the diphenylcarbazone acts as an indicator, changing from pink to blue when the first excess of mercury(II) appears. In an experiment, $Hg(NO_3)_2(aq)$ solution is standardized by titrating 2.00 mL of 0.0108 M NaCl solution. It takes 1.12 mL of $Hg(NO_3)_2(aq)$ to reach the diphenylcarbazone end point. A 0.500 mL serum sample is treated with 3.50 mL water, 0.50 mL of 10% sodium tungstate solution, and 0.50 mL of 0.33 M $H_2SO_4(aq)$ to precipitate proteins. After the proteins are precipitated, the sample is filtered and a 2.00 mL aliquot of the filtrate is titrated with $Hg(NO_3)_2$ solution, requiring 1.23 mL. Calculate the concentration of Cl^-. Express your answer in mmol L^{-1}. Does this concentration fall in the normal range?

71. Covalent bonding is involved in many transition metal compounds. Draw Lewis structures, showing any nonzero formal charges, for the following molecules or ions: **(a)** Hg_2^{2+}; **(b)** Mn_2O_7; **(c)** OsO_4. [*Hint:* In (b), there is one Mn—O—Mn linkage in the molecule.]

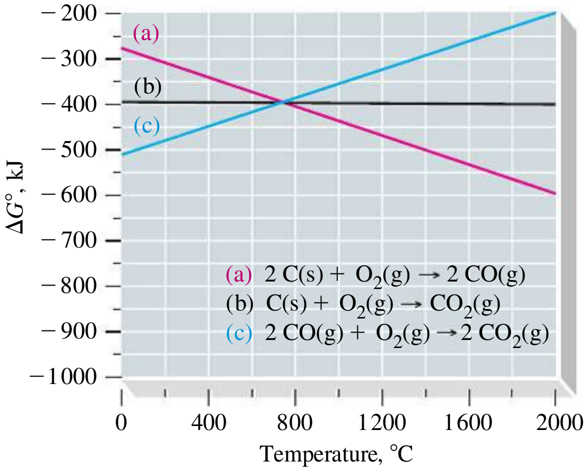
72. For a coordination number of four, the radius of Mn^{7+} has been estimated to be 39 pm. Estimate the charge density for the Mn^{7+} ion. Express your answer in C mm^{-3}. How does this compare with the charge density of Be^{2+} given in Table 21.4? Would you expect the bonding in Mn_2O_7 to be primarily ionic or primarily covalent? Explain.

73. Nitinol is a nickel–titanium alloy known as *memory metal*. The name nitinol is derived from the symbols for nickel (Ni), titanium (Ti), and the acronym for the Naval Ordinance Laboratory (NOL), where it was discovered. If an object made out of nitinol is heated to about 500 °C for about an hour and then allowed to cool, the original shape of the object is "remembered," even if the object is deformed into a different shape. The original shape can be restored by heating the metal. Because of this property, nitinol has found many uses, especially in medicine and orthodontics (for braces). Nitinol exists in a number of different solid phases. In the so-called austerite phase, the metal is relatively soft and elastic. The crystal structure for the austerite phase can be described as a simple cubic lattice of Ti atoms with Ni atoms occupying cubic holes in the lattice of Ti atoms. What is the empirical formula of nitinol and what is the percent by mass of titanium in the alloy?

Feature Problems

74. As a continuation of Problem 94 of Chapter 19 and the discussion on page 1040, consider the three graphs of ΔG° as a function of temperature shown in the following figure.

(a) Explain the shapes of the three graphs. Specifically, why is one line essentially parallel to the temperature axis, why does one have a positive slope, and why does one have a negative slope?



(b) Table 23.2 lists as an additional blast furnace reaction, $C(s) + CO_2(g) \longrightarrow 2\,CO(g)$. Determine how $\Delta G°$ for this reaction is related to the three reactions shown in the figure, and plot $\Delta G°$ for this reaction as a function of temperature. If an equilibrium is established in this reaction at 1000 °C and the partial pressure of $CO_2(g)$ is 0.25 atm, what should be the equilibrium partial pressure of CO(g)?

75. Several transition metal ions are found in cation group 3 of the qualitative analysis scheme outlined in Figure 18-7. At one point in the separation and testing of this group, a solution containing Fe^{3+}, Co^{2+}, Ni^{2+}, Al^{3+}, Cr^{3+}, and Zn^{2+} is treated with an excess of NaOH(aq), together with $H_2O_2(aq)$.
(1) The excess NaOH(aq) causes *three* of the cations to precipitate as hydroxides and *three* to form hydroxo complex ions.
(2) In the presence of $H_2O_2(aq)$, the cation in one of the insoluble hydroxides is oxidized from the +2 to the +3 oxidation state, and one of the hydroxo complex ions is also oxidized.
(3) The three insoluble hydroxides are found as a dark precipitate.
(4) The solution above the precipitate has a yellow color.
(5) The dark precipitate from (3) reacts with HCl(aq), and all the cations return to solution; one of the cations is reduced from the +3 to the +2 oxidation state.
(6) The solution from (5) is treated with 6 M $NH_3(aq)$, and a precipitate containing one of the cations forms.
(a) Write equations for the reactions referred to in item (1).
(b) Write an equation for the most likely reaction in which a hydroxide precipitate is oxidized in item (2).
(c) What is the ion responsible for the yellow color of the solution in item (4)? Write an equation for its formation.
(d) Write equations for the dissolution of the precipitate and the reduction of the cation in item (5).
(e) Write an equation for the precipitate formation in item (6). [*Hint:* You may need solubility product and complex-ion formation data from Appendix D, together with descriptive information from this chapter and from elsewhere in the text.]

Self-Assessment Exercises

76. In your own words, define the following terms: **(a)** domain; **(b)** flotation; **(c)** leaching; **(d)** amalgam.

77. Briefly describe each of the following ideas, phenomena, or methods: **(a)** lanthanide contraction; **(b)** zone refining; **(c)** basic oxygen process; **(d)** slag formation.

78. Explain the important distinctions between each pair of terms: **(a)** ferromagnetism and paramagnetism; **(b)** roasting and reduction; **(c)** hydrometallurgy and pyrometallurgy; **(d)** chromate and dichromate.

79. Describe the chemical composition of the material called **(a)** pig iron; **(b)** ferromanganese alloy; **(c)** chromite ore; **(d)** brass; **(e)** aqua regia; **(f)** blister copper; **(g)** stainless steel.

80. Three properties expected for transition elements are **(a)** low melting points; **(b)** high ionization energies; **(c)** colored ions in solution; **(d)** positive standard electrode (reduction) potentials; **(e)** diamagnetism; **(f)** complex ion formation; **(g)** catalytic activity.

81. The only diamagnetic ion of the following group is **(a)** Cr^{2+}; **(b)** Zn^{2+}; **(c)** Fe^{3+}; **(d)** Ag^{2+}; **(e)** Ti^{3+}.

82. All of the following elements have an ion displaying the +6 oxidation state except **(a)** Mo; **(b)** Cr; **(c)** Mn; **(d)** V; **(e)** S.

83. The best oxidizing agent of the following group of ions is **(a)** $Ag^+(aq)$; **(b)** $Cl^-(aq)$; **(c)** $H^+(aq)$; **(d)** $Na^+(aq)$; **(e)** $OH^-(aq)$.

84. To separate Fe^{3+} and Ni^{2+} from an aqueous solution containing both ions, with one cation forming a precipitate and the other remaining in solution, add to the solution **(a)** NaOH(aq); **(b)** $H_2S(g)$; **(c)** HCl(aq); **(d)** $NH_3(aq)$.

85. Of the following, the two solids that will liberate $Cl_2(g)$ when heated with HCl(aq) are **(a)** NaCl(s); **(b)** $ZnCl_2(s)$; **(c)** $MnO_2(s)$; **(d)** CuO(s); **(e)** $K_2Cr_2O_7(s)$; **(f)** NaOH(s).

86. Provide the missing name or formula for the following:
(a) chromium(VI) oxide _____
(b) _____ K_2MnO_4
(c) _____ $Cr(CO)_6$
(d) barium dichromate _____
(e) _____ $La_2(SO_4)_3 \cdot 9\,H_2O$
(f) gold(III) cyanide trihydrate _____

87. Balance the following oxidation–reduction equations.
(a) $Fe_2S_3(s) + H_2O + O_2(g) \longrightarrow Fe(OH)_3(s) + S(s)$
(b) $Mn^{2+}(aq) + S_2O_8{}^{2-}(aq) + H_2O \longrightarrow MnO_4{}^-(aq) + SO_4{}^{2-}(aq) + H^+(aq)$
(c) $Ag(s) + CN^-(aq) + O_2(g) + H_2O \longrightarrow [Ag(CN)_2]^-(aq) + OH^-(aq)$

88. Explain why Zn, Cd, and Hg resemble the group 2 metals in some of their properties.

89. Explain why gold dissolves in aqua regia but not in $HNO_3(aq)$.

90. Explain why 1.0 M $Fe(NO_3)_3(aq)$ is acidic.

24

Complex Ions and Coordination Compounds

Turquoise is a mineral of copper, $CuAl_6(PO_4)_4(OH)_8 \cdot 4\ H_2O$. The distinctive color of this gemstone and many others is a consequence of the nature of metal–ligand bonding in complex ions, a central topic of this chapter.

Chapter 23 included discussions of several situations involving a succession of color changes that were attributed to changes in oxidation state. The color changes discussed in this chapter are not generally caused by oxidation–reduction reactions. Instead, they are observed with changes in the groups (ligands) bound to a metal center, even though the oxidation state of the metal remains unchanged. Explanation of this observation requires a fuller exploration of the nature of complex ions and coordination compounds, a subject that was briefly introduced in Chapter 18. One topic we will consider is the geometric structure of complex ions, which reveals new possibilities for isomerism: the existence of compounds having identical compositions but different structures and properties. We will also examine the nature of the bonding between ligands and the metal centers to which they are attached. It is through an understanding of bonding in complex ions that we can gain some insight into the origin of their colors.

24-1 Werner's Theory of Coordination Compounds: An Overview

▲ **Alfred Werner (1866–1919)** Werner's success in explaining coordination compounds came in large part through his application of new ideas: the theory of electrolytic dissociation and principles of structural chemistry.

Prussian blue (page 1053), accidentally discovered early in the eighteenth century, was perhaps the first known coordination compound—the type explored in this chapter. However, nearly a century passed before the uniqueness of these compounds came to be appreciated. In 1798, B. M. Tassaert obtained yellow crystals of a compound having the formula $CoCl_3 \cdot 6\,NH_3$ from a mixture of $CoCl_3$ and $NH_3(aq)$. What seemed unusual was that both $CoCl_3$ and NH_3 are stable compounds capable of independent existence, yet they combine to form still another stable compound. Such compounds made up of two simpler compounds came to be called **coordination compounds**.

In 1851, another coordination compound of $CoCl_3$ and NH_3 was discovered. This one had the formula $CoCl_3 \cdot 5\,NH_3$ and formed purple crystals. The two compounds are shown in Figure 24-1. Their formulas follow.

$$\underset{\substack{\text{(yellow)}\\\text{(a)}}}{CoCl_3 \cdot 6\,NH_3} \qquad \underset{\substack{\text{(purple)}\\\text{(b)}}}{CoCl_3 \cdot 5\,NH_3}$$

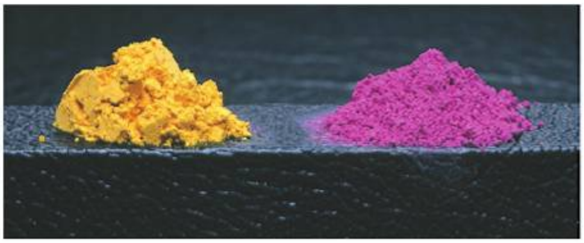
The mystery of coordination compounds deepened as more were discovered and studied. For example, when treated with $AgNO_3(aq)$, compound (a) formed *three* moles of AgCl(s), as expected, but compound (b) formed only *two* moles of AgCl(s).

Inorganic coordination chemistry was a hot field of research in the second half of the nineteenth century, and all the pieces started to fall into place with the work of the Swiss chemist Alfred Werner. Werner's theory of coordination compounds explained the reactions of compounds (a) and (b) with $AgNO_3(aq)$ by considering that, in aqueous solutions, these two compounds ionize in the following way:

$$\text{(a)} \quad [Co(NH_3)_6]Cl_3(s) \xrightarrow{H_2O} [Co(NH_3)_6]^{3+}(aq) + 3\,Cl^-(aq)$$

$$\text{(b)} \quad [CoCl(NH_3)_5]Cl_2(s) \xrightarrow{H_2O} [CoCl(NH_3)_5]^{2+}(aq) + 2\,Cl^-(aq)$$

Thus, compound (a) produces the three moles of Cl^- per mole of compound necessary to precipitate three moles of AgCl(s), while compound (b) produces only two moles of Cl^-. Werner's proposal of this ionization scheme was based on extensive studies of the electrical conductivity of coordination compounds. Compound (a) is a better conductor than compound (b), consistent with producing four ions per formula unit compared to three for compound (b). $CoCl_3 \cdot 4\,NH_3$ is a still poorer conductor, corresponding to the formula $[CoCl_2(NH_3)_4]Cl$. $CoCl_3 \cdot 3\,NH_3$ is a *nonelectrolyte*, corresponding to the formula $[CoCl_3(NH_3)_3]$.



▲ FIGURE 24-1
Two coordination compounds
The compound on the left is $[Co(NH_3)_6]Cl_3$. The compound on the right is $[CoCl(NH_3)_5]Cl_2$.

The heart of Werner's theory, proposed in 1893, was that certain metal atoms, primarily those of transition metals, have two types of valence or bonding capacity. One, the *primary* valence, is based on the number of electrons the atom loses in forming the metal ion. A *secondary* valence is responsible for the bonding of other groups, called **ligands**, to the central metal ion.

In modern usage, a **complex** is any species involving coordination of ligands to a metal center. The metal center can be an atom or an ion, and the complex can be a cation, an anion, or a neutral molecule. In a chemical formula, a complex—a metal center and attached ligands—is set off by square brackets, [ ]. Compounds that are complexes or contain complex ions are known as coordination compounds.

$[Co(NH_3)_6]^{3+}$	$[CoCl_4(NH_3)_2]^-$	$[CoCl_3(NH_3)_3]$	$K_4[Fe(CN)_6]$
Complex cation	Complex anion	Neutral complex	Coordination compound

The **coordination number** of a complex is the number of points around the metal center at which bonds to ligands can form. Coordination numbers ranging from 2 to 12 have been observed, although 6 is by far the most common number, followed by 4. Coordination number 2 is limited mostly to complexes of Cu(I), Ag(I), and Au(I). Coordination numbers greater than 6 are not often found in members of the first transition series, but are more common in those of the second and third series. Stable complexes with coordination numbers 3 and 5 are rare. The coordination number observed in a complex depends on a number of factors, such as the ratio of the radius of the central metal atom or ion to the radii of the attached ligands.

Coordination numbers of some common ions are listed in Table 24.1. The four most commonly observed geometric shapes of complex ions are shown in Figure 24-2. One practical use of the coordination number is to assist in writing and interpreting formulas of complexes, as illustrated in Example 24-1.

TABLE 24.1 Some Common Coordination Numbers of Metal Ions

Cu^+	2, 4		
Ag^+	2		
Au^+	2, 4	Al^{3+}	4, 6
		Sc^{3+}	6
		Cr^{3+}	6
Fe^{2+}	6	Fe^{3+}	6
Co^{2+}	4, 6	Co^{3+}	6

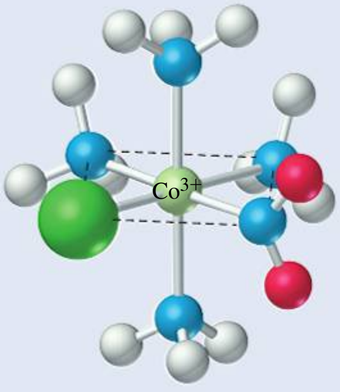
▲ FIGURE 24-2
Structures of some complex ions
Attachment of the NH_3 molecules occurs through the lone-pair electrons on the N atoms. In each complex, all the ligands are the same and hence no distortions of these shapes are observed.

EXAMPLE 24-1 Relating the Formula of a Complex to the Coordination Number and Oxidation State of the Central Metal

What are the coordination number and oxidation state of Co in the complex ion $[CoCl(NO_2)(NH_3)_4]^{+}$?



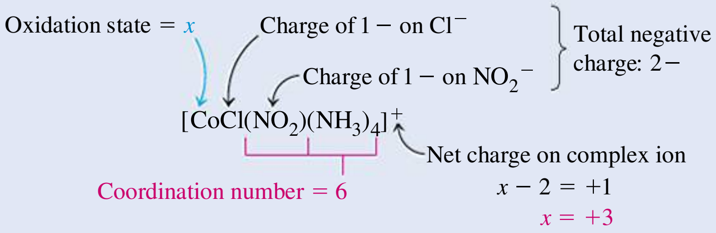
▲ The complex ion $[CoCl(NO_2)(NH_3)_4]^{+}$

Analyze

In determining the oxidation state of the metal ion in a complex, it is important to recognize which ligands are charged (invariably negatively charged) and which are neutral.

Solve

The complex ion has as ligands *one* Cl^- ion, *one* NO_2^- ion, and *four* NH_3 molecules. The coordination number is 6. Of these six ligands, *two* carry a charge of 1− each (the Cl^- and NO_2^- ions) and four are *neutral* (the NH_3 molecules). The total contribution of the anions to the net charge on the complex ion is 2−. Because the net charge on the complex ion is 1+, the oxidation state of the central cobalt ion is +3. Diagrammatically, we can write



Oxidation state = x
Charge of 1 − on Cl^-
Charge of 1 − on NO_2^-
Total negative charge: 2 −
$[CoCl(NO_2)(NH_3)_4]^{+}$
Net charge on complex ion
Coordination number = 6
$x - 2 = +1$
$x = +3$

Assess

The oxidation state of the metal can be determined by using the following relationship:

$$\text{charge on the complex ion} = \text{oxidation state of the metal} + \text{sum of charges on the ligands}$$

In this case,

$$\begin{aligned}(1+) &= \text{oxidation state of the metal} + (1-) + (1-)\\ \text{oxidation state of the metal} &= +3\end{aligned}$$

PRACTICE EXAMPLE A: What are the coordination number and oxidation state of nickel in the ion $[Ni(CN)_4I]^{3-}$?

PRACTICE EXAMPLE B: Write the formula of a complex with cyanide ion ligands, an iron ion with an oxidation state of +3, and a coordination number of 6.

24-1 CONCEPT ASSESSMENT

A complex of Al(III) can be formulated as $AlCl_3 \cdot 3\,H_2O$. The coordination number is not known but is expected to be 4 or 6. Describe how Werner's methods, that is, reaction with $AgNO_3(aq)$ or conductivity measurements, could help elucidate the actual coordination number.

24-2 Ligands

A common feature shared by the ligands in coordination complexes is the ability to donate electron pairs to central metal atoms or ions. Ligands are *Lewis bases*. In accepting electron pairs, central metal atoms or ions act as *Lewis acids*. A ligand that uses one pair of electrons to form one point of attachment to the central metal atom or ion is called a **monodentate** ligand. Some examples of monodentate ligands are monatomic anions such as the halide ions, polyatomic anions such as hydroxide ion, simple molecules, such as ammonia (called *ammine* when it is a ligand), and more complex molecules, such as methylamine, CH_3NH_2 (Table 24.2).

KEEP IN MIND

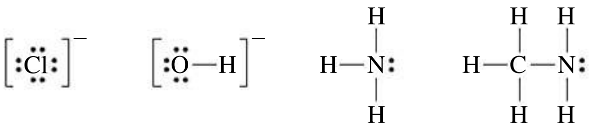
that the covalent bond formed in the Lewis acid–base reaction is a *coordinate* covalent bond. Thus we can think of the coordination number of a transition metal ion in a complex as the number of coordinate covalent bonds in the complex.

TABLE 24.2 Some Common Monodentate Ligands

Formula	Name as Ligand	Formula	Name as Ligand	Formula	Name as Ligand
Neutral molecules		Anions		Anions	
H_2O	Aqua	F^-	Fluoro	SO_4^{2-}	Sulfato
NH_3	Ammine	Cl^-	Chloro	$S_2O_3^{2-}$	Thiosulfato
CO	Carbonyl	Br^-	Bromo	NO_2^-	Nitrito-*N*-[a]
NO	Nitrosyl	I^-	Iodo	ONO^-	Nitrito-*O*-[a]
CH_3NH_2	Methylamine	O^{2-}	Oxo	SCN^-	Thiocyanato-*S*-[b]
C_5H_5N	Pyridine	OH^-	Hydroxo	NCS^-	Thiocyanato-*N*-[b]
		CN^-	Cyano		

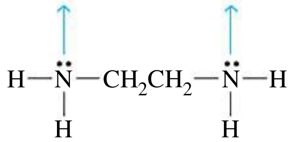
[a] If the nitrite ion is attached through the N atom ($—NO_2$), the designation *nitrito-N-* is used; if attached through an O atom (—ONO), *nitrito-O-*.

[b] If the thiocyanate ion is attached through the S atom (—SCN), the name *thiocyanato-S-* is used; if attachment is through the N atom (—NCS), *thiocyanato-N-*.



Ligand name: Chloro Hydroxo Ammine Methylamine

Some ligands are capable of donating more than a single electron pair from *different* atoms in the ligand and to *different* sites in the geometric structure of a complex. These are called **polydentate** ligands. The molecule *ethylenediamine* (en) can donate two electron pairs, one from each N atom. Since en attaches to the metal center at two points, it is called a **bidentate** ligand.



Three common polydentate ligands are shown in Table 24.3.

KEEP IN MIND

that the lone pairs of electrons of a polydentate ligand must be far enough apart to attach to the metal center at two or more points; the donated pairs of electrons must be on different atoms.

KEEP IN MIND

that the $EDTA^{4-}$ ligand is not planar as suggested in Table 24.3. Use VSEPR theory to gain an insight into the shape of this polyatomic anion. Also, refer to Figure 24-23.

TABLE 24.3 Some Common Polydentate Ligands (Chelating Agents)

Abbreviation	Name	Formula
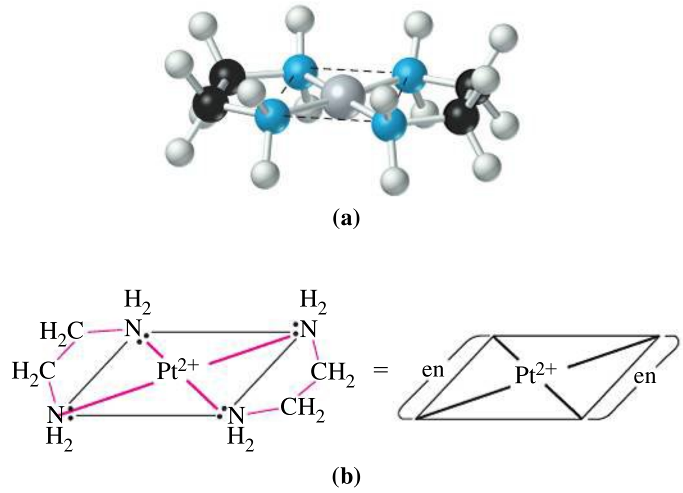
en	Ethylenediamine	ox^{2-}[a]	Oxalato	$EDTA^{4-}$[b]	Ethylenediaminetetraacetato	
[a] Oxalic acid is a diprotic acid denoted H_2ox. It is the ox^{2-} anion that binds as a bidentate ligand.

[b] Ethylenediaminetetraacetic acid, a tetraprotic acid, is denoted H_4EDTA.



▶ FIGURE 24-3
Three representations of the chelate $[Pt(en)_2]^{2+}$
(a) Overall structure. **(b)** The ligands attach at adjacent corners along an edge of the square. They do *not* bridge the square by attaching to opposite corners. Bonds are shown in red, and the square-planar shape is indicated by the black parallelogram.

Figure 24-3 represents the attachment of two ethylenediamine (en) ligands to a Pt^{2+} ion. Here is how we can establish that each ligand is attached to two positions in the coordination sphere around the Pt^{2+} ion.

- Because Pt^{2+} ion exhibits a coordination number of 4 with monodentate ligands, and because $[Pt(en)_2]^{2+}$ is unable to attach additional ligands such as NH_3, H_2O, or Cl^-, we conclude that each en group must be attached at two points.
- The en ligands in the complex ion exhibit no further basic properties. They cannot accept protons from water to produce OH^-, as they would if they had an available lone pair of electrons. Both $—NH_2$ groups of each en molecule must be tied up in the complex ion.

Note the two five-member rings (pentagons) outlined in Figure 24-3(b). They consist of Pt, N, and C atoms. When the bonding of a polydentate ligand to a metal ion produces a ring (normally with five or six members), we refer to the complex as a **chelate** (pronounced KEY-late). The polydentate ligand is called a **chelating agent**, and the process of chelate formation is called *chelation*.

24-2 CONCEPT ASSESSMENT

The ligand diethylenetriamine (abbreviated det), $H_2NCH_2CH_2NHCH_2CH_2NH_2$, can form complexes. Classify this ligand as mono-, bi-, tri-, or quadridentate.

24-1 ARE YOU WONDERING...

How such strange terms as *ligand*, *monodentate*, and *chelate* got into the vocabulary of chemistry?

Ligand comes from the Latin word *ligare*, which means to bind. It is quite appropriate to describe groups that are bound to a metal center as ligands. Dentate is also derived from a Latin word, *dens*, meaning tooth. Figuratively speaking, a monodentate ligand has one tooth; a bidentate ligand has two teeth; and a polydentate ligand has several. A ligand attaches itself to the metal center in accordance with the number of "teeth" it possesses. This is an easily remembered and colorful metaphor. Chelate is derived from the Greek word *chela*, which means a crab's claw. The way in which a chelating agent attaches itself to a metal ion resembles a crab's claw—another colorful metaphor.

24-3 Nomenclature

The system of naming complexes originated with Werner, but it has been modified several times over the years. Even today, usage varies somewhat. Our approach will be to consider a few general rules that permit us to relate names and formulas of simple complexes. We will not consider any of the complicated cases for which writing names and formulas is more challenging.

1. *Anions as ligands are named by using the ending* -o. As implied by Table 24.2, normally -*ide* endings change to -*o*, -*ite* to -*ito*, and -*ate* to -*ato*.
2. *Neutral molecules as ligands generally carry the unmodified name.* For example, the name ethylenediamine is used both for the free molecule and for the molecule as a ligand. Aqua, ammine, carbonyl, and nitrosyl are important exceptions (see Table 24.2).
3. *The number of ligands of a given type is denoted by a prefix.* The usual prefixes are *mono* = 1, *di* = 2, *tri* = 3, *tetra* = 4, *penta* = 5, and *hexa* = 6. As in many other cases, the prefix *mono*- is often not used. If the ligand name is a composite name that itself contains a numerical prefix, such as ethylene*di*amine, place parentheses around the name and precede it with *bis* = 2, *tris* = 3, *tetrakis* = 4, and so on. Thus, dichloro signifies *two* Cl^- ions as ligands, and *penta*aqua signifies *five* H_2O molecules. To indicate the presence of *two* ethylenediamine (en) ligands, we write *bis*(ethylenediamine).
4. *When we name a complex, ligands are named first, in alphabetical order, followed by the name of the metal center. The oxidation state of the metal center is denoted by a Roman numeral. If the complex is an anion, the ending* -ate *is attached to the name of the metal.* Prefixes (*di, tri, bis, tris, . . .*) are ignored in establishing the alphabetical order. Thus, $[CrCl_2(H_2O)_4]^+$ is called tetraaquadichlorochromium(III) ion; $[CoCl_2(en)_2]^+$ is dichlorobis(ethylenediamine)cobalt(III) ion; and $[Cr(OH)_4]^-$ is tetrahydroxochromate(III) ion. For complex anions of a few of the metals, the English name is replaced by the Latin name given in Table 24.4. Thus, $[CuCl_4]^{2-}$ is the tetrachlorocuprate(II) ion.
5. *When we write the formula of a complex, the chemical symbol of the metal center is written first, followed by the formulas of anions and then neutral molecules.* If there are two or more different anions or neutral molecules as ligands, they are written in alphabetical order according to the first chemical symbols of their formulas. Thus, in the formula of the tetraaminechloronitrito-*N*-cobalt(III) ion, Cl^- precedes NO_2^-, and both are placed ahead of the neutral NH_3 molecules: $[CoCl(NO_2)(NH_3)_4]^+$.
6. *In names and formulas of coordination compounds, cations come first followed by anions.* This is the same order as in simple ionic compounds like NaCl for sodium chloride. For example, the formula $[Pt(NH_3)_4][PtCl_4]$ represents the coordination compound tetraammineplatinum(II) tetrachloroplatinate(II).

◀ Occasionally, the metal center will be in the oxidation state 0, as in $[W(CO)_6]$ hexacarbonyltungsten(0).

TABLE 24.4 Names for Some Metals in Complex Anions

Iron	⟶	Ferrate
Copper	⟶	Cuprate
Tin	⟶	Stannate
Silver	⟶	Argentate
Lead	⟶	Plumbate
Gold	⟶	Aurate

EXAMPLE 24-2 Relating Names and Formulas of Complexes

(a) What is the name of the complex $[CoCl_3(NH_3)_3]$? **(b)** What is the formula of the compound pentaaquachlorochromium(III) chloride? **(c)** What is the name of the compound $K_3[Fe(CN)_6]$?

Analyze

To translate a chemical formula into the appropriate IUPAC name, we need to determine the oxidation state of the metal center (as done in Example 24-1), and then focus on naming the ligands. Translating an IUPAC name to a chemical formula is a simpler exercise, provided we know the names of common ligands and understand the meanings of the various prefixes.

(continued)

Solve

(a) $[CoCl_3(NH_3)_3]$ consists of *three* ammonia molecules and *three* chloride ions attached to a central Co^{3+} ion; it is electrically neutral. The name of this neutral complex is triamminetrichlorocobalt(III).

(b) The central metal ion is Cr^{3+}. There are five H_2O molecules and one Cl^- ion as ligands. The complex ion carries a net charge of 2+. Two Cl^- ions are required to neutralize the charge on this complex cation. The formula of the coordination compound is $[CrCl(H_2O)_5]Cl_2$.

(c) This compound consists of K^+ cations and complex anions having the formula $[Fe(CN)_6]^{3-}$. Each cyanide ion carries a charge of 1−, so the oxidation state of the iron must be +3. The Latin-based name "ferrate" is used because the complex ion is an anion. The name of the anion is hexacyanoferrate(III) ion. The coordination compound is potassium hexacyanoferrate(III).

Assess

The number of counter ions is never stated explicitly but is derived from the name. In part **(b)**, for example, the number of chloride ions is not stated.

PRACTICE EXAMPLE A: What is the formula of the compound potassium hexachloroplatinate(IV)?

PRACTICE EXAMPLE B: What is the name of the compound $[Co(SCN)(NH_3)_5]Cl_2$?

Although most complexes are named in the manner just outlined, some common, or trivial, names are still in use. Two such trivial names are ferrocyanide for $[Fe(CN)_6]^{4-}$ and ferricyanide for $[Fe(CN)_6]^{3-}$. These common names suggest the oxidation state of the central metal ions through the *o* and *i* designations (*o* for the ferrous ion, Fe^{2+}, in $[Fe(CN)_6]^{4-}$ and *i* for the ferric ion, Fe^{3+}, in $[Fe(CN)_6]^{3-}$). These trivial names do not indicate that the metal ions have a coordination number of 6, however. The systematic names—hexacyanoferrate(II) and hexacyanoferrate(III)—are more informative.

24-3 CONCEPT ASSESSMENT

A student named a coordination complex tripotassium dichlorodibromodihydroxoiron. The student's instructor pointed out that although the correct formula for the compound could be deduced, this name violates the IUPAC convention. How does this name violate IUPAC rules, and what is the correct name?

24-4 Isomerism

As previously noted (page 95), *isomers* are substances that have the same formulas but differ in their structures and properties. Several kinds of isomerism are found among complex ions and coordination compounds. These can be lumped into two broad categories: **Structural isomers** differ in basic structure or bond type—what ligands are bonded to the metal center and through which atoms. **Stereoisomers** have the same number and types of ligands and the same mode of attachment, but they differ in the way in which the ligands occupy the space around the metal center. Of the following five examples, the first three are types of structural isomerism (ionization, coordination, and linkage isomerism), and the remaining two are types of stereoisomerism (geometric and optical isomerism).

▶ Structural isomers are also known as constitutional isomers.

Ionization Isomerism

The two coordination compounds whose formulas are shown here have the same central ion (Cr^{3+}), and five of the six ligands (NH_3 molecules) are the same. The compounds differ in that one has SO_4^{2-} ion as the sixth ligand, with a Cl^- ion to neutralize the charge of the complex ion, whereas the other has Cl^- as the sixth ligand and SO_4^{2-} to neutralize the charge of the complex ion.

$[CrSO_4(NH_3)_5]Cl$
Pentaamminesulfatochromium(III) chloride
(a)

$[CrCl(NH_3)_5]SO_4$
Pentaamminechlorochromium(III) sulfate
(b)

Coordination Isomerism

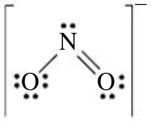
A situation somewhat similar to that just described can arise when a coordination compound is composed of both complex cations and complex anions. The ligands can be distributed differently between the two complex ions, as are $NH_3(aq)$ and CN^- in these two compounds.

$[Co(NH_3)_6][Cr(CN)_6]$
Hexaamminecobalt(III) hexacyanochromate(III)
(a)

$[Cr(NH_3)_6][Co(CN)_6]$
Hexaaminechromium(III) hexacyanocobaltate(III)
(b)

Linkage Isomerism

Some ligands may attach to the central metal ion of a complex ion in different ways. For example, the nitrite ion, a monodentate ligand, has electron pairs available for coordination both on the N and O atoms.



Whether attachment of this ligand is through the N or an O atom, the formula of the complex ion is unaffected. The properties of the complex ion, however, may be affected. When attachment occurs through the N atom, the ligand can be referred to as nitro or, more properly, nitrito-*N*- when naming the complex. Coordination through an O atom can be referred to as nitrito or, more properly, nitrito-*O*- when naming the complex.

$[Co(NO_2)(NH_3)_5]^{2+}$
Pentaamminenitrito-*N*-cobalt(III) ion
(a)

$[Co(ONO)(NH_3)_5]^{2+}$
Pentaamminenitrito-*O*-cobalt(III) ion
(b)

The structures of these compounds are illustrated in Figure 24-4 on page 1078.

Geometric Isomerism

If a single Cl^- ion is substituted for an NH_3 molecule in the square-planar complex ion $[Pt(NH_3)_4]^{2+}$ in Figure 24-2, it does not matter at which corner of the square this substitution is made. All four possibilities are alike. If a *second* Cl^- is substituted for an NH_3, there are two distinct possibilities (Fig. 24-5b). The two Cl^- ions can either be along the same edge of the square (***cis***) or on opposite corners, across from each other (***trans***). To distinguish clearly between these two possibilities, we must either draw a structure or refer to the appropriate name. The formula alone will not distinguish between them. (Note that this complex is a neutral species, not an ion.)

$[PtCl_2(NH_3)_2]$
cis-diamminedichloroplatinum(II)
or
trans-diamminedichloroplatinum(II)

◀ The term *cis* means "on this side" in Latin, and *trans* means "across." Domestic airline flights in the United States are *cis*atlantic, whereas flights to Europe are *trans*atlantic.

The type of isomerism described here in which the positions of the ligands produce distinct isomers is called **geometric isomerism**. Interestingly, if a *third*

Cl^- ion is substituted, isomerism disappears (Fig. 24-5c). There is only one complex ion with the formula $[PtCl_3(NH_3)]^-$.

With an octahedral complex, the situation is a bit more complicated. Take the complex ion $[Co(NH_3)_6]^{3+}$ of Figure 24-2 as an example. If one Cl^- is substituted for an NH_3, a single structure results. With the substitution of *two* Cl^- ions for NH_3 molecules, *cis* and *trans* isomers result. The *cis* isomer has two Cl^- ions along the same edge of the octahedron (Fig. 24-6a). The *trans* isomer has two Cl^- ions on opposite corners, that is, at opposite ends of a line drawn through the central metal ion (Fig. 24-6b). One difference between the two is that the *cis* isomer has a purple color and the *trans* has a bright green color.

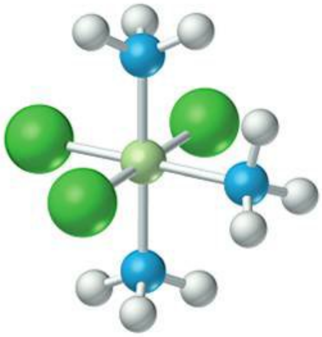
fac-$[CoCl_3(NH_3)_3]$



mer-$[CoCl_3(NH_3)_3]$

▲ **The geometric isomers of $[CoCl_3(NH_3)_3]$**

If a *third* Cl^- is substituted for an NH_3 in Figure 24-6(a), two possibilities exist. If this third substitution is at either the top or bottom of the structure, the result is that three Cl^- ions appear on the same face of the octahedron. This is called a *fac* (facial) isomer. If the third substitution is at either of the other two positions, the result is three Cl^- ions around a perimeter or meridian of the octahedron. This is a *mer* (meridional) isomer.

24-4 CONCEPT ASSESSMENT

Explain why the substitution of a *fourth* Cl^- for an NH_3 in *mer*-$[CoCl_3(NH_3)_3]$ may produce some of the same product as the substitution of a fourth Cl^- for an NH_3 in *fac*-$[CoCl_3(NH_3)_3]$, or it may also produce a different product.

EXAMPLE 24-3 Identifying Geometric Isomers

Sketch structures of all the possible isomers of $[CoCl(ox)(NH_3)_3]$.

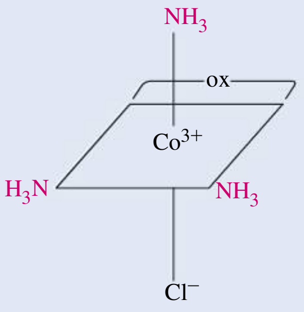
Analyze

The Co^{3+} ion exhibits a coordination number of 6. The structure is octahedral. Recall that ox (oxalate ion) is a bidentate ligand carrying a charge of 2– (see Table 24.3). Also, as shown in Figure 24-3, a bidentate ligand must be attached in *cis* positions, not *trans*.

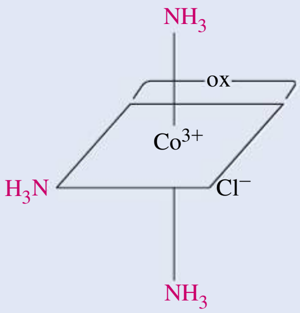
Solve

Once the ox ligand is placed, any position is available to the Cl^-. This leaves two possibilities for the three NH_3 molecules. They can be situated (1) on the same face of the octahedron (*fac* isomer) or (2) around a perimeter of the octahedron (*mer* isomer).

(continued)



fac isomer



mer isomer

Assess

We can also draw these stereoisomers by using the dashed and solid wedge symbols, together with a line diagram for the oxalate anion.

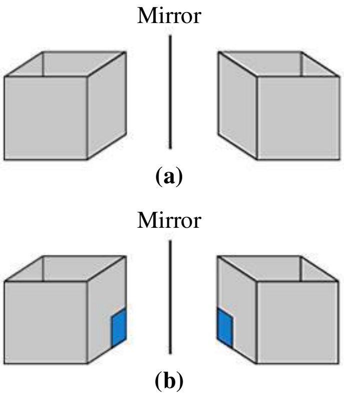
PRACTICE EXAMPLE B: Sketch the geometric isomers of $[MoCl_2(C_5H_5N)_2(CO)_2]^+$.

Optical Isomerism

To understand optical isomerism, we need to understand the relationship between an object and its mirror image. Features on the right side of the object appear on the left side of its image in a mirror, and vice versa. Certain objects can be rotated in such a way as to be *superimposable* on their mirror images, but other objects are *nonsuperimposable* on their mirror images. An unmarked tennis ball is superimposable on its mirror image, but a left hand is nonsuperimposable on its mirror image (a right hand).

Consider the open-top cardboard box pictured in Figure 24-7(a). There are a number of hypothetical ways in which the box can be superimposed on its mirror image. Now imagine that a distinctive sticker is placed at a corner of one side of the box (Fig. 24-7b). In this case, there is no way that the box and its mirror image can be superimposed; they are clearly different. This is equivalent to saying that there is no way that a formfitting left glove can be worn on a right hand (turning it inside out is not allowed).



▲ FIGURE 24-7
Superimposable and nonsuperimposable objects—an open-top box
(a) You can place the box into its mirror image (hypothetically) in several ways. The box and its mirror image are superimposable. **(b)** No matter how you place the box in its mirror image, the stickers will not appear in the same position. This box and its mirror image are nonsuperimposable.

The two structures of $[Co(en)_3]^{3+}$ depicted in Figure 24-8 are related to each other as are an object and its image in a mirror. Furthermore, the two structures are *nonsuperimposable*, like a left and a right hand. The two structures represent two different complex ions; they are isomers.

Structures that are nonsuperimposable mirror images of each other are called **enantiomers** and are said to be **chiral** (pronounced KYE-rull). (Structures that are superimposable are *achiral*.) Whereas other types of isomers may differ significantly in their physical and chemical properties,

◀ The prefixes *dextro* and *levo* are derived from the Latin words *dexter*, "right," and *levo*, "left."

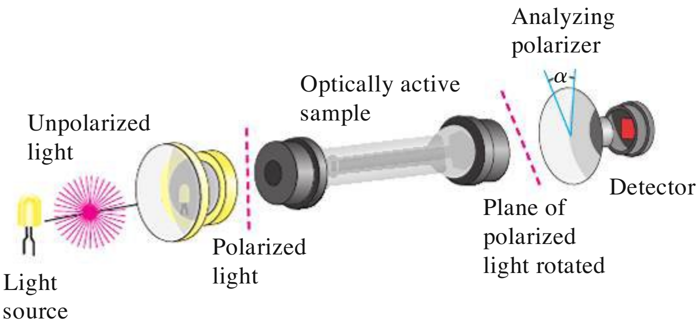
enantiomers have identical properties except in a few specialized situations. These exceptions involve phenomena that are directly linked to chirality, or handedness, at the molecular level. An example is *optical activity*, pictured in Figure 24-9.



Analyzing polarizer
α
Optically active sample
Unpolarized light
Detector
Plane of polarized light rotated
Polarized light
Light source

▲ FIGURE 24-9
Optical activity
Light from an ordinary source consists of electromagnetic waves vibrating in all planes; it is unpolarized. This light is passed through a polarizer, a material that screens out all waves except those vibrating in a particular plane. The plane of polarization of transmitted polarized light is then changed by passage through an optically active substance. The angle through which the plane of polarization has been rotated is determined by rotating an analyzer (a second polarizer) to the extent that all the polarized light is absorbed.

◀ Rotation of plane polarized light is a physical property. Chemical activity, or lack of it, is not a physical property. The physical and chemical properties, however, both depend on the existence of a center of asymmetry.

▶ A process based on chirality would be creating the maximum number of matched pairs of gloves from a bin of gloves of identical sizes of which 90 are for the right hand, but only 10 are for the left hand.

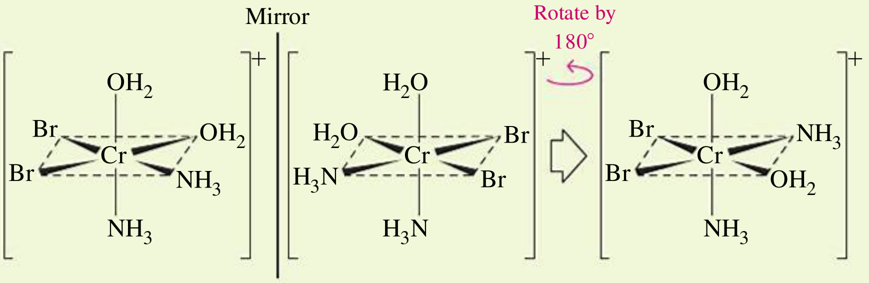
Interactions between a beam of polarized light and the electrons in an enantiomer cause the plane of the polarized light to rotate. One enantiomer rotates the plane of polarized light to the right (clockwise) and is said to be *dextrorotatory* (designated + or *d*). The other enantiomer rotates the plane of polarized light to the same extent, but to the left (counterclockwise). It is said to be *levorotatory* (− or *l*). Because they can rotate the plane of polarized light, the enantiomers are said to be *optically active* and are referred to as **optical isomers**.

When an optically active complex is synthesized, a mixture of the two optical isomers (enantiomers) is obtained, such as the two $[Co(en)_3]^{3+}$ isomers in Figure 24-8. The optical rotation of one isomer just cancels that of the other. The mixture, called a *racemic mixture*, produces no net rotation of the plane of polarized light. Separating the *d* and *l* isomers of a racemic mixture is called *resolution*. This separation can sometimes be achieved through chemical reactions controlled by chirality, with the two enantiomers behaving differently. Many phenomena of the living state, such as the effectiveness of a drug, the activity of an enzyme, and the ability of a microorganism to promote a reaction, involve chirality. We will discuss chirality again in Chapters 26, 27, and 28.

24-2 ARE YOU WONDERING...

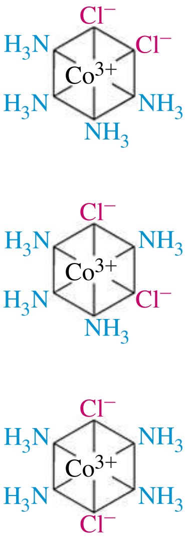
How to tell if a molecule is superimposable on its mirror image?

The complex ion $[CrBr_2(H_2O)_2(NH_3)_2]^+$ has five isomers; one is shown below with its mirror image. To test if the mirror image is superimposable on the original, imagine rotating the mirror image about the vertical axis ($H_2O—Cr—NH_3$) by 180° so that the two Br^- ligands are in the same position as in the original molecule. We see that the NH_3 and H_2O ligands that are in the same plane as the two Br^- ligands are in reversed positions when compared with the original molecule. Thus the molecule and its mirror image are not superimposable. The molecule is potentially optically active.



Isomerism and Werner's Theory

The study of isomerism played a crucial role in the development of Werner's theory of coordination chemistry. Werner proposed that complexes with coordination number 6 have an octahedral structure, but other possibilities were also proposed. For example, Figure 24-10 shows a hypothetical hexagonal structure for $[CoCl_2(NH_3)_4]^+$. However, this hexagonal structure would require the existence of *three* isomers, but a third isomer was never found; the only two isomers are those pictured in Figure 24-6. Additional direct evidence came with the discovery of optical isomerism in the tris(ethylenediamine) cobalt(III) ion (Fig. 24-8). Neither the hexagonal structure nor alternative

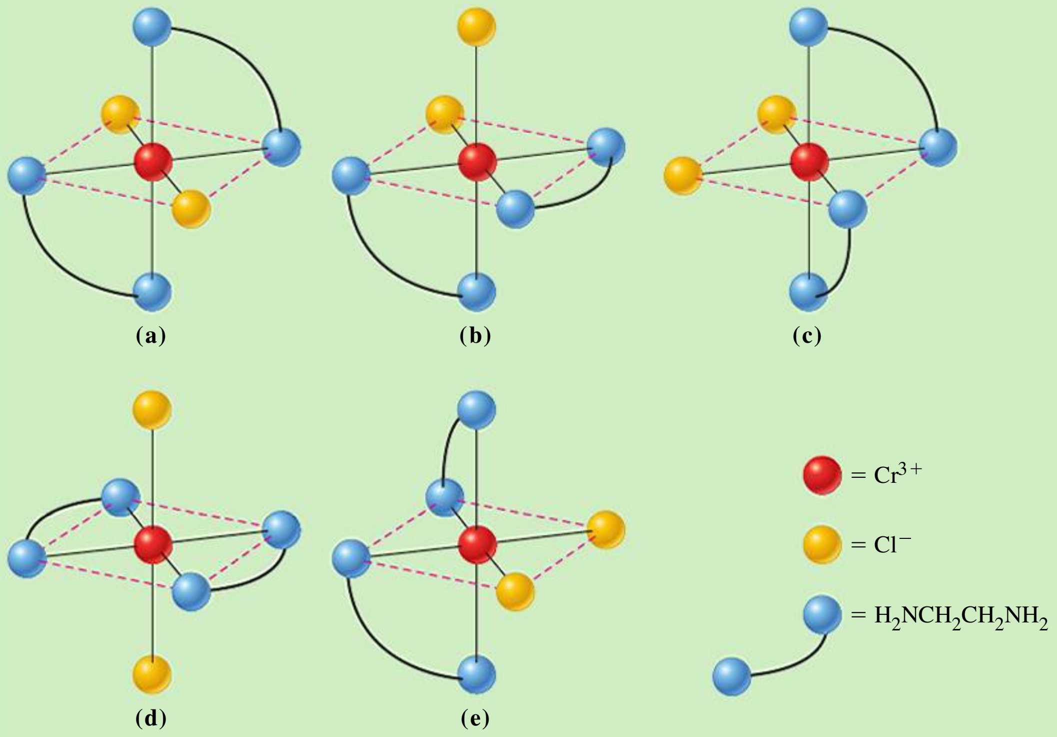


▲ FIGURE 24-10
Hypothetical structures for $[CoCl_2(NH_3)_4]^+$
If the complex ion had this hexagonal structure, there should be *three* distinct isomers, but only two isomers exist—*cis* and *trans*.

structures can account for this isomerism—but, as we have seen, the octahedral structure does. Werner even succeeded in preparing an optically active octahedral complex with only inorganic ligands, to overcome objections that the optical activity of tris(ethylenediamine)cobalt(III) ion owed its optical activity to its carbon atoms and not to its geometric structure.

24-5 CONCEPT ASSESSMENT

Of the following complex cations, which are identical, which are geometrical isomers, which are enantiomers?



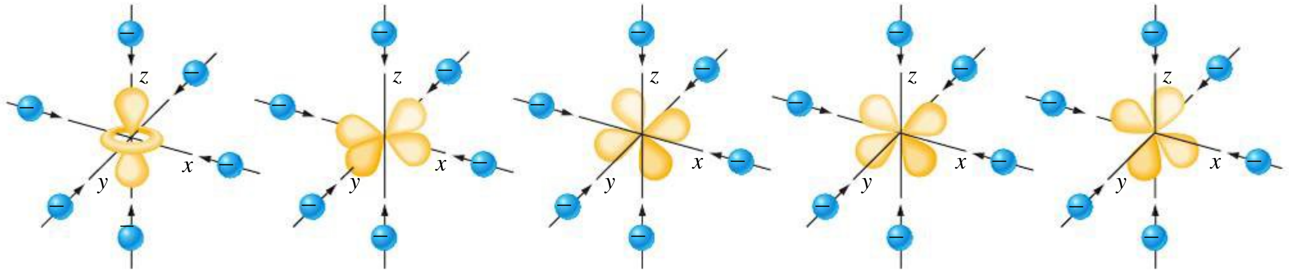
24-5 Bonding in Complex Ions: Crystal Field Theory

The theories of chemical bonding that were so useful in earlier chapters do not help much in explaining the characteristic colors and magnetic properties of complex ions. In transition metal ions, we need to focus on how the electrons in the *d* orbitals of a metal ion are affected when they are in a complex. A theory that provides that focus and an explanation of these properties is crystal field theory.

In the **crystal field theory**, bonding in a complex ion is considered to be an electrostatic attraction between the positively charged nucleus of the central metal ion and electrons in the ligands. Repulsions also occur between the ligand electrons and electrons in the central ion. In particular, the crystal field theory focuses on the repulsions between ligand electrons and *d* electrons of the central ion.

◀ Modifications of the simple crystal field theory that take into account such factors as the partial covalency of the metal–ligand bond are called *ligand field theory*. This term is often used to signify both the purely electrostatic crystal field theory and its modifications.

First, a reminder about the *d* orbitals introduced in Figure 8-30: All five of the orbitals are alike in energy when in an isolated atom or ion, but they are *unlike* in their spatial orientations. One of them, d_{z^2}, is directed along the *z* axis, and another, $d_{x^2-y^2}$, has lobes along the *x* and *y* axes. The remaining three have



(a) d_{z^2} (b) $d_{x^2-y^2}$ (c) d_{xy} (d) d_{xz} (e) d_{yz}

▲ FIGURE 24-11
Approach of six anions to a metal ion to form a complex ion with octahedral structure
The ligands (anions, in this case) approach the central metal ion along the *x*, *y*, and *z* axes. Maximum repulsion occurs with the d_{z^2} and $d_{x^2-y^2}$ orbitals, and their energies are raised. Repulsions with the other *d* orbitals are not as great. A difference in energy results between the two sets of *d* orbitals.

lobes extending into regions between the perpendicular *x*, *y*, and *z* axes. In the presence of ligands, because repulsions exist between ligand electrons and *d* electrons, the *d*-orbital energy levels of the central metal ion are raised. As we will soon see, however, they are not all raised to the same extent.

Figure 24-11 depicts six anions (ligands) approaching a central metal ion along the *x*, *y*, and *z* axes. This direction of approach leads to an octahedral complex. Repulsions between ligand electrons and *d*-orbital electrons are strengthened in the direct, head-to-head approach of ligands to the d_{z^2} orbitals (Fig. 24-11a) and $d_{x^2-y^2}$ orbitals (Fig. 24-11b). These two orbitals have their energy raised with respect to an average *d*-orbital energy for a central metal ion in the field of the ligands. For the other three orbitals (d_{xy}, d_{xz}, and d_{yz}, Figure 24-11c–e), ligands approach between the lobes of the orbitals and there is a gain in stability over the head-to-head approach; these orbital energies are lowered with respect to the average *d*-orbital energy. The difference in energy between the two groups of *d* orbitals is called *crystal field splitting* and is represented by the symbol Δ_o, with the subscript o emphasizing that the crystal field splitting shown in Figure 24-12 is for an octahedral complex.

The removal of the degeneracy of the *d* orbitals by the crystal field has important consequences for the electron configurations of transition metal ions having between 4 and 7 *d* electrons. Consider the transition metal ion Cr^{2+} with a d^4 configuration. If the four *d* electrons are assigned to the orbitals of lowest energy first, the first three electrons go into the d_{xy}, d_{xz}, and d_{yz} orbitals according to Hund's rule (page 339)—but what about the fourth

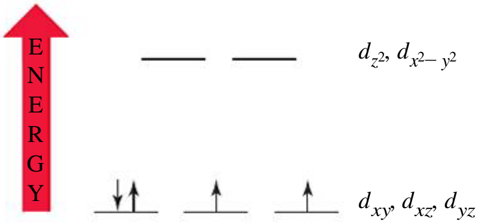
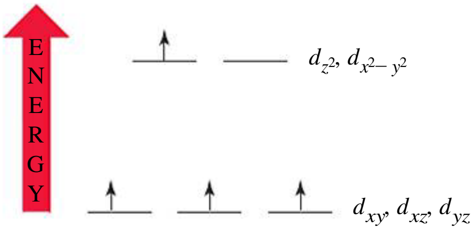
electron? The aufbau process (page 340) suggests that the fourth electron should pair up with any one of the three electrons already in the d_{xy}, d_{xz}, and d_{yz} orbitals.



KEEP IN MIND

that the configurations $d_{xy}^2 d_{xz}^1 d_{yz}^1$, $d_{xy}^1 d_{xz}^2 d_{yz}^1$, and $d_{xy}^1 d_{xz}^1 d_{yz}^2$ all represent the same energy state and are indistinguishable. Thus, the paired electrons in the diagram at the left can be placed in any one of the three *d* orbitals in the lower-energy subset.

Placing the fourth electron in the lower level confers extra stability (lower energy) on the complex, but some of this stability is offset because it requires energy, called the **pairing energy** (*P*), to force an electron into an orbital that is already occupied by an electron. Alternatively, the electron could be assigned to either the $d_{x^2-y^2}$ or d_{z^2} orbital, avoiding the pairing energy.



Placing the fourth electron in the upper level requires energy and offsets the extra stability acquired by placing the first three electrons in the lower level. To pair or not to pair, that is the question.

Whether the fourth electron enters the lowest level and becomes paired or, instead, enters the upper level with the same spin as the first three electrons depends on the magnitude of Δ_o. If Δ_o is greater than the pairing energy, *P*, greater stability is obtained if the fourth electron is paired with one in the lower level. If Δ_o is less than the pairing energy, greater stability is obtained by keeping the electrons unpaired. Thus, for octahedral chromium(II) complexes, there are two possibilities for the number of unpaired electrons. In one case, there are four unpaired electrons when $\Delta_o < P$; this situation corresponds to the maximum number of unpaired electrons and is referred to as **high spin**. Ligands such as H_2O and F^- produce only a small crystal field splitting, leading to high-spin complexes; such ligands are said to be *weak-field ligands*. As an example, $[Cr(H_2O)_6]^{2+}$ is a weak-field complex. In the other case, when $\Delta_o > P$, there are two unpaired electrons; this corresponds to the minimum number of unpaired electrons and is referred to as **low spin**. Ligands, such as NH_3 and CN^-, produce large crystal field splitting, leading to low-spin complexes; such ligands are said to be *strong-field ligands*. $[Cr(CN)_6]^{4-}$ is a strong-field complex.

◀ These two possibilities exist for complex ions because the crystal field splitting and pairing energies are small and of comparable value. In considering the electron configurations in atoms, the spacing between energy levels is much greater than the pairing energy.

Different ligands can be arranged in order of their abilities to produce a splitting of the *d* energy levels. This arrangement is known as the **spectrochemical series**.

High-spin complex
$[CoF_6]^{3-}$
$\Delta_o < P$
Low-spin complex
$[Co(NH_3)_6]^{3+}$
$\Delta_o > P$

So far, we have considered just octahedral complexes. In the formation of complex ions of other geometric structures, ligands approach from different directions and produce different patterns of splitting of the *d* energy level. Figure 24-13 shows the pattern for tetrahedral complexes, and Figure 24-14 shows the pattern for square-planar complexes. In comparisons of hypothetical complexes of different structures having the same combinations of ligands, metal ions, and metal–ligand distances, we find the greatest energy separation of the *d* levels for the square-planar complex and the smallest energy separation for the tetrahedral complex. Because the tetrahedral splitting is small, almost all tetrahedral complexes are high spin.

24-3 ARE YOU WONDERING...

If the two groups of orbitals split equally with respect to the average energy of the *d* orbitals?

The answer is no. The reason is that the total energy must be constant. If we consider a d^{10} ion such as Zn^{2+} in an octahedral field, the destabilization caused by the four electrons in the $d_{x^2-y^2}$ and d_{z^2} orbitals must be offset by the stabilization gained by the six electrons in the d_{xy}, d_{xz}, and d_{yz}, orbitals. This requires that

$$(6 \times \text{the energy of } d_{xy}, d_{xy}, d_{yz} \text{ orbitals}) + (4 \times \text{the energy of } d_{x^2-y^2}, d_{z^2}) = 0$$

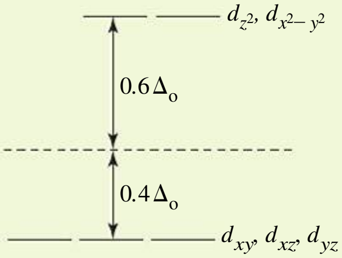
That is, the energy gained equals the energy lost. Also, the energy difference between the orbitals is

$$(\text{the energy of } d_{x^2-y^2}, d_{z^2}) - (\text{the energy of } d_{xy}, d_{xy}, d_{yz} \text{ orbitals}) = \Delta_o$$

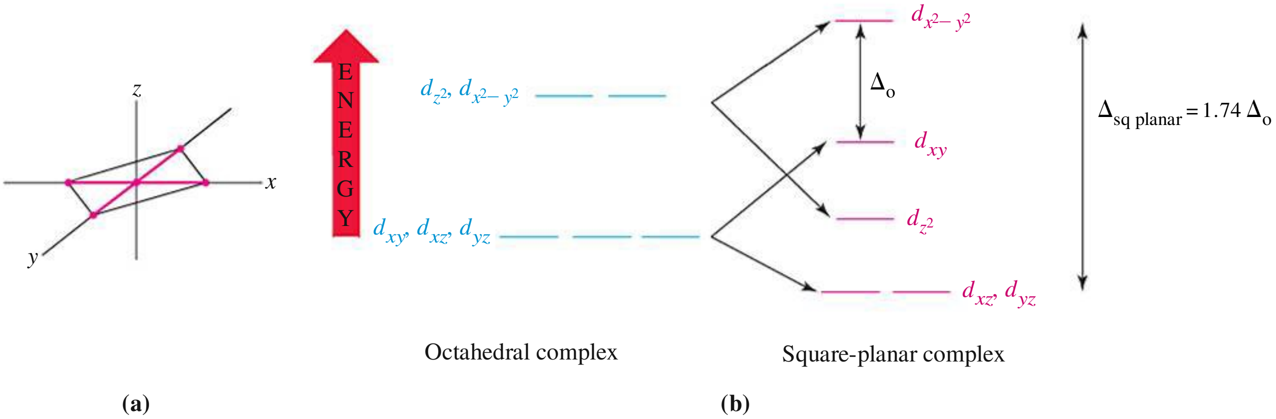
To satisfy these two relationships, it is necessary that

$$\text{the energy of } d_{xy}, d_{xz}, d_{yz} \text{ orbitals} = -0.4\ \Delta_o$$
$$\text{the energy of } d_{x^2-y^2}, d_{z^2} = 0.6\ \Delta_o$$

The splitting is as shown.



The splitting of the two groups of orbitals is not equal with respect to the average energy of the *d* orbitals.



▲ FIGURE 24-14
Comparison of crystal field splitting in a square-planar and an octahedral complex
(a) The positions of attachment of ligands to a metal ion leading to the formation of a square-planar complex. **(b)** Splitting of the *d* energy level in a square-planar complex can be related to that of the octahedral complex. There are no ligands along the *z* axis in a square-planar complex, so we expect the repulsion between ligands and d_{z^2} electrons to be much less than in an octahedral complex. The d_{z^2} energy level is lowered considerably from that in an octahedral complex. Similarly, the energy levels of the d_{xz} and d_{yz} orbitals are lowered slightly because the electrons in these orbitals are concentrated in planes perpendicular to that of the square-planar complex. The energy of the $d_{x^2-y^2}$ orbital is raised because the *x* and *y* axes represent the direction of approach of four ligands to the central ion. The energy of the d_{xy} orbital is also raised because this orbital lies in the plane of the ligands in the square-planar complex. The energy difference between the d_{xy} and $d_{x^2-y^2}$ orbitals in a square-planar complex is the same as in an octahedral complex because these orbitals are equally affected by ligand repulsions in both complexes. The maximum energy difference between *d* orbitals in a square-planar complex is $\Delta_{\text{sq planar}} = 1.74\Delta_o$.

24-6 CONCEPT ASSESSMENT

From the following crystal field splitting diagrams identify: **(i)** a tetrahedral Mn^{2+} complex, **(ii)** a strong-field octahedral complex of Co^{3+}, **(iii)** a weak-field octahedral complex of Fe^{2+}, **(iv)** a tetrahedral Ni^{2+} complex, **(v)** a high-spin octahedral complex of Fe^{3+}.

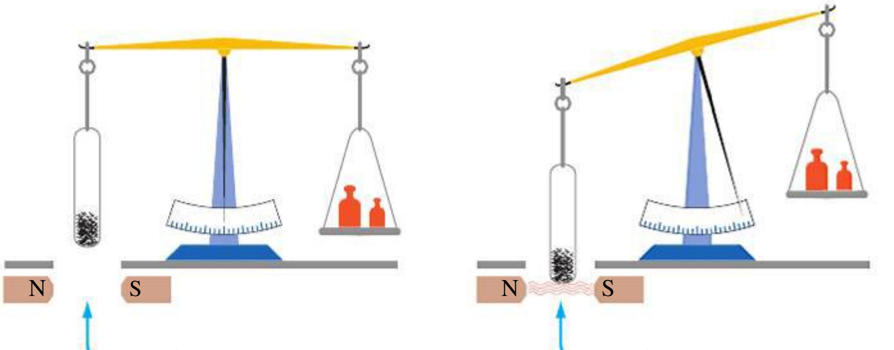
24-6 Magnetic Properties of Coordination Compounds and Crystal Field Theory

The paramagnetism of the dioxygen molecule was dramatically illustrated in Chapter 10 (Figure 10-3, page 401) by the interaction of liquid oxygen with the poles of a strong magnet. The origin of the paramagnetism is the existence of unpaired electrons in the molecule. Transition metal coordination compounds exhibit varying degrees of paramagnetism. Some are diamagnetic. A paramagnetic substance is pulled into, and a diamagnetic substance is pushed out of, a magnetic field. A straightforward way to measure magnetic properties is to weigh a substance "in" and "out" of a magnetic field, as illustrated in Figure 24-15. The mass of the substance is the



(a) No magnetic field **(b)** Magnetic field turned on

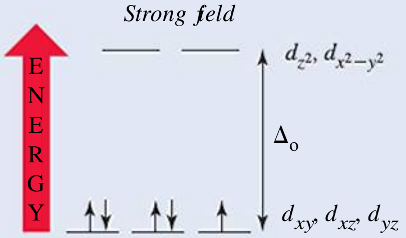
▲ FIGURE 24-15
Paramagnetism—illustrated
(a) A sample is weighed in the absence of a magnetic field. **(b)** When the field is turned on, the balanced condition is upset. The sample gains weight because it is now subjected to two attractive forces: the force of gravity *and* the force of interaction of the external magnetic field and the unpaired electrons.

same whatever magnetic property the substance possesses. However, if the substance is diamagnetic, it is slightly repelled by a magnetic field and *weighs* less within the field. If the substance is paramagnetic, it *weighs* more within the field.

The degree to which a substance weighs more in the magnetic field depends on the number of unpaired electrons. In the previous section, we saw that a high-spin d^n complex has more unpaired electrons than a low-spin d^n complex. Thus, measuring the change in weight of the complex in a magnetic field allows us to determine whether a complex is high or low spin. The magnetic properties of a complex depend on the magnitude of the crystal field splitting. Strong-field ligands tend to form low-spin, weakly paramagnetic, or even diamagnetic, complexes. Weak-field ligands tend to form high-spin, strongly paramagnetic complexes. The results of measuring the magnetic properties of coordination compounds can therefore be interpreted from crystal field theory, as demonstrated in Examples 24-4 and 24-5.

EXAMPLE 24-4 Using the Spectrochemical Series to Predict Magnetic Properties

How many unpaired electrons would you expect to find in the octahedral complex $[Fe(CN)_6]^{3-}$?



Low-spin complex
$[Fe(CN)_6]^{3-}$
$\Delta_o > P$

Analyze

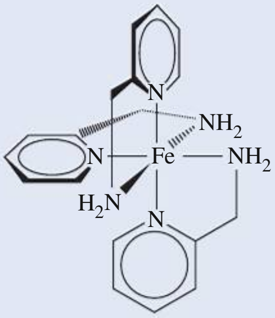
We expect complexes with strong field ligands (that is, ligands that are high in the spectrochemical series) to be low spin.

Solve

The Fe atom has the electron configuration $[Ar]3d^64s^2$. The Fe^{3+} ion has the configuration $[Ar]3d^5$. CN^- is a strong-field ligand. Because of the large energy separation in the d levels of the metal ion produced by this ligand, we expect all the electrons to be in the lowest energy level. There should be only one unpaired electron.

Assess

When dealing with ligands at the extremes of the spectrochemical series, it is easier to determine whether the complex is high or low spin. Occasionally, the crystal field splitting is comparable to the pairing energy; in such cases, changes in pressure or temperature can cause a crossover from low spin to high spin. Such a phenomenon is called *spin crossover*. A complex that displays spin crossover is tris(2-picolylamine)iron(II).



Tris(2-picolylamine)iron(II)

PRACTICE EXAMPLE A: How many unpaired electrons would you expect to find in the octahedral complex $[MnF_6]^{2-}$?

PRACTICE EXAMPLE B: How many unpaired electrons would you expect to find in the tetrahedral complex $[CoCl_4]^{2-}$? Would you expect more, fewer, or the same number of unpaired electrons as in the octahedral complex $[Co(H_2O)_6]^{2+}$?

EXAMPLE 24-5 Using the Crystal Field Theory to Predict the Structure of a Complex from Its Magnetic Properties

The complex ion $[\text{Ni(CN)}_4]^{2-}$ is diamagnetic. Use ideas from the crystal field theory to speculate on its probable structure.

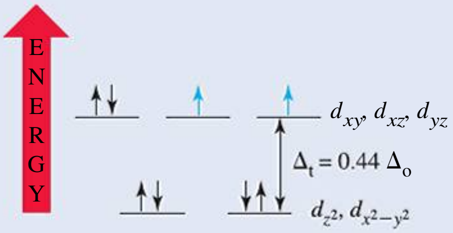
Analyze

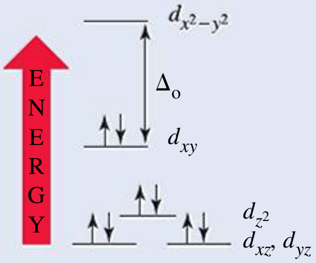
We can eliminate an octahedral structure because the coordination number is 4 (not 6). Our choice is between tetrahedral and square-planar geometries. We compare the crystal field splitting diagrams for each.

Solve

The electron configuration of Ni is $[\text{Ar}]3d^84s^2$, and that of Ni(II) is $[\text{Ar}]3d^8$. Because the complex ion is diamagnetic, all $3d$ electrons must be paired. Let us see how we would distribute these $3d$ electrons if the structure were tetrahedral (recall Figure 24-13). We would place four electrons (all paired) into the two lowest d levels. We would then distribute the remaining four electrons among the three higher-level d orbitals. Two of the electrons would be unpaired, and the complex ion would be paramagnetic.

Because the tetrahedral structure would be paramagnetic, we can conclude that the structure of the diamagnetic $[\text{Ni(CN)}_4]^{2-}$ ion must be square-planar. Let's also demonstrate that this is a reasonable conclusion based on the d-orbital energy-level diagram for a square-planar complex (recall Figure 24-14). First, the three lowest-energy orbitals are filled with electrons (six), and then we assume that the energy separation between the d_{xy} and $d_{x^2-y^2}$ orbitals is large enough that the final two electrons remain paired in the d_{xy} orbital. This corresponds to a diamagnetic complex ion.





Assess

To decide between the two possible geometries, we needed to know the magnetic properties of the complex. Although $[\text{NiCl}_4]^{2-}$ is paramagnetic and tetrahedral, the stronger field ligands in $[\text{Ni(CN)}_4]^{2-}$ increase the energy separation of the d orbitals, making the square-planar geometry more stable. (VSEPR theory predicts that the tetrahedral geometry is more stable.)

PRACTICE EXAMPLE A: The complex ion $[\text{Co(CN)}_4]^{2-}$ is paramagnetic with three unpaired electrons. Use ideas from the crystal field theory to speculate on its probable structure.

PRACTICE EXAMPLE B: Would you expect $[\text{Cu(NH}_3)_4]^{2+}$ to be diamagnetic or paramagnetic? Can you use this information about the magnetic properties of $[\text{Cu(NH}_3)_4]^{2+}$ to help you determine whether the structure of $[\text{Cu(NH}_3)_4]^{2+}$ is tetrahedral or square-planar? Explain.

24-7 Color and the Colors of Complexes

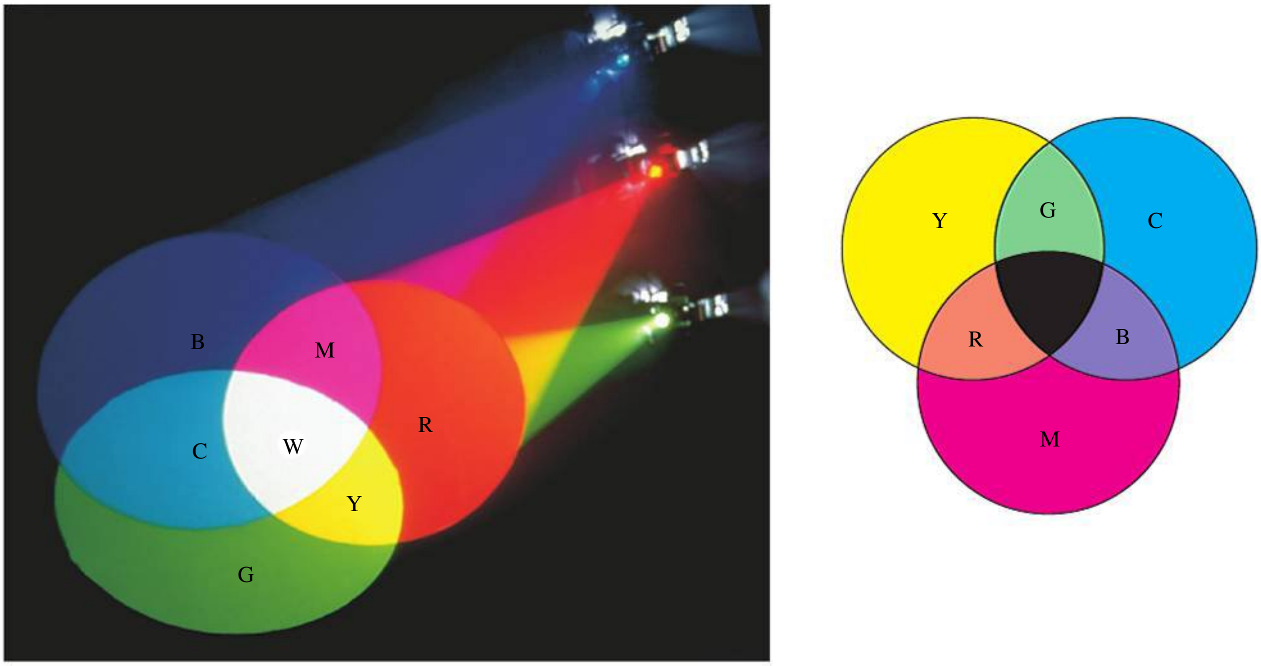
Figure 24-16 uses two situations for mixing color to help clarify the nature of colors. Figure 24-16(a) represents *additive mixing*, the type of color mixing that occurs when colored spotlights are superimposed. Figure 24-16(b), conversely, represents *subtractive mixing*, the type of color mixing that occurs when paint pigments or colored solutions are mixed.

Primary, Secondary, and Complementary Colors

For the additive mixing of light beams in Figure 24-16(a), the **primary colors** are defined as any three colors that, when combined, yield white light (W). The colors used in the figure are *red* (R), *green* (G), and *blue* (B); their sum can be represented as $\text{R} + \text{G} + \text{B} = \text{W}$. The **secondary colors** are those produced by combining two primary colors. Figure 24-16(a) indicates that the secondary colors are *yellow* $(\text{Y} = \text{R} + \text{G})$, *cyan* $(\text{C} = \text{G} + \text{B})$, and *magenta* $(\text{M} = \text{B} + \text{R})$.

Each secondary color is a **complementary color** of one of the primary colors. Again, from Figure 24-16(a), *cyan* (C) is the complementary color of red (R);

▶ Additive color mixing is used in color monitors and color television screens. Subtractive color mixing is used for all the photographs and art in this text.



(a) Additive color mixing

(b) Subtractive color mixing

▲ FIGURE 24-16

The mixing of colors

(a) The additive mixing of three beams of colored light: red (R), green (G), and blue (B). The secondary colors—yellow (Y), cyan (C), and magenta (M)—are produced in regions where two of the beams overlap. The overlap of all three beams produces white light (W). **(b)** The subtractive mixing of three pigments with the primary colors magenta (M), yellow (Y), and cyan (C). Here, the secondary colors—red (R), green (G), and blue (B)—form when two of the primary colors are mixed. A mixture of all three primary colors produces a very dark brown to black color.

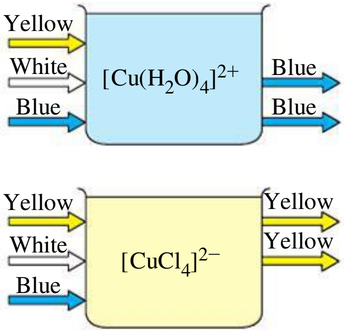
In four-color printing, such as in this book and in color printers in computer systems, the basic inks used are magenta, yellow, cyan, and black. In photographs and drawings in this book, very small dots of these four basic colors, printed singly and in various combinations, produce the colored images you see. (With a magnifying glass, you can see individual dots of color.)

magenta (M), of green (G); and yellow (Y), of blue (B). Figure 24-16(a) shows that when a primary color and its complementary color are mixed, the result is white light. This must be the case: Because cyan, for example, is itself the combination of two of the primary colors—green and blue $(\mathrm{C} = \mathrm{G} + \mathrm{B})$—the combination of cyan and red $(\mathrm{C} + \mathrm{R})$ is the same as the combination of the three primary colors: $\mathrm{G} + \mathrm{B} + \mathrm{R} = \mathrm{W}$.

In subtractive color mixing, some of the wavelength components of white light are removed by absorption, and the reflected light (for example, from a painted surface or colored fabric) or transmitted light (as seen through glass or a solution) is deficient in some wavelength components. The reflected or transmitted light is colored. In subtractive color mixing (Fig. 24-16b), there are also primary, secondary, and complementary colors. In this case, *magenta* (M), *yellow* (Y), and *cyan* (C) are the primary colors and *green* (G), *blue* (B), and *red* (R) are the secondary colors. If a material absorbs all three primary colors, there is essentially no light left to be reflected or transmitted; the material appears black, or nearly so. If a material absorbs one color, primary or secondary, the reflected or transmitted light is the complementary color. Thus, a magenta sweater has that color because the dye it contains strongly absorbs green light and reflects magenta, the complement of green. A solution of red food dye has that color because the dye absorbs cyan light and transmits red.

Colored Solutions

Now let's direct our attention specifically to colored solutions. Colored solutions contain species that can absorb photons of visible light and use the energy of those photons to promote electrons in the species to higher energy levels. The energies of the photons must just match the energy differences through which the electrons are to be promoted. Because the energies of photons are related to the frequencies (and wavelengths) of light (recall Planck's equation, $E = h\nu$), only certain wavelength components are absorbed as white light passes through the solution. The emerging light, because it is lacking some wavelength components, is no longer white; it is colored.



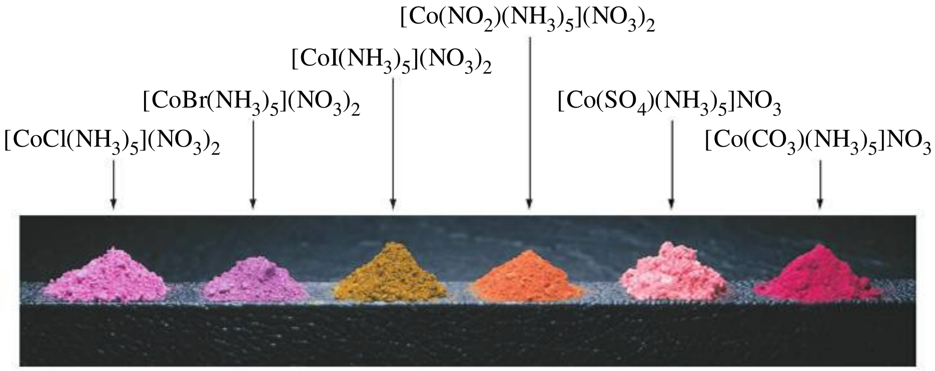
▲ FIGURE 24-17
Light absorption and transmission
$[Cu(H_2O)_4]^{2+}$ absorbs in the yellow region of the spectrum and transmits blue light. $[CuCl_4]^{2-}$ absorbs in the blue region of the spectrum and transmits yellow light.

Ions having (1) a noble-gas electron configuration, (2) an outer shell of 18 electrons, or (3) the "18 + 2" configuration (18 electrons in the $n - 1$ shell and two in the n, or outermost, shell) do not have electron transitions in the energy range corresponding to visible light. White light passes through these solutions without being absorbed; these ions are colorless in solution. Examples are the alkali and alkaline earth metal ions, the halide ions, Zn^{2+}, Al^{3+}, and Bi^{3+}.

Crystal field splitting of the d energy levels produces the energy difference, Δ, that accounts for the colors of complex ions. Promotion of an electron from a lower to a higher d level results from the absorption of the appropriate components of white light; the transmitted light is colored. Subtracting one color from white light leaves the complementary color. A solution containing $[Cu(H_2O)_4]^{2+}$ absorbs most strongly in the yellow region of the spectrum (about 580 nm). The wavelength components of the light transmitted combine to produce the color *blue*. Thus, aqueous solutions of copper(II) compounds usually have a characteristic blue color. In the presence of high concentrations of Cl^-, copper(II) forms the complex ion $[CuCl_4]^{2-}$. This species absorbs strongly in the blue region of the spectrum. The transmitted light is *yellow*, as is the color of the solution. Figure 24-17 suggests light absorption by these solutions. The colors of some complex ions of chromium are given in Table 24.5. The colors of six related coordination compounds of cobalt(III) are shown in Figure 24-18.

TABLE 24.5 Some Coordination Compounds of Cr^{3+} and Their Colors

Isomer	Color
$[Cr(H_2O)_6]Cl_3$	Violet
$[CrCl(H_2O)_5]Cl_2$	Blue-green
$[Cr(NH_3)_6]Cl_3$	Yellow
$[CrCl(NH_3)_5]Cl_2$	Purple



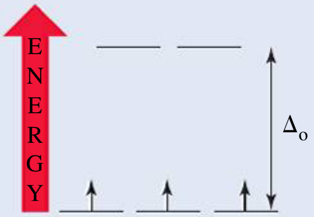
▶ FIGURE 24-18
Effect of ligands on the colors of coordination compounds
These compounds all consist of a six-coordinate cobalt complex ion in combination with nitrate ions. In each case, the complex ion has five NH_3 molecules and one other group as ligands.

EXAMPLE 24-6 Relating the Colors of Complexes to the Spectrochemical Series

Table 24.5 lists the color of $[Cr(H_2O)_6]Cl_3$ as violet, whereas that of $[Cr(NH_3)_6]Cl_3$ is yellow. Explain this difference in color.

Analyze

Both chromium(III) complexes are octahedral, and the electron configuration of Cr^{3+} is $[Ar]3d^3$. From these facts, we can construct the energy-level diagram shown here. The three unpaired electrons go into the three lower-energy *d* orbitals. When a photon of light is absorbed, an electron is promoted from a *d* orbital of lower energy to a *d* orbital of higher energy. The quantity of energy required for this promotion depends on the energy level separation, Δ_o.



Solve

According to the spectrochemical series, NH_3 produces a greater splitting of the *d* energy level than does H_2O. We should expect $[Cr(NH_3)_6]^{3+}$ to absorb light of a *shorter* wavelength (higher energy) than does $[Cr(H_2O)_6]^{3+}$. Thus, $[Cr(NH_3)_6]^{3+}$ absorbs in the violet region of the spectrum, and the transmitted light is *yellow*. $[Cr(H_2O)_6]^{3+}$ absorbs in the yellow region of the spectrum, and the transmitted light is *violet*.

Assess

If we measure the wavelength, λ, of the photon absorbed, we can then calculate the splitting energy, $\Delta_o = hc/\lambda$. Stronger field ligands increase the magnitude of Δ_o; therefore, shorter wavelengths of light are absorbed and longer wavelengths are transmitted.

PRACTICE EXAMPLE A: The color of $[Co(H_2O)_6]^{2+}$ is pink, whereas that of tetrahedral $[CoCl_4]^{2-}$ is blue. Explain this difference in color.

PRACTICE EXAMPLE B: One of the following solids is yellow, and the other is green: $Fe(NO_3)_2 \cdot 6\,H_2O$; $K_4[Fe(CN)_6] \cdot 3\,H_2O$. Indicate which is which, and explain your reasoning.

24-8 Aspects of Complex-Ion Equilibria

In Chapter 18, we learned that complex-ion formation can have a great effect on the solubilities of substances, as in the ability of $NH_3(aq)$ to dissolve rather large quantities of AgCl(s). To calculate the solubility of AgCl(s) in $NH_3(aq)$, we had to use the formation constant, K_f, of $[Ag(NH_3)_2]^+$. Equations 24.1 and 24.2 illustrate how we dealt with formation constants in Chapter 18, with $[Zn(NH_3)_4]^{2+}$ as an example.

$$Zn^{2+}(aq) + 4\,NH_3(aq) \rightleftharpoons [Zn(NH_3)_4]^{2+}(aq) \tag{24.1}$$

$$K_f = \frac{[[Zn(NH_3)_4]^{2+}]}{[Zn^{2+}][NH_3]^4} = 4.1 \times 10^8 \tag{24.2}$$

In fact, cations in aqueous solution exist mostly in *hydrated* form. That is, $Zn^{2+}(aq)$ is actually $[Zn(H_2O)_4]^{2+}$. As a result, when NH_3 molecules bond to Zn^{2+} and form an ammine complex ion, they do not enter an empty coordination sphere. They must displace H_2O molecules. This displacement occurs in a stepwise fashion. The reaction

$$[Zn(H_2O)_4]^{2+} + NH_3 \rightleftharpoons [Zn(H_2O)_3NH_3]^{2+} + H_2O \tag{24.3}$$

for which

$$K_1 = \frac{[[Zn(H_2O)_3NH_3]^{2+}]}{[[Zn(H_2O)_4]^{2+}][NH_3]} = 3.9 \times 10^2 \tag{24.4}$$

is followed by

$$[Zn(H_2O)_3NH_3]^{2+} + NH_3 \rightleftharpoons [Zn(H_2O)_2(NH_3)_2]^{2+} + H_2O \tag{24.5}$$

for which

$$K_2 = \frac{[[\mathrm{Zn(H_2O)_2(NH_3)_2}]^{2+}]}{[[\mathrm{Zn(H_2O)_3NH_3}]^{2+}][\mathrm{NH_3}]} = 2.1 \times 10^2 \qquad \textbf{(24.6)}$$

and so on.

KEEP IN MIND

that the product relationship between equilibrium constants is equivalent to a summation of $\Delta G°$ values. Hence, when an overall $\Delta G°$ is used to evaluate K_n

$$\begin{aligned}\Delta G° \text{ (overall)} &= \Delta G_1° + \Delta G_2° + \Delta G_3° + \cdots \\ &= -RT \ln K_1 - RT \ln K_2 - RT \ln K_3 - \cdots \\ &= -RT \ln(K_1 \times K_2 \times K_3 \cdots) \\ &= -RT \ln \beta_n = -RT \ln K_f\end{aligned}$$

The value of K_1 in equation (24.4) is often designated as β_1 and called the formation constant for the complex ion $[\mathrm{Zn(H_2O)_3NH_3}]^{2+}$. The formation of $[\mathrm{Zn(H_2O)_2(NH_3)_2}]^{2+}$ is represented by the *sum* of equations (24.3) and (24.5),

$$[\mathrm{Zn(H_2O)_4}]^{2+} + 2\,\mathrm{NH_3} \rightleftharpoons [\mathrm{Zn(H_2O)_2(NH_3)_2}]^{2+} + 2\,\mathrm{H_2O} \qquad \textbf{(24.7)}$$

The formation constant β_2, in turn, is given by the *product* of equations (24.4) and (24.6).

$$\beta_2 = \frac{[[\mathrm{Zn(H_2O)_2(NH_3)_2}]^{2+}]}{[[\mathrm{Zn(H_2O)_4}]^{2+}][\mathrm{NH_3}]^2} = K_1 \times K_2 = 8.2 \times 10^4 \qquad \textbf{(24.8)}$$

For the next ion in the series, $[\mathrm{Zn(H_2O)(NH_3)_3}]^{2+}$, $\beta_3 = K_1 \times K_2 \times K_3$. For the final member, $[\mathrm{Zn(NH_3)_4}]^{2+}$, $\beta_4 = K_1 \times K_2 \times K_3 \times K_4$, and it is this product of terms that we called the formation constant in Section 18-8 and listed as K_f in Table 18.2. Additional stepwise formation constants are presented in Table 24.6.

The large numerical value of K_1 for reaction (24.3) indicates that $\mathrm{Zn^{2+}}$ has a greater affinity for $\mathrm{NH_3}$ (a stronger Lewis base) than it does for $\mathrm{H_2O}$. Displacement of ligand $\mathrm{H_2O}$ molecules by $\mathrm{NH_3}$ occurs even if the number of $\mathrm{NH_3}$ molecules present in aqueous solution is much smaller than the number of $\mathrm{H_2O}$ molecules, as in dilute $\mathrm{NH_3(aq)}$. The fact that the successive K values decrease regularly in the displacement process, at least for displacements involving neutral molecules as ligands, is due in part to statistical factors: An $\mathrm{NH_3}$ molecule has a better chance of replacing a $\mathrm{H_2O}$ molecule in $[\mathrm{Zn(H_2O)_4}]^{2+}$, in which each coordination position is occupied by $\mathrm{H_2O}$, than in $[\mathrm{Zn(H_2O)_3NH_3}]^{2+}$, in which one of the positions is already occupied by $\mathrm{NH_3}$. Also, once the degree of substitution of $\mathrm{NH_3}$ for $\mathrm{H_2O}$ has become large, the chances improve for $\mathrm{H_2O}$ molecules to replace $\mathrm{NH_3}$ molecules in a reverse reaction. Again, this tends to reduce the value of K. If irregularities arise in the succession of K values, it is often because of a change in structure of the complex ion at some point in the series of displacement reactions.

If the ligand in a substitution process is polydentate, it displaces as many $\mathrm{H_2O}$ molecules as there are points of attachment. Thus, ethylenediamine (en)

TABLE 24.6 Stepwise and Overall Formation (Stability) Constants for Several Complex Ions

Metal[a] Ion	Ligand	K_1	K_2	K_3	K_4	K_5	K_6	β_n (or K_f)[b]
$\mathrm{Ag^+}$	$\mathrm{NH_3}$	2.0×10^3	7.9×10^3					1.6×10^7
$\mathrm{Zn^{2+}}$	$\mathrm{NH_3}$	3.9×10^2	2.1×10^2	1.0×10^2	5.0×10^1			4.1×10^8
$\mathrm{Cu^{2+}}$	$\mathrm{NH_3}$	1.9×10^4	3.9×10^3	1.0×10^3	1.5×10^2			1.1×10^{13}
$\mathrm{Ni^{2+}}$	$\mathrm{NH_3}$	6.3×10^2	1.7×10^2	5.4×10^1	1.5×10^1	5.6	1.1	5.3×10^8
$\mathrm{Cu^{2+}}$	en	5.2×10^{10}	2.0×10^9					1.0×10^{20}
$\mathrm{Ni^{2+}}$	en	3.3×10^7	1.9×10^6	1.8×10^4				1.1×10^{18}
$\mathrm{Ni^{2+}}$	EDTA	4.2×10^{18}						4.2×10^{18}

[a] In many tabulations in the chemical literature, formation-constant data are presented as logarithms: that is, $\log K_1$, $\log K_2, \ldots,$ and $\log \beta_n$.

[b] The β_n listed is for the number of steps shown: e.g., for $[\mathrm{Ag(NH_3)_2}]^+$, $\beta_2 = K_f = K_1 \times K_2$; for $[\mathrm{Ni(en)_3}]^{2+}$, $\beta_3 = K_f = K_1 \times K_2 \times K_3$; and for $[\mathrm{Ni(EDTA)}]^{2-}$, $\beta_1 = K_f = K_1$.

displaces H_2O molecules in $[Ni(H_2O)_6]^{2+}$ two at a time, in three steps. The first step is

$$[Ni(H_2O)_6]^{2+} + en \rightleftharpoons [Ni(en)(H_2O)_4]^{2+} + 2\,H_2O \qquad K_1(\beta_1) = 3.3 \times 10^7 \quad \textbf{(24.9)}$$

Note from Table 24.6 that the complex ions with polydentate ligands have much larger formation constants than do those with monodentate ligands. For example, K_f (that is, β_3) for $[Ni(en)_3]^{2+}$ is 1.1×10^{18}, whereas K_f (that is, β_6) for $[Ni(NH_3)_6]^{2+}$ is 5.3×10^8. The additional stability of chelates over complexes with monodentate ligands is known as the **chelation (or chelate) effect**. This effect can be partly attributed to the increase in entropy associated with chelation. In the displacement of H_2O by NH_3, the entropy change is small [two particles on each side of an equation such as (24.3)]. An ethylenediamine molecule, conversely, displaces *two* H_2O molecules [two particles on the left and three on the right of equation (24.9)]. The larger, positive value of $\Delta S°$ for the displacement by ethylenediamine means a more negative $\Delta G°$ and a larger K.

24-7 CONCEPT ASSESSMENT

The Cr(III) cation in aqueous solution can form 6-coordinate complexes with ethylenediamine and $EDTA^{4-}$. Which complex do you expect to be the most stable if all water molecules in the six-coordinate $Cr^{3+}(aq)$ ion are replaced?

24-9 Acid–Base Reactions of Complex Ions

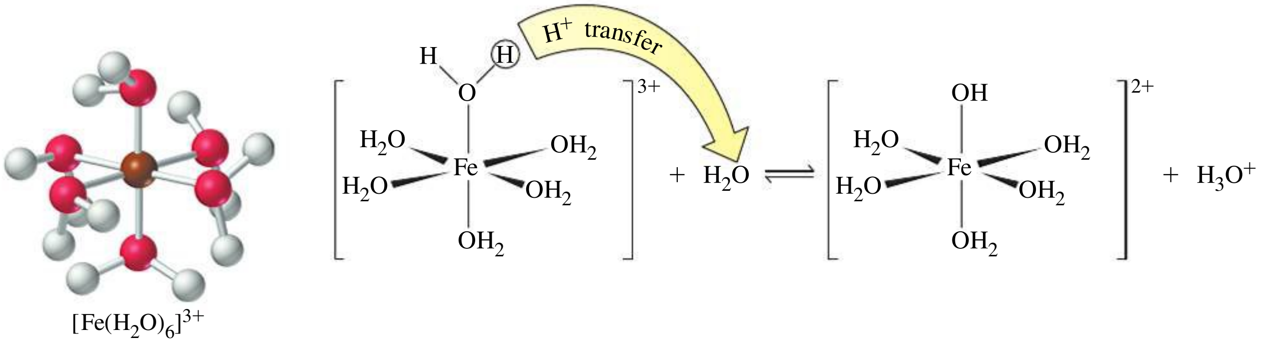
We have described complex-ion formation in terms of Lewis acids and bases. Complex ions may also exhibit acid–base properties in the Brønsted–Lowry sense; that is, they may act as proton donors or acceptors. Figure 24-19 represents the ionization of $[Fe(H_2O)_6]^{3+}$ as an acid. A proton from a *ligand* water molecule in hexaaquairon(III) ion is transferred to a *solvent* water molecule. The H_2O ligand is converted to OH^-.

$$[Fe(H_2O)_6]^{3+} + H_2O \rightleftharpoons [FeOH(H_2O)_5]^{2+} + H_3O^+ \quad K_{a_1} = 9 \times 10^{-4} \quad \textbf{(24.10)}$$

The second ionization step is

$$[FeOH(H_2O)_5]^{2+} + H_2O \rightleftharpoons [Fe(OH)_2(H_2O)_4]^{+} + H_3O^+ \quad K_{a_2} = 5 \times 10^{-4} \quad \textbf{(24.11)}$$

From these K_a values, we see that $Fe^{3+}(aq)$ is fairly acidic (compared, for example, with acetic acid, with $K_a = 1.8 \times 10^{-5}$). To suppress ionization (hydrolysis) of $[Fe(H_2O)_6]^{3+}$, we need to maintain a low pH by the addition of acids such as HNO_3 or $HClO_4$. The ion $[Fe(H_2O)_6]^{3+}$ is violet in color, but aqueous solutions of $Fe^{3+}(aq)$ are generally yellow because of the presence of hydroxo complex ions.



▲ FIGURE 24-19
Ionization of $[Fe(H_2O)_6]^{3+}$

The ions Cr^{3+} and Al^{3+} behave in a manner similar to Fe^{3+} except that, with them, hydroxo complex-ion formation can continue until complex anions are produced. $Cr(OH)_3$ and $Al(OH)_3$, as we previously noted, are soluble in alkaline as well as acidic solutions; they are amphoteric.

Regarding the acid strengths of aqua complex ions, a critical factor is the charge-to-radius ratio of the central metal ion. Thus, the small, highly charged Fe^{3+} attracts electrons away from an O—H bond in a ligand water molecule more strongly than does Fe^{2+}. Hence, $[Fe(H_2O)_6]^{3+}$ is a stronger acid ($K_{a_1} = 9 \times 10^{-4}$) than is $[Fe(H_2O)_6]^{2+}$ ($K_{a_1} = 1 \times 10^{-7}$).

24-10 Some Kinetic Considerations

When $NH_3(aq)$ is added to an aqueous solution containing Cu^{2+}, there is a change in color from pale blue to very deep blue. The reaction involves NH_3 molecules displacing H_2O molecules as ligands.

$$\underset{\text{(pale blue)}}{[Cu(H_2O)_4]^{2+}} + 4\,NH_3 \longrightarrow \underset{\text{(very deep blue)}}{[Cu(NH_3)_4]^{2+}} + 4\,H_2O$$

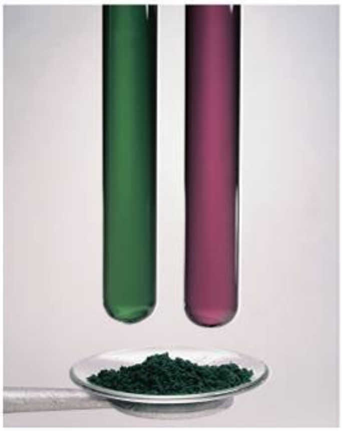
This reaction occurs very rapidly—as rapidly as the two reactants can be brought together. The addition of HCl(aq) to an aqueous solution of Cu^{2+} produces an immediate color change from pale blue to green, or even yellow if the HCl(aq) is sufficiently concentrated.

$$\underset{\text{(pale blue)}}{[Cu(H_2O)_4]^{2+}} + 4\,Cl^- \longrightarrow \underset{\text{(yellow)}}{[CuCl_4]^{2-}} + 4\,H_2O$$

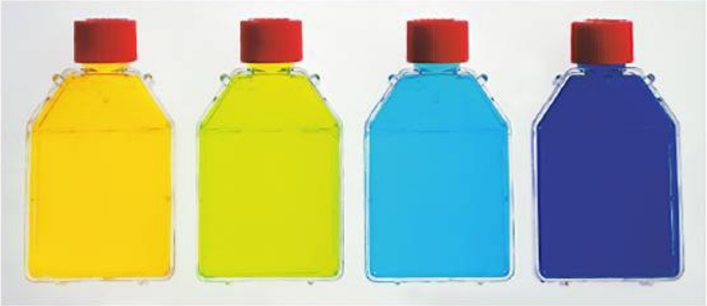
Complex ions in which ligands can be interchanged rapidly are said to be **labile**. $[Cu(H_2O)_4]^{2+}$, $[Cu(NH_3)_4]^{2+}$, and $[CuCl_4]^{2-}$ are all labile (Fig. 24-20).

In freshly prepared $CrCl_3(aq)$, the ion *trans*-$[CrCl_2(H_2O)_4]^+$ produces a green color, but the color gradually turns to violet (Fig. 24-21). This color change results from the very slow exchange of H_2O for Cl^- ligands. A complex ion that exchanges ligands slowly is said to be *nonlabile*, or **inert**. In general, complex ions of the first transition series, except for those of Cr(III) and Co(III), are kinetically labile. Those of the second and third transition series are generally kinetically inert. Whether a complex ion is labile or inert affects the ease with which it can be studied. The inert ones are easiest to isolate and characterize, which may explain why so many of the early studies of complex ions were based on Cr(III) and Co(III).

▶ The terms *labile* and *inert* are not related to the thermodynamic stabilities of complex ions or to the equilibrium constants for ligand-substitution reactions. The terms are *kinetic* terms, referring to the rates at which ligands are exchanged.



▲ FIGURE 24-21
Inert complex ions
The green solid $CrCl_3 \cdot 6\,H_2O$ produces the green aqueous solution on the left. The color is due to *trans*-$[CrCl_2(H_2O)_4]^+$. A slow exchange of H_2O for Cl^- ligands leads to a violet solution of $[Cr(H_2O)_6]^{3+}$ in one or two days (right).

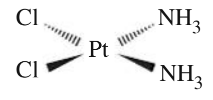


▲ FIGURE 24-20
Labile complex ions
The exchange of ligands in the coordination sphere of Cu^{2+} occurs very rapidly. The solution at the extreme left is formed by dissolving $CuSO_4$ in concentrated HCl(aq). Its yellow color is due to $[CuCl_4]^{2-}$. When a small amount of water is added, the mixture of $[Cu(H_2O)_4]^{2+}$ and $[CuCl_4]^{2-}$ ions produces a yellow-green color. When $CuSO_4$ is dissolved in water, a light blue solution of $[Cu(H_2O)_4]^{2+}$ forms. NH_3 molecules readily displace H_2O molecules as ligands and produce deep blue $[Cu(NH_3)_4]^{2+}$ (extreme right).

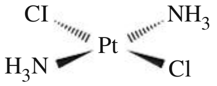
24-11 Applications of Coordination Chemistry

The applications of coordination chemistry are numerous and varied. They range from analytical chemistry to biochemistry. The several brief examples in this section give some idea of this diversity.

Cisplatin: A Cancer-Fighting Drug



cis-$[Pt(NH_3)_2Cl_2]$
(cisplatin)



trans-$[Pt(NH_3)_2Cl_2]$
(transplatin)

Chemotherapy is a treatment used for some types of cancer. The treatment employs anticancer drugs to destroy cancer cells. An important cancer-fighting drug is cisplatin, which is commonly used to treat testicular, bladder, lung, esophagus, stomach, and ovarian cancers.

Cisplatin was first synthesized in 1845 by Michel Peyrone, an Italian doctor, but its structure was not elucidated until almost fifty years later, in 1893, by Werner. The anticancer activity of cisplatin was discovered in the 1960s by Barrett Rosenberg, a professor of chemistry at Michigan State University. Not only did Rosenberg discover the anticancer activity of cisplatin, but he was also the first to report that the *trans* isomer (transplatin) was ineffective in killing cancer cells.

Before examining the anticancer activity of cisplatin, let's first consider its synthesis. One method for making cisplatin starts from $K_2[PtCl_4]$, which is converted to $K_2[PtI_4]$, by treatment with an aqueous solution of KI:

$$K_2[PtCl_4] + KI \longrightarrow K_2[PtI_4] + 4\,KCl$$

In the next step, NH_3 is added, forming a yellow compound, *cis*-$[PtI_2(NH_3)_2]$. The formation of *cis*-$[PtI_2(NH_3)_2]$ is a key step, which occurs in two stages.
